Introduction

The ability to communicate through language distinguishes humans from all other animals. Spoken language allows us to convey information, express our feelings and demonstrate social affiliations. It also provides a vehicle for organizing our thoughts and memories, enabling us to construct complex lines of reasoning, and to contemplate past, future and hypothetical events, rather than remaining grounded in present reality. The development of written language provides even more dramatic release from the here-and-now, making it possible to transcend space and time.

All known human cultures have language, but there is huge diversity in how languages are structured, both in terms of the sounds used to express meaning (phonemes) and the ways in which linguistic elements are combined (syntax). For instance, French has two different vowels that sound like ‘oo’ to a speaker of English, but which are phonemically distinct; they signal contrasts in meaning, so that ‘rue’ and ‘roux’ mean different things. In English, on the other hand, we make a phonemic contrast between the sounds ‘th’ and ‘z’ (e.g. ‘bathe’ vs. ‘baize’), which are not distinguished in French. In tone languages, such as Chinese Mandarin, the pitch at which a word is spoken signals meaning, so that ‘ba’ has four completely different meanings depending on whether the pitch is rising (‘to uproot’), falling (‘a harrow’), changing from fall to rise (‘to hold’) or at a level high pitch (‘eight’).

Moving to grammar; in English, relationships between entities are indicated by a mixture of word order and grammatical morphemes (e.g. inflectional endings such as ‘-ing’ or ‘-ed’, and small function words such as ‘by’). Thus it is the boy who is doing the kissing in ‘the boy kisses the girl’, but is the recipient of the kiss in ‘the girl kisses the boy’ or ‘the boy is kissed by the girl’. In some languages, such as Turkish, word order generally obeys the sequence subject–object–verb, and inflectional suffixes do all the work of expressing relationships. Other languages, such as Chinese Mandarin, have virtually no inflections. Word order, particles and prepositions are used to indicate how the elements of a sentence interrelate.

Clearly, language acquisition involves far more than learning labels for things. The child must work out which speech sound contrasts are meaningful in the ambient language, and how to combine words and grammatical morphemes to express relationships between things and events. Most children master this complex skill with no explicit instruction and with relative ease,

so that the bulk of phonology and syntax is acquired by around 4 years of age. There are, however, frequent exceptions, and these are the topic of this chapter.

Delay in learning to talk is a common reason for a parent to seek advice from a family doctor or paediatrician. Because human communication is complex, assessment and diagnosis of speech and language difficulties in children is a particularly challenging problem that requires expertise in several different areas, including linguistics, audiology, child development, neuropsychology, paediatric neurology and psychiatry. This chapter will use the diagnostic flow chart shown in Fig. 39.1 to introduce a range of different conditions that can lead to speech and language difficulties in children. This depicts the sequence of decisions the clinician needs to make when first assessing a child who presents with poor communication. However, recent research suggests that this diagnostic process should not be confined to those cases where communicative impairment is the presenting complaint, but should be extended much more broadly to all children referred to psychiatric services. The reason is simple: surveys of children attending psychiatric clinics reveal that a high proportion of them have some kind of communicative impairment, and in many cases this goes unrecognized unless a formal assessment is made. Cohen (1996) summarized findings from a Canadian study in which 399 consecutive psychiatric referrals of children aged from 4 to 12 years were given a detailed language assessment. Children with autistic disorder, general developmental delay, neurological damage, hearing impairment or a non-English-speaking home background had been excluded from this sample. Around one-quarter of the children had previously identified language impairments. Of the remainder, none of whom was thought to be language-impaired, 34% met criteria for language impairment. There appeared to be two reasons why communicative difficulties had been overlooked in these children. First, they did not have such overt expressive language difficulties as children with previously identified problems, although their receptive language skills were as poor as that group. Secondly, they were more likely to have externalizing psychiatric disorders, which may have diverted attention from communication. Cohen *et al.* (1998) suggested that language function should be incorporated routinely into the assessment and treatment process for children with psychiatric impairments. Some suggestions for how to implement this recommendation are given below in the section on Assessment.

In the next section, different diagnostic entities will be reviewed, with a main focus on specific developmental language

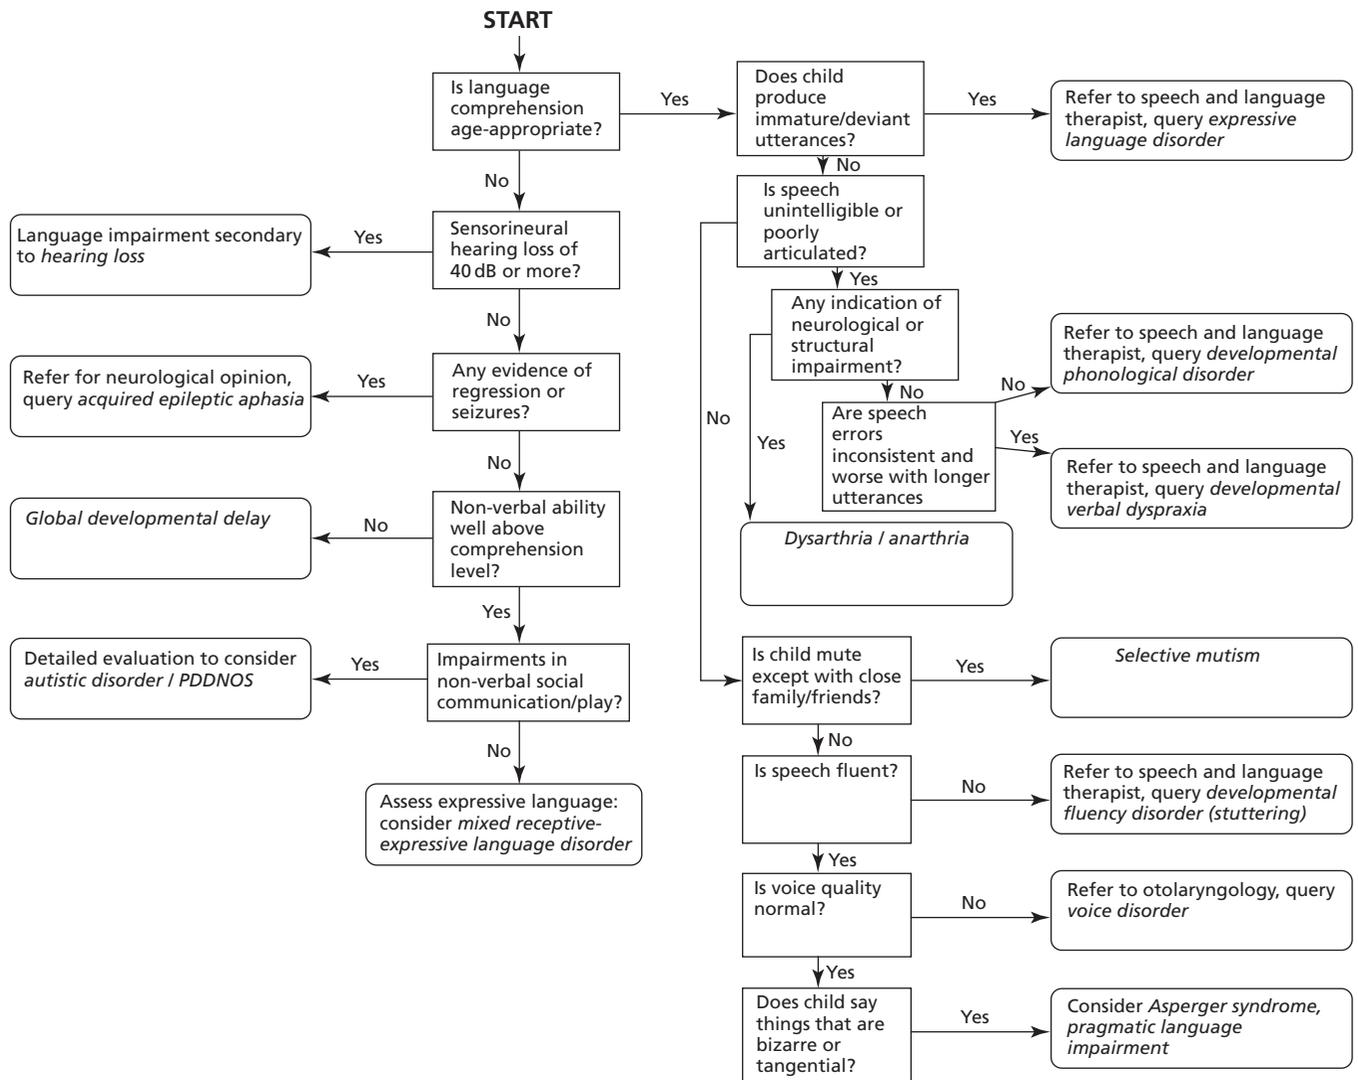

Fig. 39.1 Decision tree for diagnosing speech and language disorders in children.

disorder. Assessment procedures will briefly be reviewed in a later section.

A decision tree for diagnosis

In Fig. 39.1, the question of whether comprehension is age-appropriate is placed at the top of the decision tree. There are good reasons for this. First, whereas problems with expressive speech and language are usually fairly easy to detect on the basis of informal observation, comprehension is much harder to estimate this way. Secondly, different diagnoses need to be considered for the child with comprehension problems than for one whose problems are confined to speech output or sentence formulation.

Methods for testing comprehension are discussed at the end

of this chapter, but it is worth noting here that assessment can be difficult in children with major behavioural difficulties. It is tempting to assume that the child can understand but is uncooperative, but it is at least as likely that the behavioural difficulties stem from fear and frustration in a child who comprehends very little. If the child does not co-operate with formal comprehension testing, proceed down the decision tree on the left-hand side of the diagram.

As shown in Fig. 39.1, results from a comprehension assessment are not sufficient for a diagnosis, but they determine which diagnoses should be considered, and also help the clinician to adjust his or her language level to the child's level of understanding, for instance when conducting a psychiatric interview. Where comprehension is unimpaired, we can exclude autistic disorder and mental handicap. It is also unlikely that hearing loss or acquired epileptic aphasia is implicated.

Hearing loss

The first diagnosis to consider in a child with comprehension difficulties is hearing loss. Note that in Fig. 39.1 evaluation of hearing comes before assessment of non-verbal ability. It is all too easy to assume that if a child has low IQ then the language impairment has been explained. However, impaired hearing is a common correlate of many syndromes that affect general intelligence, and an audiological evaluation should always be undertaken in a child with poor understanding, regardless of IQ level. Furthermore, one should beware of relying on hearing tests carried out some years previously: some conditions lead to progressive hearing loss. It is salutary to note that on follow-up in adulthood, Mawhood *et al.* (2000) found bilateral hearing losses exceeding 40 dB in three out of 23 children who had been identified as having severe receptive language disorder in childhood.

A vexed question is what level of hearing loss is sufficient to explain language impairment. The research literature suggests that most children with severe and profound hearing losses will have major problems acquiring oral language and literacy skills, even if they are diagnosed early and given hearing aids and auditory training (Conrad 1979). Most of these children will demonstrate normal communicative ability in the visuomotor modality if exposed early to a sign language (Orlansky & Bonvillian 1985), and there is no evidence that learning to sign interferes with acquisition of spoken language (Bishop 1983). Recently, dramatic gains in spoken language acquisition have been seen in some children who have received cochlear implants early in life (Miyamoto *et al.* 1997; Tomblin *et al.* 1999) and it seems likely that this intervention will become increasingly widespread. Nevertheless, outcome can be very variable, and some children make disappointing progress. It is also worth noting that there is strong resistance to cochlear implants from some members of the deaf community, who maintain that if the child learns sign language, deafness need not be a handicap (Lane 1990).

Much less is known about the impact of mild and moderate sensorineural hearing loss on language development. The handful of studies that include children with mild or moderate hearing impairment typically find language levels intermediate between those of normally hearing and more severely hearing-impaired children (Brannon & Murry 1966). However, the average results may mask substantial variation. A recent small study of children with sensorineural hearing losses in the range of 20–70 dB HL, showed age-appropriate levels of language comprehension and expression in 78% of children (Norbury *et al.*, 2001). All of these were attending regular classrooms, most had mild losses (20–40 dB), and most wore hearing aids. None used sign language. This suggests that mild hearing loss can act as a risk factor for language impairment, but that, given appropriate intervention, many children compensate well for their hearing difficulties.

Otitis media with effusion (OME) is a common childhood complaint that is often associated with mild conductive hearing

loss. It is often cited as a cause of speech and language difficulties, but recent research suggests that the effect may have been overestimated in the past by relying on clinical samples (Bishop & Edmundson 1986; Bishop 1988). Epidemiological studies have found only weak influences, if any, on long-term speech, language and literacy outcomes (Grievink *et al.* 1993; Peters *et al.* 1994). It is also important to be aware just how common OME is. A Dutch epidemiological study of children screened at 3-monthly intervals between 2 and 4 years of age found that 55% of children had at least one episode of bilateral OME during this period (Zielhuis *et al.* 1990).

For simplicity, progress through the flow chart is halted when a primary diagnosis (in italic type) is arrived at. However, it is, of course, entirely possible that more than one pathology is present. The question the clinician needs to consider is whether the primary diagnosis can adequately explain the child's communicative profile, or whether there are some features that are not accounted for. For instance, we would expect a child with a severe sensorineural hearing loss to be slow in acquiring spoken language, but to make excellent progress in mastering a sign language, if exposure to this mode of communication was provided early in development (Petitto 2000). Even if no signed input is available, we would expect to see good use of non-verbal communication (gesture and facial communication). Thus, if a hearing-impaired child shows little sign of communicating non-verbally, this is an indication that the hearing loss is not the whole story, and further diagnoses need to be considered.

The flow chart in Fig. 39.1 explicitly recommends continuing through the decision tree if a child has a conductive hearing loss or a mild sensorineural loss (under 40 dB). This does not mean that mild or intermittent losses should be ignored, nor that they are irrelevant in the aetiology of speech and language problems, but they are unlikely to be the whole explanation for a child's difficulties. In so far as detrimental long-term effects of OME have been reported, they tend to occur in samples with other risk factors present, e.g. low birth weight and/or socioeconomic disadvantage (Gravel *et al.* 1996).

Acquired epileptic aphasia (Landau–Kleffner syndrome)

Acquired epileptic aphasia (AEA) should be suspected when language regresses after a period of normal development. Typically, the child becomes increasingly unresponsive to spoken language, sometimes over a period of months but sometimes within a matter of days. Deterioration in expressive language typically follows. Deafness may be suspected, but normal hearing thresholds are obtained. In classic Landau–Kleffner syndrome, the clinical picture is one of severe and selective receptive aphasia, with the child retaining good non-verbal intelligence (Landau & Kleffner 1957). This has also been described as an auditory agnosia, which may extend to affect perception of non-verbal as well as verbal sounds.

The epileptic basis of the disorder may be overlooked because

over 50% of these children do not present with frank seizures. However, abnormal electrical activity, usually involving the temporal lobes, is evident on sleep electroencephalography (EEG), although this abnormality typically dies down by adolescence, making retrospective diagnosis difficult.

The developmental course of AEA is highly variable. In some children, the disease follows a fluctuating course, with periods of improvements followed by regression. On average, the younger the child at onset, the worse the outcome for language, but this generalization hides a great deal of variability (Bishop 1985). Many children with onset before 5 years of age have serious and lifelong difficulties in understanding spoken language. Nevertheless, a long-term case study suggests that gradual improvement of language skill can continue over many years (Van Dongen *et al.* 1989). Regarding seizures, the outcome is much more favourable, with these usually disappearing by adolescence.

It is particularly important that child psychiatrists are aware of this rare disorder, because the appearance of communicative difficulties in a previously normal child often prompts a psychiatric referral, especially if there are associated behavioural disturbances, as is not uncommonly the case (Appleton 1995). Differential diagnosis from deafness should be unproblematic if proper audiological assessment is carried out. AEA differs from selective mutism in that language comprehension is usually intact in the latter condition, and the child can be observed to talk normally under certain restricted conditions. Neither is true for AEA. As noted by Genton & Guerrini (1993), it is essential to conduct an EEG recording for one full sleep cycle in any child who develops an unexplained language disorder, as this will clearly demonstrate the underlying functional abnormality in the brain of the child with AEA.

As with so many of the conditions reviewed in this chapter, the boundaries of AEA are not clear-cut, and diagnosis of atypical cases poses particular problems. Cases have been described in which only expressive language is disturbed. In other children, the regression affects social interaction and adaptive behaviour as well as language, making it difficult to draw a sharp line between AEA and autistic regression (Deonna 2000).

The prevalence of AEA is hard to determine as it is a rare disorder, which is often misdiagnosed as either deafness or selective mutism (see below). Appleton (1995) noted that over 200 cases have been reported since the condition was first described in 1957, and this number is increasing as the availability of new methods of brain imaging makes it possible to discover more about the underlying abnormality (Morrell & Lewine 1994; Guerreiro *et al.* 1996). Most clinicians, however, can expect to see only one or two cases during a lifetime.

The aetiology of AEA remains a mystery. No structural brain lesion has been demonstrated, and magnetic resonance imaging (MRI) and computed tomography (CT) scan are usually normal, but metabolic abnormalities, predominantly in the temporal lobes, are apparent on functional imaging (Guerreiro *et al.* 1996; Da Silva *et al.* 1997). A variety of diseases, ranging from cerebral arteritis to subacute encephalitis, have been mooted but

no consistent cause has been demonstrated. A pair of discordant monozygotic twins has been reported, ruling out a purely genetic aetiology (Feekery *et al.* 1993).

Medical interventions typically involve use of anticonvulsants to control the epileptic activity, but although this is often effective in controlling seizures, it does not necessarily normalize the underlying EEG abnormality and does not always lead to improvement in language. Some authorities have recommended aggressive treatment with corticosteroids (Lerman *et al.* 1991), or neurosurgical intervention in cases where it is possible to isolate the epileptic focus (Morrell *et al.* 1995). For both treatments, some cases of dramatic improvement have been reported, but such success is not invariable, making it difficult to weigh the risks of adverse effects against the possibility of recovery, especially in a disorder that may, in any case, follow a fluctuating course. It is generally agreed that an educational approach that relies on developing visual forms of language (written or signed) is more effective than attempting to overcome the child's auditory impairment.

There has been some debate in the literature as to whether, even after excluding those with Landau-Kleffner syndrome, there is an unusually high rate of EEG abnormality in children with language impairments (Echenne *et al.* 1992; Parry-Fielder *et al.* 1997), and whether a similar pathophysiological process might be present in children with more typical forms of developmental language disorder. For the present, this remains a speculation without firm evidence (Deonna 2000). Where a child presents with language disorders and seizures but does not have the clinical picture of AEA, it is recommended that the diagnostic process continues through the decision tree.

Global developmental delay

It is customary to make a diagnostic distinction between cases where non-verbal ability and verbal ability are equally impaired, and those where poor verbal skills are discrepant with normal non-verbal ability. Terminology in this area is something of a minefield. Clinically, the term 'global developmental delay' is used frequently, although rather imprecisely, to refer to children who function well below age level in a range of domains, including verbal and non-verbal ability, adaptive skills and motor development. Terms such as 'mental handicap' and 'intellectual retardation' are still used in some quarters to refer to children with an overall IQ below 70 (2 SD below the mean), but these labels have fallen out of favour because of negative social connotations. In the UK, the preferred term in many clinical and educational contexts is 'learning difficulty' or 'learning disability', but this has enormous potential for confusion, because outside the UK people tend to restrict the use of these terms to children with normal intelligence and a *specific* learning disability in one domain, such as specific reading disability. The term 'global developmental delay' is used here, while recognizing it is far from ideal (especially as 'delay' implies, unrealistically, that there may be subsequent catch-up).

Sadly, a diagnosis of global developmental delay is often the prelude to relative neglect of the child's language difficulties. There is a tendency to assume that the level of non-verbal ability sets some kind of limit on the level of language that can be achieved. There is evidence against this viewpoint from two sources. First, some syndromes are associated with a phenotype in which intelligence is impaired but language is an area of relative strength. The most well-known case is that of Williams syndrome. This is sometimes misleadingly described as though language is normal and other skills impaired. The reality for most children is that both verbal and non-verbal abilities are well below average but, nevertheless, skills such as verbal memory, vocabulary and syntax are far better than those seen in other children with different aetiologies who have similar levels of IQ (Morris & Mervis 1999). Furthermore, there may be relative sparing of aspects of syntax and morphology that give especial difficulty to children with developmental language disorders (Clahsen & Almazan 1998). The second point is that intervention studies suggest that in many cases children of low IQ can benefit from language intervention just as much as those of average IQ (Fey *et al.* 1994).

Although the flow chart shows global developmental delay and autistic disorder as separate entities, these disorders commonly co-occur, and so it is important to evaluate social communication, play and repetitive behaviour in children with a global developmental delay.

Autistic disorder and related conditions

Delayed language development and poor comprehension are hallmarks of autistic disorder, and the issue of differential diagnosis between autistic disorder and specific developmental language disorder frequently crops up in clinical settings. A diagnosis of autistic disorder should be suspected if the child's comprehension difficulties are accompanied by more pervasive difficulties affecting social interaction, non-verbal communication and play, or if the child shows unusual repetitive or ritualistic behaviours, or restricted interests. The clinician needs to consider whether language development is merely delayed, or whether there are deviant features that would not be regarded as normal at any age, such as repetitive use of stereotyped catch-phrases, unusual and exaggerated intonation, pronoun reversal, and a frequent failure to respond when the parent attempts to attract the child's attention. An intriguing observation in some children with autism is that scores on tests of expressive language (such as picture naming) may be higher than those on receptive tests (such as selecting a named picture). Whereas most children with communicative problems will use non-verbal means of expression, children with autism often have difficulty in both interpreting and producing appropriate non-verbal communication. Imaginative play does not develop normally in children with autism; instead there may be repetitive routines, such as forming long lines of toy cars, or the child may be preoccupied with everyday artefacts such as lights or switches, and disregards toys that most children would find attractive.

A core characteristic of autism is lack of social sensitivity. It is sometimes thought that all autistic children live in a world of their own, ignoring all other people. This is far too extreme a picture: many children with autism will enjoy cuddles and rough-and-tumble play, but they may neither seek nor offer comfort or affection. In older, verbal, high-functioning children, one may find a strong desire to interact with other people, but a severe lack of understanding of how to do this. The concept of friendship as a reciprocal emotionally supportive relationship is hard for a child with autism to grasp.

Diagnosis depends on historical information about early development as well as observation and assessment of the child's current behaviour and abilities. Specific instruments developed for the diagnosis of autistic disorder include the Autism Diagnostic Interview-Revised (ADI-R), which is a parental interview, and the Autism Diagnostic Observation Schedule (ADOS-G), which has four modules, to cover the age range from infancy to adulthood, each involving direct observation of the child or young person in situations designed to elicit autistic behaviours (Lord *et al.* 1994, 2000). Autistic disorder is covered thoroughly by Lord & Bailey (Chapter 38), so in this section I shall focus just on areas of diagnostic difficulty.

Textbook cases of autistic disorder or developmental language disorder are easy enough to recognize, but many children present with a pattern of symptoms that does not fit unambiguously in either category, while showing some features of both. Thus their difficulties extend beyond the highly selective impairment of language structure seen in developmental language disorder, but they do not have the full triad of autistic impairments in severe enough form to merit a diagnosis of autistic disorder. O'Hare *et al.* (1998) carried out an audit of 103 children referred to a speech clinic at Edinburgh Children's Hospital, and found that eight of them met diagnostic criteria for autism, but a further 14 had autistic symptomatology that fell short of meeting diagnostic criteria, in most cases because only two elements of the triad of autistic impairments were present. All but one of these children was rated as having abnormal receptive language on a speech therapy assessment. Although the diagnosis of Asperger syndrome is sometimes used in such cases, this is not appropriate if the child's language milestones are delayed.

In the UK, the term 'autistic spectrum disorder' is used quite widely, although often without clear diagnostic criteria. In the USA, and increasingly elsewhere, the DSM-IV (American Psychiatric Association 1994) term 'pervasive developmental disorder not otherwise specified' (PDDNOS) is frequently applied. However, this is not very satisfactory, as this was clearly intended as a default category to be used in rare cases when a child showed autistic symptomatology but diagnostic criteria for autistic disorder were not met. Furthermore, it provides little information about symptomatology and does not help decisions about educational placement. Bishop (2000) suggested that these difficulties probably reflect the fact that diagnostic labels impose a categorical structure on what is in reality a multidimensional space, with children varying in terms of the severity of impairments in language, social interaction and range of inter-

ests. The solution is not to force every child into the Procrustean bed of either autistic disorder or specific developmental language disorder, but rather to give the diagnosis that has the best chance of giving the child access to appropriate educational and remedial provision, while noting that the overall symptom profile may be atypical. Bishop (2000) suggested that the term 'pragmatic language impairment' might be useful for describing children who do not show repetitive behaviours and restricted interests, but whose language difficulties affect social communication and use of language in context. This label does not mean that we are dealing with a new syndrome; rather it may be helpful in characterizing that subset of children who have a symptom profile intermediate between autistic disorder and developmental language disorder, with pragmatic difficulties the most noticeable feature.

Specific developmental language disorder

In DSM-IV, an explicit contrast was drawn between specific developmental disorders and pervasive developmental disorders. Two features were important in making the distinction. The first is the specificity of the impairment: a single domain in specific developmental disorders, and multiple areas of functioning in pervasive developmental disorders. The second is the nature of the impairment: specific developmental disorder is seen as characterized by development that is delayed but not otherwise abnormal, whereas in a pervasive developmental disorder one sees behavioural deviations that are not normal for any stage of development.

In line with this dichotomy, a diagnosis of specific developmental language disorder (DLD) is appropriate when the child's language lags well behind age level, but development is proceeding normally in other respects, and when there is no obvious explanatory factor for language delay (such as grossly abnormal home environment, global developmental delay, hearing loss or acquired neurological lesion). It is important to be aware that a range of different terms has been used for this condition. Here, I follow DSM usage, but the term 'specific language impairment' is the more usual one in the research literature, whereas 'developmental dysphasia' or 'development aphasia' are now largely obsolete, although sometimes encountered in medical contexts.

Differential diagnosis

The diagnostic criteria of DSM-IV and ICD-10 (World Health Organization 1993) are similar. Both capture the notion that a developmental language disorder has three essential features.

1 Language skills are out of keeping with other aspects of intellectual development. In practice, this is often interpreted as meaning that there must be a discrepancy of at least 1 SD between a standard score on a language test and a non-verbal IQ test.

2 There should be evidence of disability associated with the language impairment: it has an adverse impact on the child's social or academic functioning.

3 The child does not meet criteria for pervasive developmental disorder.

Previous diagnostic formulations have also excluded a range of other conditions, such as intellectual retardation or sensory impairment, but these exclusions were relaxed in DSM-IV, which specifies that if they are present, the problems with language are worse than would normally be expected with such conditions.

DSM-IV draws a distinction between expressive DLD and mixed receptive–expressive DLD and this distinction is followed in the flow chart in Fig. 39.1. These are defined to be mutually exclusive, so that a diagnosis of expressive DLD is made only if criteria are not met for mixed receptive–expressive DLD. In reviewing characteristics of DLD I shall depart from the sequence of Fig. 39.1 here and treat both together, because most research studies do not distinguish between these subtypes. Furthermore, although there have been suggestions that the two subtypes are qualitatively distinct (Lahey & Edwards 1995), much of the evidence justifies treating them as points on a continuum of severity (Bishop 1979). Thus, although the distinction between receptive–expressive and pure expressive DLD may be useful clinically for educational placement and prognosis, it has yet to be shown to distinguish meaningfully between clinical entities. This is not to imply that there is a single homogeneous type of DLD: this is quite unlikely given the wide range of clinical manifestations one can observe. However, the dimensions on which children appear to differ have more to do with which components of language (e.g. morphosyntax, vocabulary, pragmatics) are affected, rather than with the expressive–receptive distinction (Bishop & Rosenbloom 1987; Rapin 1996).

The diagnostic criteria of DSM-IV and ICD-10 have come under attack in recent years. Much of the debate has centred on the question of whether it is appropriate to require a large mismatch between non-verbal ability and language level to meet diagnostic criteria for DLD. Aram *et al.* (1992) found that adoption of this discrepancy criterion overidentified normally developing children, and underidentified children who had been diagnosed as language impaired on clinical grounds. Cole *et al.* (1995) showed that the discrepancy between language and non-verbal ability was unstable, so that children tested on two occasions frequently changed category, even if the same measures were used. Bishop (1994a) found that identical twins were usually concordant for the presence of clinically significant language problems, but were often discordant in terms of meeting stringent discrepancy criteria based on DSM. Aram *et al.* (1993) compared various diagnostic criteria with the aim of improving agreement between clinical judgement and decisions based on psychometric data, and reported that the most sensitive index was one that diagnosed a DLD if the child had either a 15-point (1 SD) discrepancy between non-verbal IQ and a composite language test score, or had a mean length of utterance (MLU) more than 1 SD below age level. This definition captured 80% of clinically identified cases. Another source of criticism of the official diagnostic systems is their reliance on psychometric tests.

Research has shown that measures obtained from spontaneous speech samples are useful in identifying children who are deemed language impaired but who do not meet conventional psychometric criteria (Dunn *et al.* 1996). Unfortunately, such measures are time-consuming and not always practicable in clinical settings. Furthermore, adequate normative data are often lacking.

In the final analysis, the specific criteria adopted for identifying language impairment will depend partly on one's goals when making the diagnosis. Stringent criteria developed in research contexts are not always appropriate in clinical settings, where the goal is to provide a diagnosis that ensures the child has access to appropriate services. Here, one wants to use measures that have ecological validity—that have relevance for functioning in everyday communicative and social settings—and to identify those children who will benefit from intervention. If one requires a large discrepancy between verbal and non-verbal ability before children can be considered for special educational services, then many children with poor verbal skills are denied access, even though their linguistic problems may be identical to those of other children who do meet diagnostic criteria.

Developmental course and prognosis

A number of longitudinal studies have thrown light on the developmental course of DLD. There is general agreement that the child with significantly impaired receptive language skills has a poor prognosis, even if this diagnosis is made at a very early age. Comprehension problems do not usually appear to resolve spontaneously. On the contrary, the range of impairments seen in a child with receptive language difficulties often increases with age, extending to encompass social and psychiatric disorder (Rutter & Mawhood 1991), and impairment on non-verbal as well as verbal measures (Stothard *et al.* 1998; Johnson *et al.* 1999). There is much more debate about prognosis for preschool expressive language disorders, with some proposing that outcome is generally good and intervention is seldom warranted (Paul 2000), while others maintain that these children are at high risk for persisting difficulties that may only become apparent on detailed testing (Scarborough & Dobrich 1990; Rescorla *et al.* 1997). At least some of this controversy arises because different studies have used different follow-up periods to assess prognosis. In the longitudinal study conducted by Paul *et al.* (1996), the initial impression given by the first waves of follow-up was that 2 year olds with expressive language delays were at high risk of persisting communicative problems. However, the longer the follow-up, the smaller the proportion of children who had marked language impairment. It appears that the numbers of children with clinically significant language difficulties do shrink dramatically as children mature. It seems reasonable to conclude that a good long-term prognosis is usually seen in children identified as 'late talkers' before the age of 3 years, provided the problem is restricted to expressive language and the delay is not too severe (Whitehurst & Fischel 1994). Bishop

(1994b) offered guidelines that still seem relevant in the light of current research: children whose expressive vocabularies consist of less than 50 words at the age of 24 months should be carefully monitored, but long-term problems are unlikely in those with vocabularies of more than eight words who have good comprehension.

There are a number of longitudinal studies showing that the child whose language is significantly impaired at 4–5 years of age is at high risk of developing literacy problems (Bishop & Adams 1990; Tallal *et al.* 1997; Stothard *et al.* 1998; Johnson *et al.* 1999). Although it is commonly believed that oral language problems disappear with age to be replaced by literacy problems, this is seldom seen. Rather, the oral language problems become less obvious in casual interactions, but can be readily demonstrated on formal testing. It would be wrong to give the impression that all language-impaired 4 year olds are destined for academic failure: some children do show marked improvement. However, these tend to be children with predominantly expressive difficulties that have resolved by the age of 5½ years (Bishop & Edmundson 1987; Bishop & Adams 1990).

DLD is associated with increased risk for psychiatric as well as language and literacy problems. The underlying nature of this association has been the cause of much speculation (Rutter & Lord 1987). Comorbidity could reflect the influence of common aetiological risk factors, or the causal effect of one condition on the other (Beitchman *et al.* 1996). For instance, for some children affective disorders and low self-esteem may be a consequence of growing awareness of communicative inadequacy.

Prevalence

Two recent epidemiological surveys, in the USA and Canada, estimated the prevalence of specific language impairment (SLI) in 5 year olds at around 7% (Tomblin *et al.* 1997; Johnson *et al.* 1999). However, it should be noted that neither study adopted the stringent 'discrepancy' criteria of DSM-IV and ICD-10, but rather diagnosed SLI if the child scored below cut-off on standardized language tests, but had a non-verbal IQ of 80 or above and no other exclusionary criteria. Furthermore, in the study by Tomblin *et al.*, only 29% of those diagnosed as cases of SLI were already known by parents to have any speech or language difficulties. This estimate is likely therefore to be higher than would be the case if it were based on a definition such as DSM-IV or ICD-10, which requires both that there be a substantial discrepancy between verbal and non-verbal ability, and that the language impairment interferes with everyday or academic functioning.

Risk factors and aetiology

The principal risk factors for DLD are:

- male gender—in clinical samples, sex ratio of affected males : females is around 3 or 4 : 1 (Robinson 1991);

- family history of DLD—around 30% of affected children have an affected first-degree relative, compared with 3% of the general population (Stromswold 1998); and
- being a later-born child in a large family (Bishop 1997a).

Although much has been written about language outcomes of medical risk factors, such as otitis media and low birth weight, there is no strong evidence that these act as major risk factors for specific DLD, although they may act synergistically to cause impairment in a child who is already at risk from other causes (Bishop 1987). Although there is an association between low socioeconomic status and DLD (Fundudis *et al.* 1979), this is not strong, and there is little support for the commonly held view that parents can cause their child to become language impaired by inadequate verbal stimulation, except in the most extreme cases of abuse and neglect.

Over the past decade, there has been an explosion of research concerned with the genetic basis of DLD (see Bishop, 2001 for a review). Three twin studies have obtained closely similar findings of high heritability for this disorder (Lewis & Thompson 1992; Bishop *et al.* 1995; Tomblin & Buckwalter 1998). A molecular study of a three-generational family showing an autosomal dominant pattern of inheritance for severe speech and language disorder found clear evidence of linkage to a site on chromosome 7 (Fisher *et al.* 1998), although it is unclear how far these results will generalize to other cases of heritable language disorder.

Currently, there is considerable interest in two aspects of language functioning that have been postulated as behavioural markers of heritable SLI. The first is phonological short-term memory, typically assessed by asking the child to repeat nonsense words of increasing length, such as ‘hampent’ or ‘blonterstaping’ (Gathercole *et al.* 1994). Poor performance on this task characterizes many children with SLI, even those who had early difficulties that appear to have resolved. Furthermore, deficient performance on non-word repetition showed very high heritability in a twin study (Bishop *et al.* 1996). The second area in which many children with DLD have disproportionate difficulties concerns certain aspects of grammar. Children with DLD can have major problems in adding appropriate verb endings, such as past tense ‘-ed’, when given an eliciting sentence frame (e.g. Q: ‘Here the boy is raking the leaves. What has he just done?’ A: ‘Raked the leaves’) (Rice 2000). Rice & Wexler (1996) have postulated an underlying impairment of an innate system that has evolved to handle specific types of grammatical rule. With the exception of non-word repetition, the measures used to assess such hypotheses are not available as standardized tests, making them unsuitable for clinical use at present. Nevertheless, the work is promising in suggesting that we may be able to develop more selective language measures that will identify homogeneous groups of children with a common aetiology. That would be a considerable improvement on the current position, where the same child may or may not receive a diagnosis of DLD depending on which tests are used to assess verbal ability.

The fact that there is strong genetic influence on DLD

should not lead us to conclude that environmental factors are unimportant, or that nothing can be done to alleviate language difficulties. Provisional evidence suggests genes may act as risk factors that increase the probability that a child will have a language disorder, but the severity and persistence of language disorder can be highly variable, even within a pair of genetically identical monozygotic twins. A study by Bishop *et al.* (1999) suggested that environmental factors could impair the child’s ability to process non-verbal auditory stimuli, with a subsequent small knock-on effect on language development. In children who were not at genetic risk, this negative effect was not of clinical significance, but in those who were at genetic risk, for whom language learning was a more difficult task, the combination of environmental and genetic risk factors was sufficient to lead to clinically important problems in language learning.

Intervention

Intervention is usually carried out by speech and language therapists, who use a wide range of techniques to stimulate language learning. In the past, there was a vogue for drilling children in grammatical exercises, using imitation and elicitation methods, in an attempt to have the child extract the salient grammatical regularities. Such methods fell into disuse when it became apparent that there was little generalization to everyday situations. Contemporary approaches to enhancing development of language structure are more likely to adopt ‘milieu’ methods, in which the intervention is interwoven into natural episodes of communication, and the therapist builds on the child’s utterances, rather than dictating what will be talked about. In addition, there has been a move away from a focus solely on grammar and phonology toward interventions that develop children’s social use of language, often working in small groups that may include normally developing as well as language-impaired peers (Gallagher 1996; Hayden & Pukonen 1996).

Another way in which modern approaches to remediation differ from the past is that parents are more likely to be directly involved, particularly with preschool-aged children (Girolametto *et al.* 1996). Methods such as the Hanen approach* involve videoing interactions between parent and child and then using these when working with groups of parents in a constructive way to help them facilitate communication.

A radically different approach has been developed by Tallal *et al.* (1996), who have devised a computer-based intervention, FastForward, that involves prolonged and intensive training on specific components of language and auditory processing. The theory underlying this approach maintains that language difficulties are caused by a failure to make fine-grained auditory discriminations in the temporal dimension, and the training materials are designed to sharpen perceptual acuity, in much the

*See website at http://hanen.velocet.ca/programs_parent.shtml

same way as has been demonstrated in animal experiments. By embedding training in attractive computerized games, children can be persuaded to participate in thousands of training trials, in a way that would simply not be possible with a standard therapist-based interaction.

For all these types of intervention, there are few adequately controlled trials that allow one to assess clinical efficacy. In general, one does not see miracle cures, but this is not to say that gains are negligible (Bryne-Saricks 1987; Law *et al.* 1998). A clinical trial assessing the FastForword approach showed significant gains relative to a control group (Merzenich *et al.* 1996), but questions remain about the persistence and generalizability of these effects. Since the initial controlled trial, the authors have gathered a large amount of data on pre- and post-intervention language test scores of children enrolled in FastForword, but this is difficult to evaluate without controls for practice and placebo effects (Tallal 2000). Furthermore, it is not possible to know which specific components of this complex intervention are most effective, or whether the whole gamut of different exercises is essential to achieve therapeutic benefits.

Developmental phonological disorder

It is customary to draw a distinction between speech, the physical act of articulating speech sounds, and language, the whole complex system of combining elements of sound at different levels of complexity to express meaning. It is possible to have a language impairment with normal speech (e.g. in cases of DLD where the child speaks clearly but does not comprehend or produce complex syntactic constructions). The converse situation is also seen, when the child has some difficulty in producing clear speech but the underlying language skills are intact, e.g. in cases of dysarthria (see below). The child who persists in using immature or deviant sound patterns but who has no physical basis for this disorder does not fit so neatly into this dichotomous view. Speech is undoubtedly the presenting problem, but the underlying impairment appears to be linguistic rather than one of motor control: a failure to learn which speech sounds are distinctive in the ambient language. Often the speech errors involve a persistence of immature patterns. For instance, sounds produced in the back of the mouth, such as 'k' and 'g' are not distinguished in the child's output from those produced in the front of the mouth, such as 't' and 'd', so that 'cat' may be pronounced as 'tat' and dog as 'dod'. The terms 'phonological disorder' (DSM-IV) and 'phonological impairment' have superseded such labels as 'functional articulation disorder' to refer to such problems. The term 'phonological' implies that the child's difficulties are linguistic rather than motoric, perhaps akin to those of an adult mastering a foreign language. Most of us have difficulty in learning to use a new set of speech sounds, not because our articulators are in any way defective, but because we have not internalized the sound distinctions that are critical in the language.

Evidence that a phonological disorder is not just a problem in articulating sounds accurately can be obtained using specialized

phonological tests that require no speech from the child. Some children with phonological problems have difficulties in discriminating between similar speech sounds, such as 'pat' vs. 'cat', when asked, for instance, to select a picture to match what they have heard. However, the most common difficulty is not so much in telling sounds apart, as in recognizing that different exemplars of the same sound are indeed the same sound. So if asked to say whether 'bag' or 'boat' rhymes with 'rag', or to judge whether 'soup' or 'coat' begins with the same sound as 'Sam', the child with phonological problems may perform at chance levels (Bird *et al.* 1995). Such observations suggest that the difficulty is one of categorization of speech, rather than poor acuity for differences between speech sounds.

The prognosis of pure phonological disorder is much better than that of language disorder (Bishop & Adams 1990; Johnson *et al.* 1999), especially if the phonological difficulties resolve by the time the child starts school (Bird *et al.* 1995). It is difficult to estimate the prevalence of phonological problems, because studies typically do not discriminate between different types of speech problem; lispings and other deviations, specific phonological impairments, and speech problems accompanying language impairment all tend to be included together. Furthermore, prevalence appears strongly age-dependent, with speech problems declining sharply between 3 and 6 years of age (Morley 1972). After excluding children with additional handicaps, Johnson *et al.* (1999) obtained a prevalence estimate of 6.1% for specific speech-only impairments at 5 years of age. This figure excludes the children from this sample who had comorbid speech and language impairment. Shriberg *et al.* (1999) reported a prevalence of speech delay in US 6-year-olds of 3.8%, with comorbid language impairment in around 12% of these cases. Little is known about risk factors and aetiology of phonological disorders, although, as with other communication disorders, boys are at greater risk than girls (Shriberg *et al.* 1999). Intervention is carried out by speech-language therapists, and typically involves games and exercises to develop the child's awareness of phonemic contrasts (Dean *et al.* 1995).

Developmental verbal dyspraxia

Developmental verbal dyspraxia is a controversial diagnostic category that is defined differently by different experts, and not used at all by some authorities (for a review see Crary 1993). The central characteristic in most definitions is that there are difficulties in speech production that suggest an impairment of motor programming, because it is the length and complexity of what is uttered, rather than the specific speech sounds used, that is the main factor determining accuracy. In children with this diagnosis, one is likely to see speech errors that are inconsistent from one occasion to the next, that are particularly evident in polysyllabic words, and that involve transpositions of speech sounds rather than simple substitution of one sound for another. For instance, Bradford & Dodd (1996) reported a dyspraxic child whose renderings of 'elephant' on three separate occasions were 'ewint', 'wuwit' and 'uwit'.

Debate continues over the question of whether problems in sequencing non-verbal movements should be part of the diagnostic criteria: some authorities maintain that to be regarded as dyspraxic, the child should be impaired in imitating sequences of non-speech movements of the tongue and mouth. Not all children who make inconsistent phonological errors have extensive difficulties producing non-speech movements, raising the question of where they should be classified (Bradford & Dodd 1996). In addition, there is the question of whether dyspraxia should be diagnosed in a child who has broader difficulties with expressive language, or only in those with a relatively pure problem in speech output. In practice, many children who receive this diagnosis do have associated problems affecting language, literacy and phonological awareness (Stackhouse 1992).

The lack of agreed diagnostic criteria make it impossible to make generalizations about risk factors, prevalence or prognosis. The cause of developmental verbal dyspraxia remains an enigma, but it appears to be strongly familial (Morley 1972). It is also worth noting that although their grammatical difficulties have been emphasized in published accounts, the phenotype in the three-generational family mentioned in the section on DLD also involved severely dyspraxic speech (Hurst *et al.* 1990). Cray (1993) provides an overview of approaches to intervention for developmental verbal dyspraxia.

Anarthria and dysarthria

Anarthria or dysarthria is diagnosed when speech problems arise because of structural or neurological abnormalities of articulatory control. Anarthria is the term used when there is no ability to produce speech, whereas dysarthria refers to disordered articulation caused by weakness, incoordination or structural abnormalities of the articulators. It is important to distinguish these articulation problems, where speech is impaired because of problems producing articulatory movements, from developmental phonological disorders, where the child is neurologically normal and capable of producing articulatory movements (see above). Neurological conditions that can cause anarthria or dysarthria include cerebral palsy and Möbius syndrome, in which there is agenesis of cranial nerve nuclei and associated facial immobility. Structural abnormalities of articulators that can lead to dysarthric speech include cleft palate and Treacher Collins syndrome. There are a number of other genetic syndromes that are associated with unusual proportions of the articulators and/or hypotonicity which affects tongue control, e.g. Down syndrome.

Where no specific syndrome is detected, one should be alert to the possibility of dysarthria when there is poor co-ordination or weakness of facial muscles, as evidenced by drooling, feeding problems, or difficulties imitating simple oral movements such as moving the tongue from side to side or pursing the lips. Worster-Drought (1974) stressed that anarthria can occur in children in the absence of any other neurological impairment, and he gave detailed descriptions of this condition, which is known as both congenital suprabulbar paresis and Worster-

Drought syndrome. However, Clark *et al.* (2000), in a recent review of 47 cases, noted that most children with this condition have additional complex impairments, including mild pyramidal tetraplegia, learning difficulties, behaviour problems and epilepsy. Cray (1993) noted that remarkably little clinical or research attention has been paid to developmental dysarthria, although it was well described by Morley *et al.* (1954) more than 40 years ago. It appears to be a strongly familial condition.

Dysarthria and anarthria involve difficulties affecting speech rather than language, and so one would expect to find normal language comprehension and normal literacy skills in pure cases. However, quite often the aetiological factors that cause articulation difficulties also lead to problems in other areas, including hearing and language.

Selective mutism

Selective mutism is diagnosed when a child is able to speak but fails to do so except in very restricted situations, such as with close family. This disorder was previously known as 'elective mutism', but the terminology was modified in DSM-IV to avoid the connotation of volitional behaviour. The diagnosis is strongly suggested when one finds mutism in a child who has no neurological or structural abnormalities of the articulators, and who has normal language comprehension, as well as a normal early history of using language. However, the crucial point that needs to be established is that the child does speak in some situations.

As Dummit *et al.* (1997) noted, this condition is more properly regarded as a form of anxiety disorder rather than a speech and language disorder. Rates of comorbid anxiety and phobic disorders are high, both in affected children and in their first-degree relatives. However, differential diagnosis can be complicated by the fact that some children with selective mutism do have developmental language disorders (Kristensen 2000), suggesting that self-consciousness about inadequate communication skills may play a part in maintaining mutism.

Persistent selective mutism affects less than 1 in 1000 children, although the frequency of transient mutism in children starting school is much higher. Girls are two to three times more likely to be affected than boys. The causes of selective mutism remain unknown. Although conventional wisdom maintains that physical or sexual abuse or other kinds of trauma may precipitate selective mutism, there is little evidence of this (Black & Uhde 1995), and the strong familial component to the disorder suggests that Dummit *et al.* (1997) may be correct in regarding this disorder as the extreme end of a biologically based continuum of temperament and social behaviour.

Behaviour modification methods have been shown to be effective in re-establishing speech (Sluckin *et al.* 1991), but the long-term prognosis of selective mutism is nevertheless poor. There is a high rate of personality disorder and psychiatric problems associated with a history of selective mutism (Kolvin & Fundudis 1981). Dummit *et al.* (1997) argued that therapeutic interventions should focus on alleviating anxiety, but there has been no systematic research on the efficacy of this approach.

Disorders of fluency

Stuttering is the popular term for dysfluent speech that is characterized by repetitions by sounds or syllables, rather than whole words. Onset is usually between 3 and 6 years of age. Campbell *et al.* (1996) noted that the high rate of spontaneous recovery in children (estimated as between 50 and 80%) makes it difficult to know when referral is appropriate, and they proposed a list of ‘referral indicators’ to aid clinical decision-making. Factors that should prompt clinical referral include observable tension or struggling during speech, abnormal pitch associated with dysfluency, prolongations or blocks lasting more than 1 s, and presence of distorting facial or bodily movement accompanying the stuttering.

As in most of the speech and language disorders reviewed in this chapter, the aetiology of stuttering is unknown, but it appears to be strongly familial, and boys are at considerably higher risk than girls (ratio of 3 : 1 according to Campbell *et al.* 1996).

Voice disorders

A voice disorder should be suspected when a child speaks with abnormal vocal quality. This includes hoarseness, deviations of pitch and abnormally loud or soft voice. These features can have profound effects on how a child is perceived by others: a grating, squeaky or whispery voice may have consequences for the child’s socialization. Campbell *et al.* (1996) estimated that between 1 and 3% of school-aged children have clinically significant voice problems requiring intervention. They described unpublished data from their own survey of 203 consecutive referrals to a specialist clinic for investigation of abnormal vocal quality. Only 6% had normal laryngeal structure. The most common pathology was vocal nodules, i.e. mechanical trauma of the vocal folds usually caused by one vocal fold making extensive contact with the other. Surgical intervention is not usually used in such cases; behavioural treatment is the most effective approach, and involves training the child to use the voice more appropriately.

The child who presents with normal speech and language structure

To round off this section, it is necessary to say something about the child who has normal speech and language abilities on formal assessment. Obviously, one would expect to find large numbers of such children in the course of any routine screening programme, for instance when assessing all children attending a child psychiatry facility. However, a normal speech and language profile is occasionally seen in children who have been referred by a parent or professional because of specific concerns about communication. A striking illustration comes from a survey of 7-year-old children attending special classes for language-impaired children in the UK (Conti-Ramsden *et al.* 1997). On cluster analysis of language test scores, some 10% of children

fell in a subgroup that had little evidence of language deficit, with all language scores above the 13th centile, and word-reading and articulation above the 60th centile. One might imagine that these would be children for whom intervention had been effective who were ready to return to regular schooling but, when teacher impressions were added to the psychometric test data, a very different conclusion was reached. Quite often these were the children about whom teachers had the greatest concerns. They described them as having particular problems in the domains of semantics and pragmatics. Where a parent or teacher complains that a child gives odd, unexpected, inconsistent or over-literal interpretations to utterances, or makes tangential responses in conversation, one needs to be alert to the possibility that there may be pragmatic comprehension difficulties that will not necessarily be apparent on formal testing. In some cases, the child may speak with stereotyped intonation, as if acting a part on the stage. Where there are abnormalities in the social use of language, but early language milestones were normal, a diagnosis of Asperger syndrome should be considered (see Lord & Bailey, Chapter 38). Where there is a history of early language delay, but the child currently presents with normal test scores on measures of language structure but with odd communication, then more detailed evaluation may suggest a diagnosis of pragmatic language impairment (see section on Autistic disorder and related conditions). The next section will consider aspects of assessment, including suggestions for evaluating pragmatic competence.

Assessment

Interview with the caregiver

General guidelines for interviewing parents are given by Angold (Chapter 3), and this section will focus just on those issues that arise specifically in the context of children with speech and language difficulties.

Usually, one will place more reliance on results of standardized tests than on the caregiver’s descriptions for evaluating the presence or severity of a speech or language problem. However, for very young children who may not co-operate with formal assessment, an adult who knows the child well may provide invaluable information about early language milestones, vocabulary size and typical utterance length. However, care must be taken to elicit accurate information. General questions such as ‘how many words does he or she know’ are unlikely to be helpful. For children around 2 years of age, the MacArthur Communicative Development Inventory (Fenson *et al.* 1994) has proved useful in identifying children with language delays. The caregiver is presented with a list of words that young children say, and simply checks off those that are produced by the child in question. Norms for passing language milestones are shown in Table 39.1. Ideally one should identify ‘anchor points’ in the past, such as a birthday or other special event, and ask the caregiver to provide specific examples of the kinds of things that the child said at

Table 39.1 Age (in months) at passing language milestones.
(After Neligan & Prudham 1969.)

Percentile	Single words*		Sentences†	
	Boys	Girls	Boys	Girls
3rd	8.7	8.6	17.5	16.2
10th	10.0	9.8	19.1	18.4
25th	11.6	11.5	21.4	20.4
50th	12.4	12.3	23.8	22.9
75th	15.0	14.6	26.8	25.0
90th	18.0	17.3	32.5	30.8
97th	21.9	20.1	36.0+	36.0

*Three or four different words for people or objects, correctly used.

†Three or more words, strung together to make some sort of sense.

that time. It is important to establish whether the child's language development ever regressed, as this is a rare phenomenon that suggests an underlying epileptic aetiology.

The perinatal, medical and family history may provide some clues as to the aetiology, but in most cases of developmental speech and language disorder, it is difficult to identify a specific cause.

Physical examination

General aspects of examining children are covered by Bailey (Chapter 10). Where the child has abnormal speech production, it is important to assess the integrity of the articulatory apparatus. A history of difficulties with chewing, drinking from a straw, licking an ice-cream or blowing the nose should alert the clinician to the possibility of physical abnormalities, such as submucous cleft palate, and neurological impairment. Brown (1985) gives guidelines for neurological examination of speech mechanisms. Involuntary grimacing, drooling, abnormal gag reflex, and difficulties with sucking and swallowing are important upper motor neurone signs.

Motor clumsiness is a common correlate of speech and language disorder (Robinson 1991; Owen & McKinlay 1997), but one seldom finds any evidence of hard neurological signs. However, although such cases are rare, it is important to bear in mind that language delay can be the first presenting symptom of progressive diseases such as Duchenne muscular dystrophy, so it is never safe to assume that clumsiness is simply an indicator of neurodevelopmental immaturity (Kaplan & Elias 1986).

Audiological assessment

In co-operative children, behavioural audiometry provides crucial information about hearing sensitivity at different frequencies, but for some children such procedures are not feasible. A clinical audiological assessment will usually include an assess-

ment of the function of the middle ear and cochlea, with evoked response audiometry being employed if there is any doubt about the integrity of auditory pathways up to and including the brainstem. However, it is less common to have any assessment of the neural pathways from brainstem to auditory cortex. At these higher levels, auditory responsiveness is more variable and subject to attentional influences. Furthermore, the critical stimuli that elicit responses become increasingly complex. Experimental animals with bilateral ablations of auditory cortex can still detect auditory stimuli, and can learn discriminations based on changes in intensity or frequency. However, they show difficulties in discriminating between tone sequences or tone duration (Neff 1967). This raises the question of whether some children may have auditory perceptual impairments that reflect poor functioning of central auditory pathways. The concept of central auditory processing disorder (CAPD) gained momentum in the 1980s (Keith 1977), and batteries of auditory tests have been developed for diagnosing such problems as difficulty in perceiving speech in noise, or integrating inputs from two ears (Willeford 1977). Unfortunately, we still know very little about how such deficits affect language acquisition, despite several decades of research on the auditory basis of language impairments, and these methods are not in widespread clinical use.

Assessment of non-verbal ability

Where a child has impaired language, it is important to assess intelligence using methods that minimize the role of verbal expression or comprehension. It is not possible here to give a detailed review of tests, but some recommendations are offered of instruments that appear valid with language-impaired children and have adequate psychometric properties.

Probably the most widely used intelligence tests are those forming the Wechsler scales, which include a group of subtests that form a performance scale, with different versions suitable for children in the age range 3–7 years (WPPSI; Wechsler 1989) and 6–16 years (WISC-III; Wechsler 1992). The Leiter International Performance Scale–Revised (Roid & Miller 1997) has the advantage of being specifically designed for assessing intelligence without requiring any language. The examiner demonstrates what is required, rather than using verbal instruction, and the test is untimed. The revised test is considerably improved over the original version, with new norms, data on reliability and validity, and new subtests to assess attention and memory. Norms for the McCarthy Scales of Children's Abilities (McCarthy 1972) are dated, but the battery contains attractive subtests for assessing non-verbal abilities that readily engage the interest of preschool-aged children. The test is appropriate for the age range 2–8 years. The Kaufman Assessment Battery for Children (K-ABC; Kaufman & Kaufman 1983) is a well-standardized battery that includes a non-verbal scale that requires no language from tester or testee, and is suitable for ages 4–12 years. The British Ability Scales II (Elliott *et al.* 1996) and its US counterpart the Differential Ability Scales (Elliott 1990) consist of a battery of cognitive tests for children aged from 2 to

17 years, including some exclusively non-verbal subtests that can be combined to form a Special Non-verbal Scale.

There are a number of brief tests of non-verbal ability that are not suitable for clinical assessment, because they assess only a limited range of cognitive operations, but which are useful in research or screening settings. Raven's Matrices (Raven *et al.* 1986), which includes an easy version, Coloured Matrices, is suitable for children aged 5 years and above. This test correlates well with 'g', the principal factor that is extracted from other IQ tests. The Test of Non-verbal Intelligence, third edition (TONI-3; Brown *et al.* 1997) is a language-free measure of cognitive ability suitable for ages 5 years and above. Raven's Matrices and TONI-3 are both untimed and take around 15 min to administer. The Wechsler Abbreviated Scale of Intelligence (WASI; Wechsler 1999) includes two subtests to estimate Performance IQ and has norms from 6 years to adulthood.

Given the central importance of assessment of non-verbal ability in the DSM-IV and ICD-10 diagnoses of developmental speech and language disorders, it is perhaps surprising that there are few recommendations about which tests are most appropriate with this population. Tests can vary markedly in the cognitive functions that they assess, and in the extent to which performance may be affected by the use of verbal coding, even if no language is used explicitly. Tests involving perceptual matching or manipulation (e.g. shape matching or copying, block design, object assembly, mental rotation) seem least likely to be affected by language level. Those involving higher level conceptual matching (e.g. on the basis of number or superordinate semantic category) could conceivably be influenced by the child's ability to count, or knowledge of the verbal labels for categories. More difficult matrices tasks, which involve identifying salient information from two or more dimensions and combining this to form a solution, might well be facilitated by verbal encoding of the problem. In addition, tests vary in whether or not they stress speed as well as accuracy of performance. In the WISC-III, separate scores can be computed for Perceptual Organization and Processing Speed. Little work has been carried out to assess how these factors may influence performance of language-impaired children. In the absence of such information, one can only recommend that, in clinical contexts, a range of non-verbal tests should be administered, rather than relying solely on one or two subtests.

Speech

Speech difficulties are relatively easy to detect, but require specialized expertise to assess. Coplan & Gleason (1988) provide guidelines to help clinicians decide when to refer a child for speech assessment, on the basis of a parent's response to the question, 'How much of your child's speech can a stranger understand?':

- 1 less than half;
- 2 about half;
- 3 three-quarters;
- 4 all or almost all.

At 2 years, referral is suggested if the child is less than 50% intelligible, at 3 years if less than 75% intelligible, and at 4 years if less than 100% intelligible. Referral will usually be to a speech and language therapist, who will analyse the pattern of speech errors, and also assess how far the child has an isolated speech problem or more pervasive language difficulties. Where there is facial dysmorphism, or evidence of neurological dysfunction, referral to specialist medical services (paediatric neurology, otolaryngology, and/or clinical genetics) is warranted.

Language

Screening for language impairment

Before discussing detailed language assessment, we need to consider the question of how and when to embark on such an assessment for the child presenting with a psychiatric disorder, where a language disorder has not been suspected. We know from the work of Cohen (1996; Cohen *et al.* 1998) that a high proportion of such children do have measurable language deficits. However, in many clinical contexts, there are insufficient resources to enable every psychiatric referral to have a full language assessment. Information from parental interview and informal clinical observation can help guide the decision as to whether to refer the child for more detailed evaluation. Rutter (1987) and Cantwell & Baker (1987) provide useful clinical guidelines for evaluating the child's communicative history and current status. Where there is evidence of delayed language development, inconsistent or inadequate responses to the speech of others and, in a child above the age of 5 years, difficulty in giving simple information about a salient past event (such as a birthday party or holiday) or problems in following simple commands (e.g. 'Pick up the big ball and the spoon' from an array of objects), then this should alert the clinician to the possibility of a language problem.

The fact remains that reliance solely on clinical judgement is seldom adequate for detecting more subtle communicative difficulties. One solution is for the clinician to gain expertise in administration of simple language screening tests. Renfrew (1988) Language Scales have the advantage that they can be administered by those without specialist training, and provide an indication of level of grammatical competence, narrative skills and word-finding ability in children from 3 to 8 years of age. For older children, Cohen *et al.* (1998) found that a 30-min battery that included subtests from the Clinical Evaluation of Language Fundamentals-3 (CELF-3; Semel *et al.* 1995) provided good discrimination between children with and without language impairments. However, administration of this battery requires expertise in language assessment.

Measuring severity and nature of language impairment

More detailed investigation of speech and language problems will usually be undertaken by a speech and language therapist or

specialist psychologist. In English, there are now several language test batteries to choose from, but the situation is far less satisfactory in many other languages, and it is not safe to assume that difficulty of test items will remain constant if a test is translated. The instruments that are used depend on the age of the child.

This brief review will focus predominantly on language batteries that use a range of subtests to estimate receptive and expressive language abilities. For very young children, the most suitable test is the Preschool Language Scale (PLS-3; Zimmerman *et al.* 1992), which provides norms from the ages of 2 weeks to 6 years. It has separate subscales for Auditory Comprehension and Expressive Communication. The Test of Language Development (TOLD-P3; Newcomer & Hammill 1997) has norms from over 1000 children from 4 to 8 years. It has five core subtests that are combined to give an overall Language Quotient. Tomblin *et al.* (1996) have developed an algorithm for diagnosing language impairment based on TOLD scores. The Clinical Evaluation of Language Fundamentals (CELF; Semel *et al.* 1995) is widely used by speech and language therapists in both the UK and USA to diagnose specific language impairment. Scales can be combined to yield receptive and expressive scales, and a reduced subset of tests may be used for screening. There are different versions for preschool-aged children (3–6 years) and older clients (6–21 years). The Test of Adolescent and Adult Language (TOAL-3; Hammill *et al.* 1994) provides an in-depth assessment of receptive and expressive language, including some subtests involving written language.

Pinpointing the nature of a language impairment

More specialized diagnostic tests can be used to pinpoint the nature of language difficulties more precisely. For instance, one can consider whether a child with comprehension problems has difficulty in discriminating speech sounds, in recognizing words, or in decoding complex sentences (for a review see Bishop 1997b). The Goldman–Fristoe–Woodcock Test of Auditory Discrimination (Goldman *et al.* 1970) assesses ability to discriminate speech sounds in noisy and quiet conditions in children aged 3 years and above. The British Picture Vocabulary Scale (BPVS; Dunn *et al.* 1997) or its US equivalent the Peabody Picture Vocabulary Test (PPVT-R; Dunn & Dunn 1997) assess receptive vocabulary, and the Test for Reception of Grammar (TROG; Bishop 1989) assesses understanding of grammatical contrasts. The Token Test for Children (Disimoni 1978) stresses auditory verbal memory, requiring the child to respond to commands such as, ‘Pick up the big green square and the small blue circle’.

Comprehension assessment poses a particular challenge for children whose motor impairments prevent them from being able to manipulate toys or point to pictures, but it is usually possible to arrange multiple choice test materials in such a way that the child can use a communication aid, or a reliable response such as eye-pointing, to select from the alternatives.

Two points should be stressed. First, no test is a ‘pure’ measure of language functioning. Factors such as level of co-operation, attention, memory and executive functions may play a part in how children perform. A highly distractible child may impulsively point to a picture in an array because it is appealing or salient, without listening to instructions. Secondly, different tests that purport to measure the same functions may assess quite different underlying skills. For instance, the Wechsler scales include a subtest termed Comprehension that requires the child to respond to questions such as ‘What should you do if you see thick smoke coming from the window of a neighbour’s house?’ Correct performance on this test requires very different skills (including reasoning ability and response formulation) from those tapped by an auditory discrimination or receptive vocabulary test. Thus, whether a child’s language scores in the impaired range can depend as much on the specific tests used as on the characteristics of the child. There is evidence that ‘knowledge-dependent’ measures, such as vocabulary tests, exaggerate cultural and socioeconomic differences between children, whereas ‘processing’ measures that vary difficulty by manipulating the amount of material that has to be processed (e.g. Token Test, or non-word repetition) depend less on prior experience, and so give a culturally unbiased estimate of language ability (Campbell *et al.* 1997). Interestingly, the same processing measures also seem especially sensitive to residual language difficulties in older children and adults (Tomblin *et al.* 1992; Bishop *et al.* 1996).

Most standardized assessments focus on assessing accuracy and complexity of elicited language, or literal understanding of individual words and sentences, e.g. the child may be asked to select a picture where ‘the fish is on the table’. The ability to select and interpret messages appropriately in relation to the context (pragmatics) is not adequately tapped by such tasks. The Children’s Communication Checklist developed by Bishop (1998) may be helpful in obtaining information about the child’s everyday use of language when pragmatic difficulties are suspected but not detected on formal assessment. In addition, it can be useful to move away from formal assessment and consider how the child behaves in a more naturalistic situation, such as toy play or, for children of 6 years and over, adult–child conversation about the child’s past activities and planned future events. It is difficult and time-consuming to obtain objective indices of conversational competence from such data (Bishop *et al.* 2000) but it is possible to consider such general questions as: is the child’s conversation coherent, or is it difficult to keep track of what is being talked about? Does the child go off at tangents, or keep returning to favoured topics? Does the child keep asking questions, with apparent disregard for the answers? Does speech sound stilted, over-adult, pedantic, stereotyped or robotic? Is there a tendency to give over-literal answers, such as drawing a picture when asked to ‘draw the curtains’? If the answer to such questions is ‘yes’, this suggests one should consider a diagnosis on the autistic spectrum, and that broader evaluation of social interaction and repetitive behaviours and interests needs to be undertaken.

Conclusions

This chapter has been structured around the decision tree shown in Fig. 39.1, which was designed to facilitate clinical decision-making in this complex and difficult area. However, it is important to appreciate that this is something of an idealization, showing the steps one would follow to arrive at a primary diagnosis. In practice, few of these different disorders are mutually exclusive, and the clinician will not necessarily find all the evidence consistent with a single final diagnosis. For instance, global developmental delay often coexists with autistic disorder; selective mutism may co-occur with DLD. Speech and language difficulties often go hand in hand. Many children with dysarthria or anarthria also have some degree of hearing impairment or language impairment. Perhaps the most important message for the clinician is to remember that cases of 'pure' textbook conditions are the exception rather than the rule.

Introduction

The term ‘learning difficulties’ is widely applied to problems that pose obstacles to educational achievement. Learning difficulties can occur in the context of global delays in development or, more specifically, where there are circumscribed deficits in cognitive processes. It is conventional in clinical and educational practice to differentiate these two forms of learning disability. This chapter primarily considers specific learning difficulties, in contrast to general learning difficulties that cut across different domains, as a way of highlighting how relatively specific cognitive deficits impact upon learning processes. Moreover, the focus of the chapter is on reading difficulties. Reading difficulties (dyslexia) have attracted much more research interest than other types of learning problem and have been described at the biological, cognitive and behavioural levels. In addition, interventions to ameliorate reading problems have been evaluated. Much less is known about specific difficulties in arithmetic (dyscalculia) and about non-verbal learning disabilities, possibly because these problems can be hidden more easily in a literate society.

Specific learning difficulties

Problems of literacy

Specific reading difficulties

Following the landmark Isle of Wight studies, it became widely accepted that children who have specific reading difficulties (specific reading retardation) should be distinguished from children who have reading difficulties in the context of more general learning problems (reading backwardness) (Rutter & Yule 1975). The definition of specific reading difficulties depends upon the use of a regression approach. Thus, on the basis of the correlation between reading and IQ in children of the same age, a child is deemed to have a specific problem with reading if reading attainment is significantly below that predicted from general cognitive ability.

However, the regression approach is a statistical approach and as such it has its limitations. A key question is whether children with a disorder defined in this way are distinct from children who have the same learning difficulty in the context of low IQ (Rispen 1998). Current opinion is somewhat divided on this

issue. While there is a growing body of opinion that the causes of poor reading are similar in the two groups of children, evidence suggests that children with ‘discrepancy-defined reading disorders’ (specific reading retardation) differ from generally backward readers in the compensatory strategies they can use (Nation & Snowling 1998). In turn, this may influence their reading development.

The prevalence of specific reading difficulties depends upon the cut-off point taken to indicate a reading disability. Using a cut-off of 2 standard errors of measurement (SE) below their expected attainment score, Yule *et al.* (1974), reported a prevalence of specific reading retardation ranging from 3.1% among 10 year olds in the Isle of Wight to 6.3% in London, based on the discrepancy between IQ and reading accuracy. The comparable figures for specific difficulties in reading comprehension were 3.6 and 9.3%, respectively. Thus, prevalence depends both upon geographical distribution (figures were higher in an inner-city population) and also on the tests used (Rodgers 1983; Silva *et al.* 1985).

Epidemiological data also suggest that this classification of children’s reading problems is not a stable entity. Shaywitz *et al.* (1992) followed the development of 414 Connecticut children and, using a cut-off of 1.5 SE below expectation as indicative of specific reading difficulties, reported prevalence rates of 5.6% in 6 year olds, 7% in 8 year olds and 5.4% in 10 year olds. Fluctuations in the numbers of children fulfilling the criteria for specific reading retardation in the different grades may partly be explained by variations in the rate of early literacy acquisition. Later on in development, the changing demands of reading can also be expected to produce variations in prevalence rate (Snowling 2000).

Epidemiological studies have typically reported an excess of males with specific reading difficulties, three to four males to every female affected, consistent with the findings from referred samples. Shaywitz *et al.* (1990) found a more even distribution of between 1:3 and 1:5 boys to every girl affected. To some extent, differences might be explained by differences in the age of the populations sampled or by differences in the cut-offs used to define specific reading problems. None the less, a bias towards boys in those children who had been referred by their schools was noted, and there was a tendency for girls to have more severe reading problems before they were referred.

A further variable that can be expected to influence prevalence rates of specific reading difficulties is the amount of time different children spend reading. A national survey conducted

by McKenna *et al.* (1995) in the USA reported that attitudes to reading decline through the elementary school years, particularly for boys and for poorer readers. A disinclination to read may itself influence reading attainment and inflate the incidence of specific reading difficulties. Moreover, home factors account for large amounts of variance in the reading outcomes of children (Lundberg 1999). For this reason, it could be argued that a child should only be considered to have a specific reading deficit if they have had adequate opportunity to learn, although it is hard to put this exclusionary rule into practice.

It seems reasonable to infer that between 4 and 7% of children will have a specific reading difficulty at any one time, usually equivalent in practical terms to a retardation of some 18–24 months in reading relative to expectation based on age. However, it is noteworthy that the discrepancy definition of reading disorder typically conflates decoding problems and difficulties of reading comprehension (DSM-IV; American Psychiatric Association 1994). While it is the case that problems of decoding create a bottleneck to meaning and therefore compromise reading comprehension (Perfetti & Hogaboam 1975), it is not always the case that problems of reading comprehension are accompanied by word-level decoding difficulties. Furthermore, discrepancy definitions of reading difficulties are silent as to the signs that place a child at risk of reading failure, or that differentiate an adult with persisting difficulties in the domain of literacy who has compensated for a basic reading problem. For this reason, it is important to consider not only a child's current attainment when diagnosing a learning difficulty, but also their cognitive profile.

Normal literacy development: a framework

Before turning to a cognitive analysis of the causes of reading difficulties, it is important to make reference to normal theories of literacy development. In essence, to become literate, a child needs to integrate a system for processing written language with one that already exists for processing spoken language. In an alphabetic language such as English, the foundation of literacy is a system of mappings between orthography (the letters of printed words) and phonology (the speech sounds that make up the pronunciation of spoken words). The basic processes involved in establishing a system for word recognition are well captured by connectionist models of learning to read (Seidenberg & McClelland 1989). According to such models, reading involves the transfer of patterns of activation from orthographic input units to phonological output units for reading, and in the opposite direction for spelling. Furthermore, the transfer of activations between letter strings and pronunciations is conducted in the context of meaning (semantics). Activations from the meanings of words facilitate the decoding process by providing a top-down 'boost'. This facilitation is important for reading words that can only be partially deciphered by letter-sound translation and is particularly important for reading English that contains many exceptions to the 'rules' (Plaut *et al.* 1996). An important facet of connectionist models of reading is that, as knowledge

accrues within the network of mappings, it generalizes to allow novel words to be read (e.g. non-words like 'tekqip'). The models therefore provide a parsimonious account of learning to read because a system for 'self-instruction' is part of the functional architecture.

There is now unequivocal evidence that learning to read depends upon phonological skills (Goswami & Bryant 1990). Children who can reflect on the sound structure of spoken words are well prepared to establish mappings between spoken and written words. Thus, reading and spelling achievement is strongly predicted in the school years by preschool measures of phonological awareness, even when the substantial effects of IQ are controlled (Bradley & Bryant 1983; Muter *et al.* 1997). However, a virtually exclusive focus of research on the acquisition of phonological awareness and reading skills has detracted from the important role of other language processes, such as semantic and syntactic skills, to the development of literacy. In the simple model of reading, Gough & Tunmer (1986) proposed that reading was the product of decoding and language comprehension. Children not only use knowledge of print-sound correspondences to decipher print, they also use sentence context to support this process (Share 1995). Furthermore, they must integrate the meanings of words within sentences and be able to use higher level skills, such as inference-making, to ensure text cohesion (Yuill & Oakhill 1991).

The task demands of reading are such that reading difficulties can occur for many different reasons. Broadly, reading disorders fall into two types: disorders of decoding and word identification at the word level (dyslexia); and disorders of reading comprehension that affect both single word and text comprehension. There have been a number of different typologies of reading difficulties within this framework. However, all of these leave substantial numbers of children unclassified. The main terms in current use to describe 'subtypes' of reading disorder are *phonological dyslexia* (a specific difficulty with decoding), *surface dyslexia* (a specific difficulty with the development of word recognition) and *hyperlexia* (a specific difficulty in printed word comprehension in the presence of a precocious ability to decode). However, as will become clear, these labels are used primarily to describe the surface manifestations of reading problems and do not necessarily carry implications either about aetiology or for intervention.

Word recognition and decoding deficits: the concept of dyslexia

Although in a minority of cases, problems of word identification (surface dyslexia; Coltheart *et al.* 1983) can be dissociated from problems of phonological decoding (phonological dyslexia; Seymour 1986; Castles & Coltheart 1993), the majority of children with specific reading difficulties have phonological difficulties (Manis *et al.* 1996). Within the connectionist framework outlined above, dyslexic children come to the task of learning to read with poorly specified phonological representations and deficits in both decoding (Rack *et al.* 1992) and word recognition ensue (Harm & Seidenberg 1999). In contrast, read-

ing comprehension can be relatively good (Frith & Snowling 1983).

While the role of visual problems in dyslexia is a topic of continuing debate (Willows *et al.* 1993; Talcott & Stein 1999), most studies point to phonological deficits in dyslexic children (Brady 1997). In addition to problems with phonological awareness and limitations of verbal short-term memory, dyslexic children also have difficulties with verbal learning. These are the basis of many of their reported classroom learning problems, such as difficulty learning rote sequences like the months of the year, in mastering multiplication tables and in learning foreign languages.

The strength of the evidence pointing to the phonological deficits associated with dyslexia led to the proposal that dyslexia should be defined as a ‘core’ phonological deficit. Importantly, within the *phonological core–variable difference* model of dyslexia (Stanovich & Siegel 1994), poor phonology is related to poor reading performance, irrespective of IQ. Skills close to the ‘core’ of dyslexia include non-word reading and aspects of phonological awareness; all poor readers will tend to differ from normal readers in these skills. Children with specific reading difficulties differ from generally poor readers in skills farther from the core, including measures of working memory and listening comprehension.

An important advantage of the phonological deficit definition of dyslexia is that it makes sense in terms of what is known about the normal acquisition of reading. It also accounts well for the pattern of difficulties dyslexic people show across the life span when, although reading problems may be compensated, non-word reading and spelling impairments persist (Pennington *et al.* 1990; Bruck 1992; Snowling *et al.* 1997). These residual difficulties are often accompanied by problems of written expression.

Reading comprehension impairments

In contrast to dyslexic children who have deficits at the word level, children with specific difficulties in reading comprehension have good phonology and decode well but have problems understanding what they read. Nation & Snowling (1997) reported that 10% of a school sample of children had specific difficulties with reading comprehension. These difficulties often go unnoticed in the classroom because these children can read aloud competently. However, such children have poor vocabulary knowledge, poor syntactic skills (Stothard & Hulme 1995; Nation & Snowling 2000b) and poor working memory resources (Nation *et al.* 1999; Cain *et al.* 2000b). In the longer term, poor comprehenders have particular difficulty reading exception words that require semantic processing (e.g. ‘chrome’, ‘aunt’). They also have difficulty using context to support their reading (Nation & Snowling 1998) and find it difficult to monitor and repair their reading errors. Although they spell well, their written composition uses a paucity of sentence structures and lacks cohesion. More generally, the problems they have making infer-

ences (Cain *et al.* 2000a) do not bode well for academic attainment across the curriculum.

Data on the longer-term outcome of poor comprehenders are lacking. A small-scale follow-up of 14 poor comprehenders studied by Stothard & Hulme (1995) suggested that, at the age of 13, some 5 years after the initial study, these children had poor reading accuracy as well as poor reading comprehension (Snowling *et al.* 1999). Similarly, Snowling *et al.* (2000) reported that children with specific language impairment who showed specific difficulties with reading comprehension at the age of 8 had general reading problems encompassing word recognition, decoding and reading comprehension skills at school leaving age. These strands of evidence suggest that there is a reciprocal interaction of component reading skills during development, such that decoding and comprehension skills, which are initially independent, support each other in the development of adult literacy.

Spelling difficulties

The spelling skills of dyslexic children are almost always impaired because they have difficulty reflecting on the sound structure of words. Although the attempts of dyslexic children to spell are phonologically motivated (Treiman 1997), a raised incidence of phonetically unacceptable errors has often been reported. A second source of spelling difficulty is poor knowledge of orthographic conventions. As English is an opaque orthography in which spelling–sound correspondences are not consistent, phonetic spelling errors are frequently seen (e.g. biscuit → biskit; chaos → kaos).

The term ‘dyslexia’ has sometimes been applied to individuals who have spelling difficulties in the absence of reading problems. Clinically, these children tend to have higher verbal than performance IQ and they make phonetically accurate spelling errors (Nelson & Warrington 1974). As becomes clear later, some of these children may be better characterized as having non-verbal learning disabilities rather than dyslexia.

Within a normal population, children who read well but have specific spelling problems were investigated by Frith (1980). Good readers who were poor spellers spelled phonetically; they had particular difficulty knowing when it was appropriate to double consonants (e.g. the ‘n’ in ‘beginning’) and how to represent unstressed vowels in syllables, for example the [er] sound in ‘catapult’. They also found it difficult to select the correct spelling from two plausible alternatives, e.g. successful/sucesful; necessary/necessery and they did less well than good spellers in proofreading and in non-word reading. It is possible therefore that a subtle reading problem can cause spelling difficulties; indeed people with poor spelling do not read in a detailed way. While a strategy of using context and partial graphic cues suffices for reading, Frith (1980) argued that it is insufficient to ensure satisfactory spelling performance. Subsequent evidence from single-case studies has confirmed a subtle difficulty with visual processing in individuals who can read but

not spell well (Goulandris & Snowling 1991; Romani *et al.* 1999).

Cross-linguistic manifestations of reading disability

Languages differ in the difficulty they pose to young readers, differences that are related to the regularity or ‘transparency’ of their writing systems. German and Italian represent the more transparent of the European orthographies and, in these languages, letters and groups of letters (graphemes) correspond to single speech sounds (phonemes). The English writing system is, by contrast, opaque and, very frequently, a grapheme may correspond to more than one phoneme (e.g. the grapheme *e* may correspond to ‘e’ as in ‘bed’, to ‘i’ as in ‘eve’ and to ‘i’ as in ‘believe’).

A growing body of evidence indicates that children learn to read and spell more quickly in transparent languages than in opaque systems such as English (Harris & Hatano 1999). The reading and spelling symptoms of dyslexia are also different in regular orthographies. Unlike the case for English, German-speaking dyslexic children can read long unfamiliar words and also non-words as accurately as their peers, but their rate of reading is slow (Frith *et al.* 1998). Phonological awareness also develops more quickly in readers of transparent orthographies (Cossu 1999). As a consequence, the core phonological deficit of dyslexia is harder to detect in children who have learned to read in a regular orthography. In these languages, difficulties can be identified most clearly on tasks that require implicit phonological processing, such as verbal short-term memory, rapid naming and visual-verbal paired associate learning tasks (Wimmer *et al.* 1998).

Role of environmental input

Although cognitive explanations of reading disorders are compelling, it is important not to overlook the critical role of the environment in shaping a child’s reading development. Indeed, social class differences in the development of reading skills are not entirely attributable to differences in reading-related phonological skills or general intelligence (Hecht *et al.* 2000). One variable that can have a significant impact on the behavioural manifestation of a reading disorder is reading practice. In the research literature, ‘print exposure’ is considered important for ensuring progress in an opaque reading system such as English, where there are many words that cannot be decoded using spelling–sound rules. Print exposure, measured by questionnaires that require participants to differentiate real book titles or real author’s names from distracter items, and which document reading habits, accounts for variance in reading skills when other critical variables, such as IQ and phonological awareness, have been controlled (Stanovich & West 1989). It follows that clinicians need to be aware that an important source of individual differences among children with reading problems is the time they devote to reading.

Problems of numeracy

The incidence of underachievement for arithmetic (sometimes called dyscalculia) is less well documented than for reading. In the USA, the figure reported is around 6% (Baker & Cantwell 1985); in the UK, Lewis *et al.* (1994) recorded specific arithmetic difficulties of 1.3% in their epidemiological sample of 9–10 year olds; and in Israel, Gross Tsur *et al.* (1996) reported a prevalence of 6.5%, with equal numbers of boys and girls affected. It is common for arithmetic problems to co-occur with specific reading difficulties. Lewis *et al.* (1994) reported a prevalence of 2.3% for comorbid specific reading and arithmetic difficulties and Gross Tsur *et al.* (1996) reported that 17% of their sample with dyscalculia were also dyslexic.

Theoretical framework of normal development of number skills

From shortly after birth, infants can detect changes in the number of objects in visual displays of objects (Wynn 1995). This innate sense of numerosity is considered to be the foundation of later number concepts that develop rapidly during the preschool years. Gelman & Gallistel (1978) studied the development of counting from the age of around 2 years. In addition to learning the numbers and their order, children have to understand that each item in a set is labelled once and only once in the count sequence (the concept of one-to-one correspondence). The next step is to master cardinality, the knowledge that the final word in the count sequence tags its quantity. Later, children learn the principles of abstraction (that anything can be gathered together and counted) and of order irrelevance (the order in which you count things does not matter). Thus, by the time children go to school they have a foundation for the development of arithmetic skills. To become numerate demands more; children need to learn conventional systems and to use their mathematical thinking meaningfully and in logical situations (Nunes & Bryant 1996).

The earliest arithmetic skill to be taught in school is addition, a natural extension of counting skill. At first, children use a simple ‘count all’ strategy to solve addition problems (for a review see Geary 1993). By the age of 6, most are using a ‘counting on’ strategy in which they start with the smaller number and count on from this, often using fingers (MIN strategy). Later, as they learn the number bonds, they can begin to retrieve these automatically. Development involves change in the mix of strategies that are used. Importantly, the development in long-term memory of an association between the problem integers (e.g. 3+4) and the answer that is generated (7) requires practice in the execution of basic computations. With each execution, the probability of direct retrieval of that number fact or bond increases. It follows that children who have difficulty with this basic strategy will take a long time to acquire a database of number knowledge, and they may therefore fail to achieve automaticity in arithmetic skills.

While most research has been carried out on addition, analogous strategy development can be seen in subtraction, multiplication (initially approached as a set of additions) and division. Moreover, because the development of number skills is cumulative, it is easy for a child to slip behind by being unable to recover from a difficulty with a single operation that is not fully resolved before one that builds on it is introduced. Difficulty with arithmetic also causes anxiety that may compound the learning problem itself.

Classification of arithmetic difficulties

Research on number skills has distinguished between a pre-verbal number system (possibly in the right hemisphere) and a verbal number system acquired later (Dehaene 1992). In line with this view, children with language impairments have been reported as normal in their processing of non-verbal aspects of number, such as estimating the relative size of two blocks, but impaired on parallel verbal tasks, such as estimating the relative magnitude of two numbers (Donlan 1998). By analogy, it is likely that the arithmetic deficits of children with specific reading difficulty arise because of their verbal learning deficits (Geary *et al.* 1999).

Individual differences in the manifestation of number problems have been reported in the cognitive neuropsychological literature using a framework developed by McCloskey *et al.* (1985). Within this framework, the calculation system can be dissociated from the number processing system (Gross Tsur *et al.* 1996). Temple (1994) has reported single-case evidence for the existence in childhood of ‘digit dyslexia’, in which there is a specific difficulty in the acquisition of lexical processes within the number processing system (problems in encoding the meaning of numerals such as 348483), ‘procedural dyscalculia’ in which there is difficulty in learning procedures and algorithms, and ‘number fact dyscalculia’ in which there is specific difficulty in acquiring numerical facts. This approach is primarily descriptive and suggests neither what causes these different forms of arithmetic difficulty nor what ties them to impairments in underlying cognitive processes.

Cognitive deficits as an explanation of arithmetic problems

According to Geary (1990), children with mathematical difficulties use the same strategies as age-matched controls, but differ in the speed and skill of strategy execution. Typically, they make less use of the MIN strategy, they can retrieve fewer number facts, they are poor at monitoring their counting and they are poor at detecting computational errors (Geary *et al.* 1992). A slow rate of counting may contribute to their problems as may working memory deficits (Adams & Hitch 1997) or slow speed of processing (Bull & Johnston 1997).

One of the main cognitive approaches to arithmetic difficulties in children has been couched within the working memory framework of Baddeley & Hitch (1974). The working memory system has three components:

- 1 the central executive;
- 2 an attention system that controls and initiates mental operations; and
- 3 two slave systems
 - the phonological loop for the short-term maintenance and rehearsal of speech-based information; and
 - the visuospatial sketch pad for the storage of visual and spatial information (see Hulme & Roodenrys 1995 for a review of its application to children’s learning difficulties).

It is clear that arithmetic draws on working memory resources; numbers have to be held in short-term memory during the process of mental calculation and a spatial representation of the problem to be solved can be helpful in some forms of problem-solving. Importantly, the central executive will be involved in a range of control processes, not yet well understood, but which include the selection of appropriate algorithms and the monitoring of performance (for example, checking that the solution to a problem is within the estimated range). Hitch *et al.*, working with children who had specific arithmetic difficulties, delineated deficits in simple working memory tasks (e.g. span tasks that tap the phonological loop), on complex working memory tasks that tap the central executive (Hitch & McAuley 1991), in spatial working memory and some executive tasks (McLean & Hitch 1999). The involvement of executive processes in number work means that children with attentional difficulties are likely to be particularly at risk of failure in mathematics. A challenge for the future is to map the different forms of working memory deficit to the neuropsychological deficits observed and ultimately to the level of brain processes.

Non-verbal learning disabilities

Johnson & Myklebust (1967) were the first investigators to describe a group of children who had excellent auditory skills and spoke early in development but displayed deficiencies in visuospatial organization and non-verbal integration. These children showed normal word reading skills but reading comprehension was deficient where it involved inferential thinking, as was performance in arithmetic.

Semrud-Clikeman & Hynd (1990) noted considerable agreement among different classification schemes for non-verbal learning difficulties. Interestingly, arithmetic disabilities occurred in most reports, as did delayed reading, although decoding skills were relatively good compared to arithmetic abilities. Development of motor and visuospatial skills was reported as delayed; directional confusion was often noted as were deficits in social skills. Although described as a non-verbal syndrome, many children had associated speech–language difficulties including pragmatic deficits.

Non-verbal learning disabilities syndrome

The strongest proponent of the view that there is a syndrome of non-verbal learning disabilities (NLDS) is Rourke (1989, 1995), who described its principal clinical features in terms of neu-

ropsychological assets and deficits. Academically, the typical strengths of a child with NLDS are in single-word reading and spelling, with deficits in handwriting (especially its acquisition), reading comprehension, mathematics and arithmetic. The principal neuropsychological asset in NLDS is the capacity to deal with information derived through the auditory modality, whereas the primary deficits are in visuoperceptual organizational abilities, complex psychomotor skills, tactile perception, and non-verbal problem-solving. From clinical experience, Rourke (1989) considered that socioemotional and adaptive deficits characterize the syndrome and can encompass extreme difficulties in adapting to novel situations and significant deficits in social competence and social interaction.

The concept of a syndrome of non-verbal learning disabilities cuts across taxonomies, such as those discussed above, that classify children according to patterns of impairment in the academic arena. An issue of considerable importance is the relationship between NLDS and disabilities on the autism spectrum. Klin *et al.* (1995) compared 21 subjects with Asperger syndrome and 19 with high-functioning autism in terms of the criteria for NLDS. This study used a conservative algorithm for the NLDS classification requiring concordance of 10/15 deficits and 5/7 assets from those proposed by Rourke (1989). There was a strikingly high degree of concordance between Asperger syndrome and NLDS but not between NLDS and high-functioning autism. Thus, non-verbal learning difficulties are a neuropsychological marker of Asperger syndrome.

DAMP syndrome

The term ‘DAMP’ is used in Nordic countries to describe children with disorders of attention and motor perception. According to Gillberg (1999), DAMP has the following clinical characteristics:

- problems of attention;
- poor gross and fine-motor skills;
- perceptual deficits; and
- speech–language impairments.

In mild forms, some of the characteristics are not present and it encompasses children with pure developmental co-ordination disorder and pervasive attention deficit. There are synergies between the syndrome of DAMP and of NLDS, although severe dyslexia is considered a symptom of DAMP but not of NLDS. The difference may reflect the manifestations of a reading impairment in the Scandinavian languages where the concept of DAMP has been used more widely than in English-speaking countries.

Although there is no doubt that children who exhibit DAMP syndrome exist, the issue whether they constitute a coherent grouping is open to debate and whether the milder and more severe variants share common core features is not clear. In the preschool years, DAMP children are usually considered hyperactive, and show motor co-ordination problems and speech–language delays although typically not sufficiently serious to warrant clinical referral. In the early school years, these children

have difficulties in concentrating and have problems learning to read and write. They are also unable to interact with their peers in an age-appropriate fashion. By the age of 10, the clinical picture can be quite different with an increase in behavioural problems and dyslexia, problems that persist into adolescence. In adulthood, criminal behaviour is not uncommon and there can be major psychiatric problems.

Cognitive deficits in non-verbal learning disabilities

The underlying causes of non-verbal learning difficulties have been under-researched. It is possible that deficits in spatial cognition, associated with poor motor skills, are at the core of the problems and account in particular for the mathematical difficulties and writing problems encountered by this group of children. Spatial deficits also lead to a range of problems in ‘extracurricular’ activities, such as in athletics, team games and sight-reading of music, but these difficulties are mostly of little consequence in the academic arena (Denckla 1991). However, it is clear that many children described as having non-verbal learning disabilities also show aspects of autism continuum disorder, and the role that deficits in social cognition may have requires further investigation.

Comorbid problems of attention control

The term ‘comorbidity’ describes the tendency for two different conditions to occur together in the same individual (Angold *et al.* 1999). The issue of comorbidity needs to be raised here because learning difficulties may be the result of a combination of cognitive difficulties. In particular, children with dyslexia are often reported to lack concentration and teachers complain of their poor organizational abilities. In a recent survey of a large UK primary school, Adams *et al.* (1999) found that 12.5% of poor readers were rated by their teachers as having a significant problem with attention. The rate was 15.6% among children with specific reading difficulties from the same school.

Pennington *et al.* (1993) addressed the issue of whether problems of attention are direct consequences of dyslexia or whether they reflect comorbid ADHD in a study involving three groups of children:

- 1 a group of dyslexic readers who did not have attentional problems (RD);
- 2 a group of children diagnosed with ADHD; and
- 3 a comorbid group who had dyslexia and ADHD (RD+ADHD).

The children completed phonological tasks chosen to tap the core deficit in dyslexia, and executive function tasks that require sustained attention, organization and planning to investigate the putative cognitive deficit in ADHD (Pennington & Ozonoff 1996). In line with expectation, the RD group performed poorly on tests of phonological processing but had no difficulty with the executive function tasks, whereas the ADHD group showed executive deficits but normal phonological processing. Importantly, the comorbid (RD+ADHD) group performed like the

dyslexic group, showing phonological but not executive deficits. The resemblance of the comorbid group to the dyslexic group suggested that they had developed attention problems as a secondary consequence of their learning difficulties. This study highlights the value of cognitive tests to the diagnosis of learning difficulties; it was the lack of any deficit in executive function that set these poor readers apart from children with ADHD.

Biological bases of learning disabilities

Reading difficulties

Genetic factors

It has been known for many years that reading difficulties run in families and current estimates indicate that the risk to a son of being dyslexic if he has a dyslexic parent is 35–40%. For a daughter the risk is somewhat less, about 20%, regardless of which parent is affected (Gilger *et al.* 1991). Gene markers for dyslexia have been found on the long arm of chromosome 15 (Smith *et al.* 1983) and on the short arm of chromosome 6 in other families (Cardon *et al.* 1994). Interestingly, the markers on chromosome 6 are in the same region as the genes implicated in autoimmune diseases that have been reported to show a high degree of association with dyslexia (Geschwind & Behan 1984; Pennington *et al.* 1987).

An important contribution to understanding the causes of reading disability has come from the behaviour–genetic investigations of component reading subskills. Such analyses suggest that there is significant heritability for reading recognition and spelling deficits. In line with work by Stevenson *et al.* (1987) with a UK sample of twins, DeFries *et al.* (1997) found that heritability estimates decreased as a function of age for word recognition (0.64 vs. 0.47) but increased for spelling (0.52 vs. 0.68). There is a larger environmental contribution to reading comprehension than to word recognition, possibly because this depends on vocabulary knowledge derived through the educational and home environment (Olson *et al.* 1994). By systematically examining individual differences in reading strategy, Olson *et al.* inferred that phonological processing ability is genetically determined, and this underlies the development of both phonological decoding and orthographic reading skills (Castles *et al.* 1999), but the latter are more susceptible to environmental influence.

Children at risk of reading difficulties

With genetic studies as a backdrop, a number of studies have investigated the early precursors of dyslexia in children from high-risk families (Scarborough 1990; Lefly & Pennington 1996; Byrne *et al.* 1997; Elbro *et al.* 1998). The emerging consensus of these studies is that, in the preschool period, at-risk children who go on to become dyslexic show delayed speech and language development (Gallagher *et al.* 2000). By 4–5 years they show a characteristic pattern of poor phonological awareness and

limited letter knowledge that presages reading difficulties (Scarborough 1990). This evidence bolsters the view that children at risk of dyslexia come to the task of learning to read with poorly developed phonological skills and makes a clear argument for early intervention programmes that target the development of phonological awareness.

Dyslexia and the brain

Galaburda (Galaburda & Kemper 1978; Galaburda 1994) reported unusual symmetry of the planum temporale in the brains of dyslexic readers, and structural abnormalities (ectopias and dysplasias) throughout the perisylvian region of the left hemisphere. Findings of symmetrical plana in dyslexia have now been replicated in a number of studies using brain imaging techniques (Hynd & Hiemenz 1997). Moreover, an important study by Larsen *et al.* (1990) made a direct link between planum symmetry and phonological deficiency. More recently, functional brain imaging has confirmed differences in the pattern of brain activation between dyslexic and normal readers during phonological processing (for a review see Filipek 1999). Taken together, this evidence suggests that the behavioural findings of phonological processing deficits in dyslexia may be traced to differences in left hemisphere brain function.

An alternative hypothesis, proposed by Lovegrove *et al.* (1986), is that dyslexic readers have low-level visual impairments affecting the transient visual system (sometimes referred to as the magnocellular system). According to Lovegrove (1991) transient system deficits may affect the extraction of information to the right of fixation and naturally therefore impair reading. Moreover, the failure of transient responses to inhibit responses of the sustained visual system could obscure or mask information from later fixations (Hulme 1988). However, because visual problems co-occur with phonological processing impairments (Eden *et al.* 1996), it may be better to consider them to be a biological marker for dyslexia rather than of significance in explaining the genesis of the reading problem.

The right hemisphere hypothesis of non-verbal learning disabilities

Evidence for the biological bases of non-verbal disabilities is lacking but the most widely cited hypothesis is that these difficulties stem from disorders of the right hemisphere (Semrud-Clikeman & Hynd 1990). While the left hemisphere has specific modality areas, the right hemisphere has more association areas and specializes in intermodal integration. Thus, it is claimed that the right hemisphere is better at processing novel material and constructing schema that can then be transferred to the left hemisphere. While Rourke (1989) made use of this model to account for the syndrome of non-verbal learning disabilities, a clearer understanding of the core characteristics of NLDS and of the heterogeneity among affected cases is needed before further progress can be made towards understanding its biological substrate.

Relationship between reading and language difficulties

Studies of children with speech–language impairments frequently report a high incidence of reading difficulties and children who have problems in both oral language and phonological processing are at the greatest risk of failure (Catts *et al.* 1999). However, there is a high degree of variability in literacy outcome among children from clinical samples (Magnusson & Naucler 1990). Given the role of different language skills in the development of reading, as discussed above, this is perhaps unsurprising.

Specific language impairments

One of the most important predictors of literacy development among children with preschool specific language impairments is the status of their oral language skills at the time when they start to read (Bird *et al.* 1995). Bishop & Adams (1990) found that children whose spoken language difficulties had resolved by the age of 5.5 years had a good outcome for reading in its early stages. In contrast, children who continued to show specific language impairments at 5.5 years had widespread reading and spelling difficulties at 8.5 years.

At school leaving age, the children whose specific language impairments had resolved by 5.5 years continued to be indistinguishable from normal controls in spoken language skills. However, in spite of the good outcome for oral language, they had poorer literacy skills than controls (Stothard *et al.* 1998). Indeed, their difficulties with reading, spelling and reading comprehension were accompanied by non-word reading and spelling problems and were associated with deficits in phonological processing, resembling those seen in dyslexia. It must be stressed, however, that these children had followed a different developmental course to classically dyslexic children; they had experienced a good start with reading and their 8-year-old literacy skills had been within the normal range. A salutary finding was that, although as adolescents with resolved specific language impairments they were entered for the same number of school leaving examinations as controls (GCSEs in the UK), they obtained poorer grades in the core subjects of English language, mathematics and a foreign language (Snowling *et al.* 2001).

The literacy outcome and also the academic attainment of those with persistent specific language impairments were less good than those of the resolved group. At 15 years they performed almost as poorly as children who had been classified as generally delayed in development (with performance IQs below 70). Literacy outcomes were particularly poor for those with a performance IQ less than 100 and there had been a substantial drop in reading accuracy, relative to age, between the ages of 8.5 and 15 years (Snowling *et al.* 2000).

Reading in children with speech disorders

Although learning to read is heavily dependent upon speech processing, the relationship between speech production (expressive phonology) and phonological awareness is less than straightforward (Stackhouse 2000). Catts (1993) followed the progress of children with speech–language impairments from kindergarten through the first two years of school. As would be predicted by theories of reading acquisition, measures of kindergarten phonological awareness and rapid naming skill predicted word recognition and decoding skills at the end of first and second grade. Importantly, children with speech–articulation difficulties in kindergarten did not develop reading difficulties in first grade, while those with more widespread language impairments did. In similar vein, children with speech impairments associated with structural abnormalities, such as cleft palate, appear to have normal reading skills (Stackhouse 1982) as do those with motor speech disorders, such as dysarthria (Bishop 1985).

Taken together, these findings suggest that it is necessary to distinguish poor phonological production skills and phonological awareness as predictors of literacy outcome. Children with isolated impairments of expressive phonology do not appear to be at heightened risk of reading problems, but children who have deficits in phonological awareness are unlikely to read well.

Hyperlexia

An extreme form of poor reading comprehension is seen in the case of hyperlexic children. These children often learn to read before they receive any formal instruction, and at a rate much in excess of that to be predicted from their IQ. Hyperlexia often occurs in combination with other developmental disorders, such as autism, and is characterized by a preoccupation with reading to the exclusion of meaning (Healy 1982).

Most research on hyperlexia has been at the level of case studies which have not focused in any detail on the reading mechanisms that are involved (Nation 1999). Exceptions were two studies by Frith & Snowling (1983) and Snowling & Frith (1986) who reported that autistic children, classified as ‘hyperlexic’, could read words and non-words as well as reading age-matched controls and that they were sensitive to grammatical distinctions in text. However, they had more difficulty in pronouncing ambiguous words in context, such as ‘bow’ and ‘lead’, and their comprehension of the details of what they read was poorer than that of younger reading-age-matched controls. In addition to their difficulties on formal reading comprehension tests, the hyperlexic children had difficulty monitoring errors in what they read; compared with younger children of similar mental age, they had more difficulty in detecting the text anomalies, and they tended to accept implausible words as correct.

Emotional and behavioural sequelae of learning difficulties

Although it is generally believed that a significant degree of psychosocial adversity can follow from childhood learning difficulties, the evidence that substantiates this view is sparse. Moreover, the relationship between children's learning difficulties and their adult outcome will differ according to the type of learning disability they experience. The most common types of social difficulty attributed to reading difficulties (dyslexia) are behaviour problems that include offending (Jensen *et al.*, 1999). However, the majority of poor readers do not experience mental health problems and appear to be less susceptible to psychiatric disorder than children with a history of non-verbal learning disabilities.

Psychosocial outcomes for children with reading difficulties

A considerable body of research points to an association between learning difficulties and behavioural problems (Hinshaw 1992). However, it is not clear that the relationship is a direct one (Maughan 1994). An influential hypothesis has been that behaviour problems associated with reading difficulties may be mediated by progressive school failure and lowered self-esteem (Chapman & Tunmer 1997). An alternative model of the relationship is that disruptive behaviour at school, coupled with inattentiveness, interferes with the acquisition of reading skills. However, it might be argued that both models are oversimplistic; the relationship between reading and behaviour differs according to gender and turns on the stage of development that is considered.

Williams & McGee (1994) followed a cohort of 950 children from birth to adulthood. Assessments conducted at the ages of 7, 9 and 15 years found that both reading difficulties and antisocial behaviour showed continuities over time. However, while the dimensional approach revealed no significant association between early reading and later delinquency, a categorical approach that focused on the outcomes of children 'diagnosed' as having reading difficulties (dyslexia) suggested that, at least for boys, early reading disability predicted future conduct disorder at 15 years. For girls, the association was between reading problems and anxiety, rather than conduct problems, suggesting a different outcome for reading problems between the sexes. The Dunedin study also examined the relationship between reading problems and psychosocial adjustment in young adulthood at age 18, as measured by a mental health interview. For males but not females, an index of personal disadvantage at 18 was predicted by both literacy and externalizing (behaviour) disorder at 15, as well as family disadvantage at 7 years.

Maughan *et al.* (1996) came to broadly similar conclusions following a study of 127 poor readers in London from the age of 10 years into early adulthood. They found there was a tendency for reading difficulties to be associated with poor attention and

overactivity, which in turn placed poor readers at risk of behaviour problems (see also Fergusson & Lynsky 1997). Overall, high behaviour problem ratings at age 14 reflected earlier behaviour problems rather than reading difficulties. Social adversity was found to increase the risk of antisocial behaviour among girls but not among boys. Among boys with specific reading difficulties, increased rates of offending were associated with poor school attendance.

As young adults, aged 27–28, about 25% of this sample remained severely impaired in reading (Maughan & Hagell 1996). None the less, relatively positive self-reports suggested that many had gained employment in which there were restricted literacy demands and their reading problems were no longer of functional significance. In most areas, those with a history of specific reading difficulties were functioning comparably to peers. However, young women with a history of specific reading retardation were at increased risk of psychiatric disorder, possibly related to a high rate of relationship breakdowns. These appear to have been the consequence of leaving school without qualifications and entering early marriage or cohabitations. Male poor readers, in contrast, had more difficulty in gaining independence. However, these difficulties were the consequence of comorbid difficulties with peer relationships rather than reading problems. In the same way, alcohol problems were linked with behaviour rather than reading problems.

Socioemotional sequelae of non-verbal learning disabilities

Rourke & Fuerst (1995) used multivariate statistical methods to analyse the performance of learning disabled children on the Personality Inventory for Children. Although there was variation between studies, seven distinct subtypes emerged. Two of these subtypes showed relatively normal adjustment, three showed modest psychosocial dysfunction (mild hyperactive, mild anxiety and conduct disorder), one was associated with internalized psychopathology (depression, withdrawal anxiety and psychosis) and one with externalized psychopathology (delinquency, hyperactivity, poor social skills and emotionally unstable behaviour). However, these studies suffer from the lack of representative samples and appropriate control groups (Little 1993).

Gillberg *et al.* examined the psychosocial adjustment of children with DAMP syndrome by comparison to a control group selected at random for the same population (Hellgren *et al.* 1994). Problems of depression and feelings of low self-esteem were common during the early school years and peaked around 10 years when they coincided with conduct problems. In adolescence, the DAMP group showed three main types of psychiatric problem: depression, conduct disorder and autistic traits which were present in 50% of severe cases of DAMP. Gillberg (1999) suggested that, in the teenage years, anger and resentment may precipitate a conduct disorder that can include stealing, fire-setting, lying, bullying, running away from home or drug abuse. However, it is difficult to be sure that these socioemotional diffi-

culties were the consequences of the DAMP syndrome *per se*, because the inclusion of social and behavioural problems among the initial diagnostic criteria brings with it a degree of circularity.

Clinical implications

Early identification of reading difficulties

The convergence of evidence from studies of the normal development of reading, and from dyslexia, places practitioners in an excellent position both to identify children at risk of reading difficulties and to provide early intervention. Children who have a family history of dyslexia or a history of speech–language difficulties are at high risk, especially if the phonological system is affected and there are speech production deficits. A cautionary note is that children with preschool speech and language impairments may make a good start in learning to read but fail later as its demands increase. Careful monitoring of high-risk children is therefore advisable throughout the primary school years.

Just before school entry it is possible to detect, with reasonable accuracy, the children who will proceed to have reading difficulties by assessing performance on tests of phonological awareness and letter knowledge (Muter *et al.* 1997). Where the child cannot yet reflect upon the sound structure of spoken words, either to make judgements about rhyming pairs, or to detect their beginning sound, a programme of phonological awareness training should be implemented without delay, if possible harnessing the support of parents.

Interventions that foster the development of phonological awareness and letter knowledge have been found to have a positive effect on the subsequent reading achievement of unselected samples of children in their preschool years (Lundberg *et al.* 1988; Byrne & Fielding-Barnsley 1991, 1995). Interventions of this type also have a positive effect on children at high risk of dyslexia (Borstrom & Elbro 1997) although there is growing opinion that such children respond less well than normally developing children (Torgesen *et al.* 1994; Byrne *et al.* 1997). In order to have a substantial impact on the phonological awareness of children at risk for serious learning difficulties, it is usually recommended that training procedures go beyond those typically applied, both in terms of explicitness of phonological training and also in terms of intensity. Such interventions need to be delivered on a one-to-one basis by highly trained and supervised teachers (Torgesen *et al.*, 1999).

Assessment of reading difficulties

The most common referrals to clinicians are of children who have already failed to learn to read. Once a child has failed to learn to read, the starting point for the assessment of their difficulties should normally be an assessment of general cognitive ability, not least to identify the child's strengths and weaknesses, the specificity of the reading problem and to pinpoint any co-

morbid non-verbal learning difficulties. The assessment will have more value if it proceeds to assess the phonological skills that underlie reading development, and the reading strategies the child is currently using with a view to prescribing appropriate intervention. The assessment of reading must encompass assessment of word-level recognition and decoding skills, as well as of reading comprehension. It is also important to include a test of spelling and an assessment of expressive writing skills (Snowling & Stackhouse 1996). Attendant problems, such as with attention or fine motor control, require separate investigation and intervention.

The main priority for children who are failing is reading intervention. Contrary to the accepted clinical view that accurate assessment must be used to prescribe treatment, there is indeed some evidence that if tutoring is introduced early, it can be effective regardless of diagnosis. Vellutino *et al.* (1996) asked the teachers of 1407 children from 17 schools in the Albany area of New York state simply to rate their reading skills in the middle of first grade. The poor readers were then assigned at random into tutored or non-tutored groups. The tutored children received 30 min of individualized help daily, according to their needs, while the untutored children served as controls. Sixty-seven per cent of the tutored children gained reading scores within the normal range after only one semester. Moreover, tutored children maintained their status over time.

Although cognitive assessments from kindergarten were available for these children, they did not figure in the decision to remediate. Like other poor readers, the children who failed to progress well in the intervention were those who performed worse on tasks that tapped phonological skills including poor verbal short-term memory, poor phonological awareness and rapid naming deficits. The intransigence of the reading impairment in such 'hard-to-remediate' children is a priority for future research (Torgesen, 2000).

Interventions for poor readers

An influential approach to helping poor readers is 'reading recovery', a programme pioneered by Clay (1985) in New Zealand. The poorest readers in each school enter such programmes following screening at the age of 6 years, and leave around 20 weeks later when their reading attainment matches that of their peer group in the same schools. While the programme is generally regarded to be successful, there have been few systematic comparisons with other methods (Snowling 1996). Those that have done this have found that it is better to supplement such an approach with training in phonological awareness, involving exercises to link reading with phonology (Hatcher *et al.* 1994). In a review of such studies, Troia (1999) evaluated 39 interventions that conformed to rigorous methodological criteria. These studies showed that phonological training improves both phonological awareness and literacy skills in a relatively short time.

Evidence from the Colorado remediation project (Olson & Wise 1992) speaks to the efficacy of remedial approaches with

dyslexic children. The teaching technique used in these studies involves children reading from books that are computer-presented, at the appropriate level of difficulty. Whenever the child encounters an unfamiliar word they highlight it and the computer provides feedback using synthesized speech. The outstanding issue is how best to effect successful generalization when teaching children with severe reading difficulties.

In contrast to what is known about how to teach word-level reading skills, far less is known about how to promote reading comprehension. This challenge may be tantamount to building vocabulary and other IQ-related cognitive processes (Stothard 1994). In line with this view, several recent studies have shown that IQ is a strong predictor of gains in the reading comprehension of poor readers in intervention programmes (Hatcher & Hulme 1999).

Clinical management of children with non-verbal learning disabilities

It is sensible to suppose that the management of children with non-verbal learning disabilities depends upon their careful assessment, but there are no data that speak directly to this issue. As NLDS is a multifaceted disorder, assessment of academic achievement needs to be conducted in the context of a thorough evaluation of the child's perceptual, motor and attentional skills. Like any assessment of a child who is failing, this should involve the child's caregivers and teachers in evaluating the socioemotional impact of the disorder (Gillberg 1999). Once assessment is complete, a treatment programme needs to be organized to take account of the presenting problems at the stage of development the child has reached.

Many children with NLDS require special needs support. In the primary school years, help with the acquisition of reading, writing and arithmetic skills is usually needed. Later the focus may change to assistance with self-organization and study skills. In the early years, some children with NLDS require physiotherapy but, unless motor deficits are serious, this form of intervention may not be effective in the long term because such difficulties tend to diminish with age. In short, it is important to recognize the cognitive problems of children with NLDS early in development and to provide intervention that reduces the frequency of maladaptive transactions with the environment (Fletcher 1989).

Conclusions

The field of children's learning difficulties is evolving rapidly. Understanding of the causes and characteristics of children's reading difficulties is well advanced, as is knowledge about appropriate interventions. It is striking that in this domain, cognitive models of reading acquisition have had a very positive effect on progress. Far less is known about children's arithmetic difficulties although here too the influence of cognitive models is beginning to bear fruit. An advantage of the cognitive approach to

learning difficulties is that it makes contact with what is known about normal development and an understanding of the cognitive underpinnings of disorders forges a link between brain and behaviour (Morton & Frith 1995).

In contrast, research on non-verbal learning difficulties remains syndrome-based. These children have deficits of spatial cognition that may account for their arithmetic problems, but direct relationships have not been demonstrated. It is unclear how far spatial problems can explain their difficulties in the development of motor skills, and to what extent the commonly observed psychosocial problems are a reflection of comorbid disorders of the autism spectrum rather than a consequence of the learning difficulties. Future research is needed to fractionate the so-called 'right hemisphere learning difficulties' if advances in clinical and educational management are to follow.

Introduction

Although recognized since antiquity, modern interest in mental retardation dates to the late eighteenth and early nineteenth centuries as concern for children and their development increased. Reports such as that of Itard on a supposedly feral child stimulated interest in the relative contributions of ‘nature’ and ‘nurture’ (Candland 1993). Subsequently, Seguin began to develop specific systems for intervention and training. By the latter half of the nineteenth century many training and residential facilities were developed; originally the goal was to return children to their families but gradually such institutions came to emphasize custodial care. Developments in intelligence testing and the belief, particularly in the first half of the twentieth century, in the notion of ‘fixed’ intelligence led to better measures of intellectual ability and, unfortunately, to a rather regressive therapeutic stance (Hunt 1961). This philosophy began to change yet again in the latter half of the twentieth century when, as a result of legislation, legal procedures and a shift in public opinion, the emphasis was on treating children in their family context and community. A second major change during this time was the remarkable progress in understanding basic aetiological factors in mental retardation (Szymanski & King 1999).

This chapter summarizes current knowledge as well as areas of research interest and, at times, of controversy. We first consider current definitions of mental retardation, then epidemiology and natural history. The aetiology of mental retardation syndromes will be discussed using specific syndromes as examples. The final sections of the chapter focus on associated behavioural and psychiatric disorders, assessment, treatment and intervention.

Definitions

ICD-10 and DSM-IV

Historically, intelligence has been defined in rather different ways, with some emphasizing more abstract cognitive abilities and others more practical ‘real world’ capacities for solving problems (Sternberg 2000). These two tensions are jointly embodied in the formal definition of mental retardation included in ICD-10 (World Health Organization 1993) and DSM-IV (American Psychiatric Association 1994). Both subnormal intellectual functioning and commensurate deficits in adaptive

functioning (capacities for social and personal sufficiency and independence) are required. DSM-IV specifies that an appropriate standardized assessment of intelligence is generally needed, while ICD-10 does not.

The use of formal measures of intellectual functioning rests on a very substantial body of empirical work on the assessment of cognitive ability, and the reliability and stability of such measures over time (Sternberg 2000). As we discuss subsequently, the use of IQ as the *sole* criterion for mental retardation is problematic in several respects. Most importantly it includes many individuals, particularly those with IQs close to 70, who may have no actual adaptive impairment and who can cope adequately with the demands of daily life. The current approach to diagnosis is thus a compromise in which both more theoretical cognitive abilities and social adaptation must be significantly below average. Clearly, among the most severely retarded, IQ and adaptive skills are highly correlated. In contrast to more theoretical cognitive abilities, capacities for social adaptation are teachable to a greater or lesser extent, and some children with mild mental retardation lose this diagnosis in adolescence or adulthood as they become more capable of self-sufficiency (Edgerton *et al.* 1984).

American Association of Mental Retardation definition

A rather different approach to definition is embodied by the American Association of Mental Retardation (AAMR 1992) definition. In this approach, the traditional distinctions based on IQ are discarded in favour of one based on level of need for environmental support (pervasive, extensive, limited, intermittent) in each of 10 different levels of adaptive functioning. This definition allows for greater clinical judgement in that it increases the upper IQ bound to 70 or 75. What initially may appear as a small increase in IQ level actually has major implications for definition and service delivery, potentially doubling the number of cases (MacMillan *et al.* 1995). The proposed 10 areas of adaptive functioning have limited empirical support and, in practice, the AAMR definition has proven difficult to use.

Terminology

Both ICD-10 and DSM-IV continue to employ the use of various ‘levels’ of mental retardation grouped according to intellectual level: mild, moderate, severe and profound. DSM-IV allows

Table 41.1 Levels of mental retardation (MR)*.

Level	IQ range	Approximate mental age in adulthood (years)	Proportion of MR group (%)
Mild	50–70†	9–12	85
Moderate	35–49	6–9	10
Severe	20–34	3–6	3–4
Profound	<20	<31–2	

*Data from ICD-10 and DSM-IV.

†DSM-IV allows for some clinical judgement in the diagnosis of MR, e.g. a diagnosis could be made in an individual with IQ up to 75 who exhibits significant deficits in adaptive behaviour or a clinician could decide that an individual with IQ up to 55 might best be thought of as exhibiting moderate mental retardation.

slightly more leeway for clinical judgement. As would be expected, given the normal distribution of cognitive functioning, cases of mild mental retardation account for the majority of cases (Table 41.1). As has long been appreciated (Dingman & Tarjan 1960) there is a higher than expected proportion of severe and profound retardation, relative to the Gaussian distribution, which reflects the operation of specific biological insults.

For practical purposes the most basic distinction is probably between mild mental retardation (IQ 50–70) and more severe mental retardation (IQ < 50; this distinction was previously referred to as that between ‘educable’ and ‘trainable’). Individuals with IQ scores in the mild range often have minimal impairments in adaptive functioning and are, on balance, more likely to come from more disadvantaged social groups (Slone *et al.* 1998). Documented medical causes for the mental retardation are less likely and family members may also exhibit lower intellectual levels. Among individuals with more severe retardation, organic factors can be documented in many cases; family members are less likely to exhibit intellectual impairment or social disadvantage; the diagnosis is made earlier; and adaptive functioning is much more impaired. As discussed below, psychiatric disorders are more common in individuals with mild mental retardation than in the general population but are fundamentally of the same type. Among those with more severe retardation, specific disorders such as autism and overactivity become more frequent and the psychiatric presentation may be more complex (Batshaw 1997; Fox & Wade 1998). In more severe retardation, cases are more likely to represent all social classes, while in mild mental retardation lower socioeconomic status is more common (McLaren & Bryson 1987; Szymanski & King 1999).

Historically, many other terms have been used, but in the UK, USA and other countries the trend recently is towards more descriptive and less pejorative terminology. Terms such as ‘mental handicap’ or ‘mental impairment’ are used. In the UK the term ‘learning disability’ has also been used, although this introduces potential areas of confusion with the ‘specific’ learning disabilities (see Snowling, Chapter 40); in this chapter we use the term

‘mental retardation’ to avoid this confusion. As with other conditions it is important that clinicians and researchers refer to *persons* with a disability such as mental retardation, rather than equating the individual with their disability. It must be noted that labelling may, of itself, have unfortunate negative effects (Weisz 1990) and, conversely, a failure to provide appropriate services may result from a failure to assign an appropriate label (Granat & Granat 1978).

Epidemiology

Complications for epidemiological studies of mental retardation arise from several sources. IQ does not always remain constant and, except for the most impaired infants and young children, correlations between IQ scores obtained in infancy and later childhood are quite low; this complicates calculation of age-specific rates of mental retardation in younger individuals. As children begin formal schooling the correlations with subsequent IQ are reasonably robust, although in individual cases children may have major gains or losses in intellectual ability (Sternberg 2000). Differences in rates of intellectual development are also observed, e.g. in Down syndrome the IQ tends to decline in middle childhood (Hodapp *et al.* 1999). Identification of cases increases as children enter formal educational programmes which may themselves exhibit considerable regional or local variation (Massey & McDermott 1995). Differences in diagnostic practice or concerns regarding negative effects of labelling may complicate determination of rates based on administrative data; children with mild mental retardation might be classified as learning disabled instead. There also may be differential mortality associated with some forms of mental retardation.

The use of IQ < 70 as the sole criterion for mental retardation would result in prevalence rates of between 2 and 3%, or essentially close to what would be the expected 2.3% based on the normal curve. The use of IQ as the sole defining feature of mental retardation rests on a very solid body of work on cognitive functioning dating back to Galton (for a review see Sternberg & Salter 1982). If IQ and measures of social adaptation skills are highly correlated, the expectation would be of rates of mental retardation of about 3%. However, studies that require some degree of impairment as well as IQ < 70 report much lower rates, around 1%. This distinction has major importance for service planning, and is illustrated in the results of two studies where rates can be calculated depending either solely on IQ, or IQ and impairment (as judged by service providers). In the Isle of Wight study of 9, 10 and 11 year olds, Rutter *et al.* (1970) found that 2.5% of the children would be classified as intellectually retarded by IQ score alone but only about 1.3% were noted to have impairments sufficient to require services. Similarly, in Birch *et al.*'s (1970) study in Aberdeen, which included nearly all 8–10 year olds in both regular and special schools, the rate was 2.42% when only IQ was used but 0.92% when impairment was added.

Several factors complicate the interpretation of the differences which result when the social/adaptive impairment criterion is added. Clearly, at least some individuals with mild mental retardation may acquire better adaptive skills over time and may no longer be in need of services (McLaren & Bryson 1987; Roeleveld *et al.* 1997); this becomes less likely the more severe the associated intellectual impairment (Ross *et al.* 1985). Richardson & Koller (1992) noted a wide variation in levels of functioning and degree of impairment in adults with histories of mild mental retardation. Even when special services are not apparently required the individual may still be vulnerable and the presence of supportive family members, spouses or friends may assume particular importance (Birch *et al.* 1970; Granat & Granat 1978; Edgerton *et al.* 1984; Ross *et al.* 1985). In the Isle of Wight study (Rutter *et al.* 1970) the children in more 'mainstream' educational settings had various difficulties including lower academic skills and higher rates of neurological abnormality and psychiatric difficulty. While it is clear that the rate of mental retardation is somewhere between 1 and 3%, an exact figure cannot be determined. On the one hand it can be said that what appears to be a modest change in the threshold level for mental retardation may substantially increase prevalence; it has been proposed by some that this IQ threshold be changed to 75 which would potentially double the rate of the disorder.

As noted previously among individuals with mild mental retardation, psychosocial adversity is common. The nature of the factors leading to increased rates of mild mental retardation in children from disadvantaged, often minority, backgrounds remains the topic of much debate. Factors such as 'cultural bias' of intelligence tests (see Sergeant & Taylor, Chapter 6; Rutter & Nikapota, Chapter 16) have sometimes been invoked to account for elevated rates of mental retardation in disadvantaged groups. While such factors must be considered, it is the case that psychosocial adversity has empirically been shown to result in significantly lower IQ scores, e.g. in children adopted away to more advantaged families (Dumaret 1985). Gender differences in rates of mental retardation are observed with a male:female ratio of 1.5:1 generally reported (Richardson *et al.* 1986).

Course and outcome

Given the heterogeneous nature of mental retardation it is not surprising that aspects of natural history and course vary considerably depending on the severity of mental retardation and the underlying biomedical, psychological and environmental factors (Richardson & Koller 1992). Levels of communicative ability and the presence/absence of associated medical problems and psychopathology are also important determinants of adult outcome. The complex factors determining outcome can include limitations in mobility, sensory impairments and associated medical conditions such as cardiac disease or seizures. When a precise cause for the mental retardation can be established it may have important implications, e.g. individuals with Down

syndrome are at increased risk for a number of problems including cardiac difficulties and for early onset Alzheimer dementia (Aylward *et al.* 1997). Although traditionally the mild mental retardation group has been thought to be the one least likely to show associated organic difficulties, advances in genetics have shown that this is not always the case. For example, many females with fragile X syndrome and most individuals with Prader-Willi syndrome may function at this level. Individuals from minority groups are often over-represented in this group. One of the accomplishments of the past decade has been the substantial improvement in the quality of paediatric and general medical care and rising life expectancies of persons with mental retardation (Szymanski & King 1999).

Mild mental retardation, as expected, has the best outcome. In their systematic follow-up of cases from the Aberdeen project, Richardson & Koller (1992) noted that one-quarter of cases disappeared from services with the remainder having some degree of vulnerability, at least in certain contexts. In their analysis, IQ, evidence of brain dysfunction and family stability were found to weakly predict outcome although, of these three factors, family stability was the strongest predictor and IQ the weakest.

Individuals with moderate levels of mental retardation (IQ 40–55) have greater degrees of impairment, are more likely to be identified in the preschool years and to have some specific aetiology identified for their developmental difficulties. As might be expected, the prognosis for adult self-sufficiency and independence is more guarded for this group, although many individuals can live semi-independently and with partial support (Ross *et al.* 1985). For individuals with severe or profound retardation, high levels of supervision and support are generally required throughout the person's life. Goals include facilitating self-care and other skills to the extent possible; very high levels of support and supervision are typically required.

In more developed countries, various factors have acted to improve overall outcome. These factors include early diagnosis and intervention, school-based services with more emphasis on use of community-based services and resources, and adult programmes. More extensive and varied sources of support are now available to families. In both the UK and USA the recent trend, both through legislation and legal decision, has been to advocate appropriate services which are community-based with the goal of keeping individuals in, or near, their families.

Aetiological considerations

Several factors contribute to the aetiology of mental retardation: organic and sociocultural factors, and their interaction. Genetic influences can be based on specific genes that result in well-recognized syndromes, or can be more complex reflecting the operation of multiple genes or the interaction of genetic vulnerability with the environment. Studies based on twin pairs and adoption suggest that the genetic role in the transmission of intelligence is a major one, although studies that have addressed

this issue in the polygenic transmission of mental retardation are uncommon (Rutter *et al.* 1996). Biological causes are most likely to be identified in the most handicapped individuals.

'Two-group' approach

Researchers have historically described two distinct groups of people with mental retardation (Zigler 1967, 1969). One group demonstrates a clear biological or 'organic' cause for their cognitive delay, and is composed of people with known prenatal, perinatal and postnatal problems. Although estimates have varied over the years, current data suggest that approximately one-half of people with mental retardation have known 'organic' aetiologies (for a review see Hodapp 1994). The second group has no clear organic cause for their mental retardation, and is postulated to account for the vast majority of persons with mild mental retardation. From its inception to the present day, this 'two-group' approach to mental retardation has dominated both theory and research.

Although a helpful classification scheme, the two-group approach has raised more questions than it has answered. Who, exactly, comprises the group of persons with non-organic aetiologies, and what is the most appropriate label for these individuals? The term 'sociocultural familial' retardation reflected a dominant view in the 1960s and 1970s that non-organic mental retardation was attributed primarily to environmental deprivation. Although impoverished chaotic environments may indeed be the culprits in a small number of individuals, this theory has generally fallen out of favour as an explanation for the entire group. Even so, a complicating factor is that disproportionately more individuals with sociocultural familial mental retardation are poor, from minority backgrounds and of low-IQ parents (for a review see Hodapp 1994).

Other views of non-organic mental retardation are reflected in additional terms used to describe this group. 'Non-specific' or 'idiopathic' mental retardation seems to best reflect the hypothesis that persons in this group have as yet unidentified biological factors associated with their delay, including undetected genetic or neurological abnormalities. With increased diagnostic precision, and with the discovery of new genetic disorders, many workers speculate that more persons with non-specific delay will receive specific genetic diagnoses in the years ahead. Progress is much slower in identifying clear neurological aetiologies in persons with unspecified mental retardation, as most neuroimaging research is conducted with persons with known genetic or other aetiologies (Robertson & Murphy 1999).

Another term for this group, 'non-organic', perhaps best represents the idea that these individuals have no organic impairment, but simply constitute the lower end of the normal Gaussian distribution of intelligence (Zigler 1967; Simonoff *et al.* 1996). Even so, multiple genetic and environmental variables are implicated in low IQ (Lee *et al.* 1993). Assuming that non-organic mental retardation is indeed the extreme end of the normal IQ distribution, then some proportion of individuals will always belong to this group, even as progress is made uncover-

Table 41.2 Selected organic causes of mental retardation.

Prenatal	Perinatal, neonatal and postnatal
Chromosome abnormalities: trisomy 21 (Down syndrome)	Fetal distress/hypoxia
Inborn errors of metabolism (phenylketonuria, Hunter syndrome)	Complications caused by prematurity
Other genetic conditions (fragile X, tuberous sclerosis)	Endocrine (hypothyroidism)
Toxins (fetal alcohol syndrome)	Trauma (central nervous system damage)
Maternal illness (pre-eclampsia, diabetes)	Toxins (lead poisoning)
Multifactorial syndromes (seizures, cerebral palsy)	Infections (meningitis)

ing genetic or neurological aetiologies for other persons at the same IQ levels.

In the organic group too, many issues remain. Early researchers lumped people together in the same group who had many different types of organic aetiologies, often comparing these heterogeneous groups to those with familial or non-specific mental retardation; it is now clear that diverse aetiologies may be involved (Table 41.2). While remarkable progress has been made in molecular genetics, researchers are now much better able to examine people with distinctive genetic aetiologies. Indeed, as many as one-third of all persons with mental retardation have already been diagnosed with a known genetic disorder (Matalainen *et al.* 1995). Further, individuals with Down syndrome, fragile X syndrome, Prader-Willi syndrome, Williams syndrome and other disorders may comprise 10–50% of individuals with mild mental retardation (Rutter *et al.* 1996).

Behavioural phenotypes: a revision of the two-group approach

In light of these advances, many workers are turning to a line of research that examines the behaviour and development of people with distinctive genetic aetiologies (Hodapp & Dykens 1994, 2001; Dykens 1995). Research on 'behavioural phenotypes' is blossoming, and these studies typically fall into one of two general categories. On the one hand, many researchers conduct between-group studies, as they are on the hunt for unique syndromic behaviours that may fast-track our understanding of gene or brain function. Promising examples of these unique behaviours include hand-wringing in Rett syndrome (Perry 1991), hyperphagia in Prader-Willi syndrome (Holm *et al.* 1993), bouts of inappropriate laughter in Angelman syndrome (Williams *et al.* 1995), the infantile cat-like cry in 5p syndrome (Gersch *et al.* 1995) and the self-hug in Smith-Magenis syndrome (Finucane *et al.* 1994). For these and other behaviours, there appears to be a strong correspondence between the behaviour and the syndrome (see Skuse & Kuntsi, Chapter 13).

Yet even these unusual behaviours are occasionally seen in people without these diagnoses. Further, the vast majority of

Table 41.3 Cognitive/linguistic profiles in selected mental retardation syndromes.

Syndrome	Genetics	Relative weaknesses	Relative strengths
Fragile X*	CGG repeat	Sequential processing Auditory-verbal short-term memory Sustaining attention, some visuospatial	Verbal long-term memory Repertoire of acquired information
Prader-Willi†	del 15q11-13 Maternal UPD	Sequential processing Auditory, visual short-term memory	Long-term memory Visual processing, jigsaw puzzles
Williams‡	del 7q11.23	Visuomotor co-ordination Spatial organization	Auditory short-term memory Semantics, syntax, facial recognition Expressive, receptive vocabulary
Down§	Trisomy 21	Auditory processing Expressive language	Visuospatial processing

For reviews see: *Dykens *et al.*, 2000; †Dykens & Cassidy (1999); ‡Mervis *et al.* (1999); and §Hodapp *et al.* (1999).

syndromic behaviour is 'partially specific', or shared across one or more conditions (Hodapp 1997). For example, sequential processing deficits characterize Prader-Willi and fragile X syndromes (Dykens *et al.* 1994; Dykens & Cassidy 1999), and inattention and hyperactivity are seen in Williams, fragile X and 5p syndromes (Baumgardner *et al.* 1995; Dykens & Clarke 1997; Einfeld *et al.* 1997). Most syndromes, then, may have distinctive but not necessarily unique behavioural features.

A second line of work stems from the view that behavioural phenotypes are not determined, but involve an increased probability or likelihood that people with a given syndrome will show certain behavioural features relative to those without the syndrome (Dykens 1995). As variability within syndromes abounds, some researchers are examining genetic, environmental, psychosocial, and subject variables that help explain individual differences in people with the same genetic disorder. Level of cognitive delay in fragile X syndrome, for example, is tied to both age and molecular genetic status (Dykens *et al.* 1994; Tassone *et al.* 1999). Similarly, in Prader-Willi syndrome, the frequency and severity of maladaptive behaviours such as skin-picking appear to vary across genetic subtypes of this disorder (Dykens *et al.* 1999).

Both between- and within-syndrome research offers many advantages over research on heterogeneous groups of persons with mental retardation (Dykens 1995; Hodapp & Dykens, 2001). In the long term, syndromic findings facilitate the search for gene-brain-behaviour relationships, as well as contribute toward a more precise science of mental retardation. In the short term, phenotypic data refine intervention and treatment (Dykens & Hodapp 1997; Dykens *et al.* 2000).

Integrating genetic disorders into the two-group approach

What, then, does this line of work on behavioural phenotypes bring to our understanding of the 'two-group' approach to mental retardation? One of the most intriguing implications of this research concerns the so-called 'similar-structure hypothesis'.

Developmentally orientated researchers hypothesize that children with familial or non-organic mental retardation show the same cognitive structures as their non-retarded counterparts (for a review see Hodapp & Zigler 1995). Other contemporary workers have expanded these basic principles to include children with genetic and other organic aetiologies (Hodapp 1998).

Historically, typically developing children and children with non-organic mental retardation were hypothesized to show even performance across various cognitive domains, reflecting Piaget's (1952) notions of 'structures d'ensemble'. In other words, children who performed at a certain level in one domain would perform at a similar level in all other cognitive domains. However, other theorists have called this all-of-a-piece view of intelligence into question, emphasizing the modularity of language (Fodor 1983), or the presence of separate multiple intelligences (Gardner 1985) among typically developing children.

Findings from people with genetic mental retardation syndromes add an additional twist to these cross-domain relations. As summarized in Table 41.3, persons with Williams, Prader-Willi, Down and other syndromes often show distinctive patterns of cognitive or linguistic strength or weakness. Many people with Williams syndrome, for example, show relative strengths in certain aspects of expressive language, even as they show pronounced deficits in visuospatial functioning. Further, despite visuospatial deficits, many have relative sparing of facial recognition. Many, although not all, persons with Prader-Willi syndrome show remarkable skills solving jigsaw puzzles, with performances that exceed those matched for chronological age (Dykens *in press*, a). In these various genetic aetiologies, peaks and troughs rather than all-of-a-piece functioning seem to characterize development among certain cognitive and linguistic domains.

Although such profiles can be quite pronounced, it is not yet clear to what extent specific cognitive strengths or weaknesses represent distinctive or isolated cognitive structures as opposed to uneven performance in interrelated cognitive domains. It is also not clear if profiles in these syndrome groups show areas of

so-called local organization, or the idea that while some domains might be separable from others, smaller ('local') pockets of connection might nevertheless exist (Bates *et al.* 1979; Mundy *et al.* 1984). Although these issues remains unresolved, data from different syndrome groups inform our understanding of cognition in children with or without mental retardation.

Psychopathology

Prevalence

Historically, persons with mental retardation were not routinely viewed as having comorbid psychopathology or mental illness—this phenomenon has been referred to as 'diagnostic overshadowing' (Reiss *et al.* 1982). When problems were seen, clinicians typically attributed them to the intellectual deficits. Although diagnostic overshadowing is still present (White *et al.* 1995), more mental health professionals are receiving specialized training in how to assess and treat patients with mental retardation (Day 1999).

Ironically, even under the cloud of diagnostic overshadowing, one of the most robust research findings to date is that, relative to the general population, persons with mental retardation are at increased risk for psychiatric illness and severe behavioural or emotional dysfunction (Tonge 1999). Using representative samples of children with mental retardation, Rutter *et al.* (1976) found that 30% showed psychopathology, compared with just 6% of children without developmental delay. These rates are remarkably similar to Koller *et al.* (1983), who found psychopathology in 36% of children with mental retardation vs. 5% of those without developmental disabilities. Comparable figures are found among adults with and without mental retardation (Gostason 1985). Among individuals with mild mental retardation there are increased risk of various disorders including both antisocial and other disruptive behavioural disorders (Einfeld & Tonge 1996). In individuals with greater degrees of mental handicap the rates of psychiatric disorder are much higher (Corbett 1979), although in this group of individuals the application of traditional diagnostic criteria may also be more problematic and attempts have been made to clarify the nature of disorders in this group (World Health Organization 1993).

As many as 25% of persons with mental retardation may have significant psychiatric problems; these rates are much higher for behavioural difficulties (Jacobson 1999). Reported rates of psychopathology vary greatly, depending in part on the method used to ascertain subjects. For example, among 100 children with mental retardation referred to a psychiatric clinic for evaluation, as many as 87% were diagnosed with a mental disorder (Philips & Williams 1975); this is not surprising given the nature of the sample. Rates of psychopathology are lower in studies based on administrative records rather than systematic assessment, with rates as low as 10–15% reported (Jacobson 1982; Borthwick-Duffy & Eyman 1990). Rates that fall between these

extremes are found in studies based on informant checklists of behaviour problems of children and adults in non-referred samples; these rates, from 30 to 40%, are probably the most accurate (Rutter *et al.* 1976; Reiss 1990; Einfeld & Tonge 1996).

Persons with mental retardation experience the same range of psychiatric problems as seen in those without developmental disabilities (King *et al.* 1994), although the distribution of disorders differs, the rates of some disorders are increased, and issues of diagnosis can be particularly complex in persons with severe mental retardation, e.g. the diagnosis of psychosis in a mute individual. Relative to the general population, people with mental retardation are more likely to show autism and related disorders, psychosis and behaviour disorders, and less likely to be diagnosed with substance abuse and affective disorders (for a review of these issues see Moss *et al.* 1997a). For example, approximately two-thirds of children with autism also exhibit mental retardation and constitute between 1 and 2% of all children with mental retardation but about 5% of a more severely retarded population; if the broader pervasive developmental disorder (PDD) category is applied, features of autism are found in perhaps 50% of cases with severe mental retardation (Wing & Gould 1979; Volkmar *et al.* 1999; see Lord & Bailey, Chapter 38).

Prevalence rates for other disorders vary widely depending, in part, on the different methods for determining 'caseness', with common approaches including record reviews, behavioural checklists and, to a lesser extent, direct interviews. Using these techniques, some researchers have examined a broad range of DSM- or ICD-based diagnoses, while others assess maladaptive features commonly seen in the general population, such as inattention or sadness. Still others focus on a more narrow range of behaviours, seen primarily in persons with mental retardation, such as stereotypies or self-injury.

Examining a few selected diagnoses, Table 41.4 illustrates this variability in prevalence rates across several studies. Rates of schizophrenia or psychosis in persons with mental retardation range from 1 to 9% among non-referred samples, and 2.8 to 24% in referred samples. Although variable, rates are clearly higher than the 0.5–1% of the general population who suffer from schizophrenia (American Psychiatric Association 1994). Similarly, rates for depression vary from 1.1 to 11% across non-referred and clinic samples of persons with mental retardation. Among children with mental retardation, rates of attention deficit disorder or attention deficit with hyperactivity disorder ranged from 7 to 15%, which contrasts with the 3–5% prevalence estimates among non-retarded children in the population at large (American Psychiatric Association 1994). While less variability is seen when comparing similar types of samples, even then the ranges are rather high (e.g. from 1 to 3–11% for depression in the clinic referred samples in Table 41.4).

Risk factors

Although refined assessment tools are needed, researchers need to address the enduring question of why persons with mental

retardation are at increased for psychopathology. Many reasons have been discussed over the years, and most fall within the ‘biopsychosocial’ spectrum. Yet, in contrast to psychopathology in general, a comprehensive model is still lacking, in part because the unique qualities of those with mental retardation preclude researchers from simply applying to this population existing risk factors for psychopathology. Further, for most risk factors, the causal direction is unclear. For example, poor peer or social relations may be a precursor for psychopathology, or a consequence of disruptive behaviour. Even so, certain advances have been made, and increased risks for psychopathology have now been associated with the following.

- *Distinctive or aberrant personality styles*, including an outer-directed orientation, and being too wary or disinhibited with others, which may lead to dependency, withdrawal and impulsivity (Bybee & Zigler 1998; Dykens 1999b; Zigler & Bennett-Gates 1999).
- *Atypical motivational styles* or abnormally high or low levels of sensitivity to basic human drives, such as the need for attention or acceptance (Reiss & Havercamp 1998).
- *Increased risk of failure experiences* at school and in daily living, which may lead to learned helplessness, low expectancies for success, and depression (Weisz 1990; Zigler & Bennett-Gates 1999).
- *More global and less differentiated self concepts* that may lead to more sweeping negative evaluations of the entire self instead of not liking just one aspect of one’s self (Evans 1998).
- *Reinforcement of negative behaviours*, leading to more entrenched maladaptive coping or interaction styles (Reiss & Havercamp 1997).
- *Poor communication or assertiveness skills* that may lead to increased frustration and acting out behaviour (Nezu & Nezu 1994).
- *Social strain*, or stressful social interactions, which is more strongly correlated with psychopathology than low levels

of social support (Nezu *et al.* 1995; Lunsy & Havercamp 1999).

- *Social stigma*, with subsequent negative impact on daily living, vocational opportunities, adjustment and esteem (Edgerton & Gaston 1991).
- *Peer rejection and ostracism* and, among children, atypical patterns of friendship with non-retarded children marked by less shared play and laughter and more hierarchical roles (Siperstein *et al.* 1997).
- *Compromised ‘social intelligence’*, or inappropriate responses to social cues, that may exacerbate stigma and isolation from others (Greenspan & Granfield 1992).
- *Heightened risks of exploitation and abuse* that may worsen behavioural or emotional problems (Ammerman *et al.* 1994).
- *Family stress, parental psychopathology* and low levels of emotional, service or financial support to families (Minnes 1998).
- *Increased rates of seizure disorders* among persons with mental retardation (Bird 1997; Caplan *et al.* 1998).
- *Abnormal neurological functioning*, which in many cases is undetected, in part because of the lack of widespread use of neuroimaging techniques among persons with idiopathic mental retardation (Peterson 1995; Robertson & Murphy 1999).
- *Biochemical or neurological anomalies* associated with unusual behaviours such as severe self-injury (King 1993).
- *Genetic aetiologies* that carry higher than usual risks for certain maladaptive or psychiatric vulnerabilities (Dykens 1999a).

Although the identification of these factors is an important first step, the field still lacks a comprehensive model that assesses the relative importance of each for the development of psychopathology. New statistical techniques, such as individual’s growth modelling, as well as improved measures of pathology, hold much promise for a more specific, finely tuned ‘biopsychosocial’ model in the years ahead.

Genetic syndromes

Research aimed at sorting out the relative importance of these many risk factors has typically relied on heterogeneous groups of subjects with mental retardation. Yet each of the factors listed above can just as easily apply to those with or without a genetic diagnosis. Syndrome-specific work helps sort out genetic from many other biological and psychosocial risk factors. In this vein, syndromic studies allow researchers to identify the possible influence of syndromes on maladaptive behaviour or psychopathology, and may thus shed new light on genetic or other mechanisms associated with certain psychopathologies (Dykens 1995; Holland & Koot 1998).

Although a complete review of psychopathology in genetic disorders is beyond the scope of this chapter, Table 41.5 summarizes psychiatric and maladaptive features from several syndromes. In general, findings are included only if they are based on comparative studies showing increased rates of problems relative to others with mental retardation. Findings are presented for the syndromic group as a whole; individual differences in these problems abound. Indeed, identifying the genetic, developmental and psychosocial reasons for individual behavioural differences in people with the same genetic syndrome is one of the most exciting aspects of behavioural phenotype research (Dykens 1995; Dykens *et al.* 2000).

Two points are apparent from Table 41.5. First, some syndromes feature rather specific psychiatric vulnerabilities: examples include increased rates of obsessive-compulsive features in Prader-Willi syndrome (Dykens *et al.* 1996), and anxiety, fears and phobias in Williams syndrome (Dykens *in press*, b). Granted, people without these syndromes can be diagnosed with these conditions, but they occur with increased frequency in these syndromes. As such, studies on these syndromes hold much promise for differentiating genetic from other pathways to these psychiatric or maladaptive endpoints.

Secondly, certain problems are seen across one or more genetic syndromes, as in the inattention and hyperactivity that characterizes fragile X, 5p and Williams syndromes. Despite these common problems, important qualitative differences may exist in how these symptoms are manifest in each syndrome. Inattention in Williams syndrome, for example, may be associated with heightened anxiety and social disinhibition, while in fragile X syndrome, it may be best associated with hyperarousal and anomalies in the size of the posterior cerebellar vermis and caudate nucleus (Mostofsky *et al.* 1998).

Assessment

Cognitive assessment

Assessment of intellectual functioning is based on the administration of standardized tests of intelligence that have been shown to be reliable and valid (see Sergeant & Taylor, Chapter 6). Individuals with mental retardation may present special

Table 41.5 Psychopathology in people with selected mental retardation syndromes.

Syndrome	Salient maladaptive features
Fragile X*	Social anxiety, shyness, gaze aversion, autism/PDD, inattention, hyperactivity, depression (females)
Williams	Anxiety, fears, phobias, inattention, hyperactivity, social disinhibition, indiscriminate relating
Prader-Willi	Hyperphagia, non-food obsessions and compulsions, skin-picking, temper tantrums, lability, underactivity
5p	Infantile cat-like cry, hyperactivity, inattention, stereotypies, self-injury
Smith-Magenis	Hyperactivity, aggression, self-injury, stereotypies (often with mouth), sleep disturbance, self-hugging
Down	Non-compliance, stubbornness, inattention, overactivity, argumentative, depression and dementia among adults

*For reviews of these syndromes see Dykens *et al.*, 2000. PDD, pervasive developmental disorder.

problems for intellectual assessment. In addition to the obvious consideration of chronological age, the individual's receptive and expressive language ability must be considered as well as any behavioural or psychiatric difficulties which may present special challenges for assessment. Other issues to be considered include the capacity of the individual to deal with challenge and frustration, particularly to timed tasks, the level of social demands placed on the individual, and any unique features present, e.g. sensory impairments. These issues are often vividly present in individuals with autism and related disorders (see Lord & Bailey, Chapter 38) many of whom also exhibit mental retardation as well as major difficulties in social interaction and communication. The examiner should be particularly sensitive to potential cultural or language issues that complicate assessment.

While some flexibility in selection and administration of standard instruments is needed, there is also the necessity to maintain standard assessments to be able to provide valid results. On the other hand, the administration of any instrument by a skilled and observant examiner will provide considerable qualitative information which may be of great relevance for developing and implementing the treatment programme. Thus, observation of the need for structure, of strategies which facilitate learning from demonstration, of coping with off-task or maladaptive behaviours, and pace of presentation are all relevant (see Sergeant & Taylor, Chapter 6).

Adaptive behaviour

Adaptive functioning refers to the capacity for personal self-sufficiency and independence in day-to-day life. Measures of adaptive ability provide the clinician with an estimate of the degree to which the individual has been able to use his or her

cognitive potential in adapting to real-life settings; a large discrepancy between intellectual level and adaptive skills would suggest that the treatment should include a major focus on acquisition and generalization of adaptive skills.

Various measures of adaptive functioning have been proposed. The most widely used instrument is the Vineland Adaptive Behaviour Scales (Sparrow *et al.* 1984), a version of Doll's original (1935) instrument. The Vineland assesses capacities for self-sufficiency in various domains of functioning including Communication (receptive, expressive and written language), Daily Living Skills (personal, domestic and community skills), Socialization (interpersonal relationships, play and leisure time and coping skills), and Motor Skills (gross and fine). The Vineland is available in three editions: a survey form to be used primarily as a diagnostic and classification tool for normal to low functioning children or adults; an expanded form for use in the development of individual education or rehabilitative planning; and a classroom edition to be used by teachers (Sparrow *et al.* 1984). The survey and expanded editions utilize a semistructured interview format administered to a parent or primary caregiver. For individuals with mental retardation the expanded form is often particularly useful because it readily translates into goals for intervention planning. The other measures of adaptive functioning also typical day-to-day abilities. Other schedules (e.g. AAMR Adaptive Behaviour Scales; Lambert *et al.* 1993), have some different areas of emphasis, may span different age ranges and, in some cases, can be directly administered to the individual.

Assessment of psychiatric disorders

The psychiatric assessment of emotional and behavioural difficulties in the individual with mental retardation may entail some modification in usual procedures although, particularly in individuals with mild mental retardation, usual diagnostic procedures should work reasonably well. Among individuals with greater degrees of handicap, the psychiatric assessment should be comprehensive and multifocal. The presence of associated difficulties (seizures, motor impairments, sensory problems) may have important implications for assessment and treatment.

Much work has thus focused on assessing the prevalence of co-occurring mental retardation and psychiatric illness. As counting these problems depends on ways of accurately describing them, a parallel line of research has evolved on behavioural surveys and rating scales. Most of these measures are geared specifically for individuals with mental retardation, and have well-developed psychometric properties (for a review see Aman 1991). More widely used tools include the Aberrant Behaviour Checklist (Aman & Singh 1994), Reiss Screen (Reiss 1988) and Developmental Behaviour Checklist (Einfeld & Tonge 1992). While these scales are sensitive to the unique concerns of those with mental retardation, they are not necessarily compatible with DSM- or ICD-based psychiatric diagnoses. Further, each scale was designed for a slightly different purpose, and each has different sets of items and factor structures, ultimately

contributing to inconsistent findings across studies (Dykens, 2000).

In a similar vein, other researchers have raised concerns about the applicability of traditional DSM or ICD diagnoses for those with mental retardation (Sovner 1986). Many problems relate to the psychiatric interview itself, including acquiescence bias, and the more limited abilities of persons with mental retardation to express abstract thoughts and feelings, or to answer questions about the onset, duration, frequency and severity of symptoms (for a review see Moss 1999). In response to these challenges, some researchers have adapted traditional DSM or ICD criteria for those with developmental delay (King *et al.* 1994; Szymanski *et al.* 1998). Others shy away from formal diagnoses and embrace a more functional analysis of challenging behaviour (Sturmeay 1999), while still others have designed interview schedules specifically for those with mental retardation, including the Psychiatric Assessment Schedule for Adults with Developmental Disability (PASS-ADD; Moss *et al.* 1997b). When using these options, direct interviews with both respondents and informants is best, resulting in fewer cases of missed diagnoses (Moss *et al.* 1996; see Angold, Chapter 3; Fombonne, Chapter 4).

Medical assessments

In individuals with mental retardation, rates of various medical conditions may be substantially increased over the general population (Ryan & Sunada 1997). Unfortunately, as with the tendency to neglect mental health needs (Einfeld & Tonge 1996), underlying medical conditions may be unappreciated. Ryan & Sunada (1997) noted that up to 75% of persons with mental retardation who had been referred for psychiatric assessment had undiagnosed or undertreated medical conditions and nearly 50% were receiving non-psychotropic medications that could have behavioural side-effects.

The medical assessment of the individual with mental retardation should include careful history (including birth, antenatal and family history). In some cases, the clinical disorder exhibits a characteristic pattern of evolution over time and the history may provide important evidence favouring a specific aetiology, e.g. Rett and Hurler syndromes (Curry *et al.* 1997). Physical examination should include assessment of growth and development, a search for minor physical anomalies, facial features and other neurological or psychiatric findings suggestive of a specific syndrome. Evaluation of sensory capacities may be indicated as may selected diagnostic procedures, e.g. metabolic studies, chromosome analysis (including fragile X testing), assessment of organic acids, neuroimaging and skeletal radiography (see Bailey, Chapter 10).

Treatment

Over the past decades the treatment of mental retardation has undergone a marked shift in the more developed countries (see

Bernard, Chapter 67). More individuals with mental retardation now reside with their families and in their communities. More children receive services within regular educational settings and more services are available to support them and their families. At the same time it is clear that placement in the community is not sufficient in and of itself and that the provision of adequate and appropriate support is critical.

In general, treatment planning begins with a consideration of the underlying cause, if one is known, of the intellectual disability as this, in some cases, has important implications for treatment, e.g. phenylketonuria. Many aspects of treatment planning relevant to other children also apply to children with mental retardation. All the various treatment modalities, including behaviour therapy, psychotherapy and pharmacotherapy, may be used, chosen on the basis of the specifics of the individual case. The severity of the associated mental retardation may influence the choice of treatment, e.g. for the individual with profound mental retardation who is mute, verbally based interventions are less practical although behavioural procedures and modification of the environment can be helpful (Szymanski & King 1999).

Treatment priorities should ideally be established within the context of a comprehensive view of the individual; for individuals with limited verbal skills one consideration might be the attempt to foster alternative communicative modalities. Similarly, various treatments may have synergistic effects; medications that reduce levels of self-stimulatory behaviours may make the child more amenable to educational interventions. Because various professionals and caregivers are often involved, close collaboration is essential for treatment effectiveness.

Individuals with mental retardation may present with acute psychiatric difficulties. In cases of behavioural emergency (e.g. relative to aggressive or self-injurious behaviours) the first concern should be safety of the individual and his or her caregivers. Potential medical causes for acute behavioural deterioration should always be considered and these include side-effects of medications. Environmental influences should also be considered and a treatment plan formulated.

Although data on treatment efficacy are often limited and of poor quality, there is a consensus that individuals with mental retardation can benefit from various psychosocial interventions including psychotherapy (for a review see Szymanski & King 1999). Modifications in usual procedures may include adoption of a more active therapeutic stance with careful consideration of the individual's communicative abilities. The usefulness of special education and behavioural interventions has been well established, particularly for individuals with more severe mental retardation (Reiss 1994: see Howlin, Chapter 68). Individual psychotherapy or family therapy may be useful in some cases, particularly in mild mental retardation, and cognitive-behavioural techniques can also be used, e.g. in the treatment of anxiety (Lindsay *et al.* 1989).

Pharmacological interventions in the management of psychiatric and behavioural problems are relatively common. In theo-

ry these are not different from those in individuals without mental retardation; however, it is clear that in practice there are several important considerations. Issues of informed consent must be adequately addressed, particularly considering the potential for use of medications on a long-term basis, often by less experienced practitioners (Aman & Singh 1988; Szymanski & King 1999; see also Heyman & Santosh, Chapter 59). Medications should be one part of a broader programme of intervention and should be used only following a careful clinical assessment with due attention to sensible prescribing practices.

Neuroleptics are the most frequently prescribed medications and can be used to manage acute behavioural crises. Their potential for sedation and many recognized side-effects, such as tardive dyskinesia, are limiting factors. Lithium and other mood stabilizers have sometimes been used with success in the management of severe aggression with mixed results (Carlson *et al.* 1992). Stimulants can be helpful in some children with mild to moderate mental retardation who exhibit attentional problems and hyperactivity; their usefulness is more limited in individuals with severe mental retardation, and some individuals, particularly those with autism or prominent stereotyped movements, may experience an exacerbation in levels of self-stimulation (Szymanski & King 1999). There have also been some reports of behavioural disinhibition following administration of sedative hypnotics (Szymanski & King 1999). The choice of a psychopharmacological agent should encompass careful consideration of risks and benefits as part of a comprehensive treatment plan (Szymanski & King 1999). Appropriate planning, including follow-up and monitoring for side-effects, is essential. Care should be exercised in administration of multiple medications and, in general, polypharmacy should be avoided (Reiss & Aman 1998).

Prevention

Primary prevention of mental retardation is possible in some cases, e.g. with dietary treatment of phenylketonuria. For certain conditions, e.g. fragile X and Down syndromes, prenatal diagnosis is available. In other cases, mental retardation may be prevented through education of prospective parents, e.g. for the adverse effects of alcohol during pregnancy or the impact of congenital rubella (see Brent, Chapter 54; Marks *et al.* Chapter 51). For individuals with mild developmental delays, early intervention programmes aimed at preventing intellectual disability can be particularly helpful. The emphasis is on provision of habilitative services, family support and other services, with the goal of maximizing the individual's potential and minimizing levels of associated retardation (Rowitz 1991). Similarly, for individuals with mental retardation, attempts to diminish associated complications, through the adequate diagnosis and treatment of associated medical and mental disorders, are also helpful (Szymanski & King 1999).

Conclusions and future directions

Research on psychopathology in genetic syndromes adds to our understanding of psychopathology in people with mental retardation in general. Compared to even a decade ago, considerable progress has been made in how we assess, understand and treat psychopathology in those with mental retardation. Such insights increase dramatically as researchers apply these new understandings of assessment, treatment and risk factors to people with discrete genetic aetiologies.

Despite the progress in assessing, treating and supporting persons with mental retardation and their families, considerable work lies ahead. In the next decades, more individuals with mental retardation will live, learn and work in their local communities. Such trends highlight the need to clarify the uncertain relationship between low IQ and adaptive impairment in the definition and diagnosis of mental retardation. With advances in genetics, more persons with mental retardation will receive discrete diagnoses in the years ahead. Such diagnoses may inform treatment, yet research is needed now to identify the medical, behavioural and developmental profiles associated with these many genetic conditions. Work is also needed on the complex pathways in which experience and biological vulnerability interact in the pathogenesis of mental retardation. Finally, the field still lacks a comprehensive empirically based theory as to why people with mental retardation are at increased risk for psychopathology. Without such a model, our treatments risk being largely problem-orientated instead of preventative. Even so, researchers and clinicians have already worked together to increase substantially the quality of life for persons with mental retardation and their families.

Introduction

Personality refers to those personal attributes of character and temperament that make us who we are, and different from others. We use words like ‘extrovert’ to describe someone who is gregarious, the ‘life and soul of the party’, and keen to try out different hobbies or sports. We apply the term ‘neurotic’ to someone who is constantly fearful that things will go wrong. These human qualities or traits can be applied universally, can be detected from infancy and, until recently, were considered to be stable throughout life, irrespective of circumstance. However, as we will discuss later, recent research suggests that personality is not as immutable as previously thought. Learning, experiences and illness can all act to modify personality characteristics.

The idea that your personality can cause problems for yourself or others underpins the concept of ‘personality disorder’. There are several ways in which aspects of personality can be considered pathological. For example, an extremely introverted individual may find social situations so stressful that he or she avoids them, leading to social isolation and an inability to cope with daily activities. Alternatively, certain antisocial personality characteristics can be associated with criminal behaviour or total disregard for the thoughts and feelings of others.

Disorders of personality are much discussed in psychoanalytic literature and defined operationally in the major psychiatric classifications (see J. Hill, Chapter 43). As well as being ‘treated’ in their own right, personality disorders are also considered to be related to some mental disorders. However, the notion that your personality can influence the type of illness, both physical and mental, from which you will suffer has its origins in antiquity.

In this chapter we review the relationship between aspects of personality (both trait and disorder), and how these relate to health and illness. In order to set the scene, we give a brief overview of the historical background and then discuss current concepts of personality, as dimensional traits. We also examine the relationship between temperament and personality and the stability and plasticity of personality over the life span. When considering the literature that examines the relationship between personality and illness, we address whether personality and the symptoms of mental disorder are part of the same spectrum, or whether certain personality attributes act as either vulnerability or protective factors for the development of mental or physical disorder. Much of the research on personality has been undertaken on adult subjects (Rutter 1987), and so where

applicable we cite this literature as well as that pertaining to children and adolescents.

Brief historical background to the concept of personality

From Hippocrates in the fifth century BC until as recently as the seventeenth century (Burton 1652), it was believed that an individual’s vulnerability to various physical and psychological disorders was related to the blending of four body ‘humours’: black and yellow bile, blood and phlegm (Maher & Maher 1994). Four characteristic personality styles were postulated, each associated with the dominance of one of the humours. Melancholic or gloomy temperament was associated with black bile, sanguine or cheerful temperament with blood, choleric or angry temperament with yellow bile, and phlegmatic or calm temperament was associated with phlegm (Porter 1997, p. 271).

By the nineteenth century, these ancient ideas had been replaced by ‘phrenological theories’ developed by Gall and Spurzheim (Porter 1997, p. 538). Phrenology is the study of the nature and location of bony protuberances on the head, and it was believed that these determined character and personality. Despite the somewhat implausible nature of these ideas in modern times, the phrenology movement had considerable influence and acceptance and led to improved attitudes towards, and treatment of, the mentally ill.

The modern study of personality dates from the early part of the twentieth century. Woodworth’s Personal Data Sheet was possibly the first personality test (Woodworth 1919). Based on the idea of adding ‘scores’ on ‘individual items’, adopted from the IQ test model, it was used with First World War soldiers as a test to determine ‘susceptibility to shock’. The test was found to differentiate between soldiers who developed ‘shell shock’ or ‘war neurosis’ (most probably labelled post-traumatic stress disorder in current terminology) and ‘normal soldiers’ (Winter & Barenbaum 1999).

Later in the century, several attempts were made to link personality with physical attributes. The most notable of these were the theories of Kretschmer (1936) and Sheldon *et al.* (1940, 1942), on the relationship between body build and personality. Also, Alexander (1950) and Dunbar (1943) linked personality characteristics with the development and course of disease by employing psychoanalytic concepts.

One of the most important and established associations between personality and health outcome was first reported in the

1950s. The association between ‘Type A’ personality and coronary artery disease (CAD) was first described by Friedman & Rosenman (1959). Type A personality was defined as a behavioural style characterized by competitiveness, hostility, impatience and achievement striving. Over subsequent decades, evidence accumulated confirming this personality type as a risk factor for CAD (Matthews 1988). Type A individuals were shown to have greater increases in heart rate, blood pressure and neuroendocrine levels of cortisol and catecholamines (Harbin 1989) in response to stress, compared with non-Type A subjects. Consequently, it was proposed that the link with CAD was the result of such heightened physiological responses to environmental demands (Friedman & Rosenman 1974). More recently, the hostility and anger-related component of Type A behaviour has been identified as being most consistently related to this outcome, in particular the behavioural expression of anger (Miller *et al.* 1996).

This work led to a resurgence of interest in the relationship between personality and health. An increasing number of studies explored the possibility that personality factors may increase susceptibility to or protect against the development of disease, and there have been several attempts to explain the mechanisms by which such influences may be exerted. These modern studies are reviewed later in this chapter.

Temperament and personality

There have been many debates about the definitions of temperament and personality, and the difference between the two. In the main, temperament has been conceptualized as being composed of enduring ‘traits’ that have a biological underpinning and that are relatively stable over time. It is also generally assumed that these ‘traits’ are comparatively pure in early childhood and that they become modified with increasing age by the effects of environmental, social or cultural factors. In contrast, personality is generally assumed to encompass motivational and cognitive elements as well as the dispositional aspects accounted for by temperament (Rutter 1987). Personality has been described as ‘the characteristic manner in which one thinks, feels, behaves, and relates to others’ (Widiger *et al.* 1999) or, alternatively, ‘that which gives order and congruence to all the different kinds of behaviour in which an individual engages’ (Hall & Lindzey 1978).

Studies of personality and temperament have often been conducted from widely varying theoretical perspectives (Bates & Wachs 1994). However, two main themes are evident: nomothetic approaches study how individuals differ from one another on a number of attributes, while the idiographic approach aims to paint a portrait of each individual as a unique and integrated whole (Deary & Power 1998). Psychoanalytic theories provide an example of the latter.

More recently, the approach has been to identify the dimensions of personal characteristics along which all individuals differ. Research has demonstrated the temporal stability, convergent validity across sources of information and predictive validity of measuring such quantitative traits (Smith & Williams

1992), although the number of dimensions proposed often vary according to different authors (Gershenfeld & Paul 1998).

Dimensions of temperament and personality in children and adults

One of the first studies to examine temperament in children was the New York Longitudinal Study (NYLS; Thomas *et al.* 1963). This resulted in a nine-trait classification of infant temperament. The categories proposed were activity level, regularity of biological functions, approach to or withdrawal from new stimuli, adaptability to new or altered situations, the threshold of responsiveness, the intensity of reaction, the quality of mood, distractibility and persistence/attention span. Further analyses led to the clustering of these categories into three clinically useful constellations of temperament: ‘easy’, ‘difficult’, and ‘slow to warm up’. The ‘easy’ temperament was characterized by a combination of biological regularity, approach to new stimuli, quick adaptability and positive mood, and accounted for about 40% of the sample. In contrast the ‘difficult’ child displayed the reverse of these behaviours and accounted for approximately 10%. The third category, ‘slow to warm up’, which accounted for 15% of the study population, was characterized by withdrawal tendencies to novel stimuli, slow adaptability and frequent negative emotional outbursts of low intensity. Such children are often labelled as shy.

Two decades later, Buss & Plomin (1975) proposed four independent factors of temperament: emotionality (distress), activity (tempo and vigour), sociability and impulsivity (abbreviated as EASI). It was suggested that these factors were inherited traits that appeared early in the first year and remained stable over time, forming the foundation of later personality traits.

More recently, Kagan *et al.* (1988; Kagan & Snidman 1991; Kagan 1994) extensively explored the childhood trait of shyness and associated behavioural ‘inhibition’. Inhibited children are typified by timidity in response to unfamiliar situations (reminiscent of the approach/withdrawal category described by Thomas and Chess), while uninhibited children are described as sociable, talkative and less fearful when confronted by the unfamiliar. ‘Inhibited’ children were found to have a relatively high and stable heart rate, higher salivary cortisol levels and larger eye pupils when compared with the ‘uninhibited’ group. Kagan speculated that this was caused by ‘inhibited’ children being born with a lower threshold for arousal to unexpected changes in the environment. Longitudinal studies following children from 14 months to 7 years has provided evidence for the stability of this classification over time.

As regards adult personality structure, Eysenck originally proposed that personality could be conceptualized as two uncorrelated factors: neuroticism (N) and extraversion–introversion (E) (Eysenck & Eysenck 1969). Later he also introduced a third factor, psychoticism (P) and revised his original questionnaire to provide a measure of all three (Eysenck & Eysenck 1975). These three dimensions are very broad and encompass

many lower level traits. Neuroticism includes characteristics such as depression, guilt, shyness and emotionality, extraversion includes features such as sociability, liveliness, assertiveness and dominance and psychoticism includes aggressiveness, coldness, egocentricism and toughmindedness. It has been hypothesized that these personality dimensions have a biological basis. In particular, extraversion was linked to arousal and activation of the ascending reticular activating system while neuroticism was linked to the reactivity of the autonomic nervous system.

Building on this work, Cloninger (1987, 1994; Cloninger *et al.* 1993) has proposed a unified biopsychosocial theory of temperament and personality development. This model 'conceptualizes personality as a combination of heritable, neurobiologically based traits (temperament dimensions), and traits reflecting sociocultural learning (character dimensions)'. The temperament dimensions are thought to be related to activity in specific central neurotransmitter systems (Peirson *et al.* 1999) and include harm avoidance, novelty seeking, reward dependence, and persistence. Harm avoidance refers to 'a tendency to respond intensely to signals of aversive stimuli' leading to cautious, inhibited and apprehensive behaviour in high-scoring individuals. In contrast, novelty seeking is conceptualized as 'a heritable tendency toward intense exhilaration or excitement in response to novel stimuli'. The character dimensions described by Cloninger *et al.* are self-directedness, co-operativeness and self-transcendence. A self-report questionnaire (Temperament and Character Inventory) has been devised to capture these seven dimensions (Cloninger *et al.* 1993). In addition, a version for children has also been developed (Junior Temperament and Character Inventory; Luby *et al.* 1999).

Recently, another general classification of personality traits, consisting of five main dimensions, has been proposed (Costa & McCrae 1992). Termed the 'Big Five' (so named because of the breadth of features encompassed by each dimension) these dimensions were originally named to reflect the language that people use to describe personal characteristics. Consequently, they do not represent any particular theoretical perspective (John & Srivastava 1999). The five factors are usually referred to as openness, conscientiousness, extroversion, agreeableness and emotional stability (as opposed to neuroticism; acronym 'OCEAN') with each dimension encompassing a variety of more specific personality characteristics. A variety of instruments have been developed to measure the Big Five. One of the most commonly used is the NEO Personality Inventory-Revised (Costa & McCrae 1992). Originally designed to measure the three personality domains of neuroticism, extroversion and openness to experience (hence the name), it was modified to include scales for the other two dimensions of agreeableness and conscientiousness. In this scheme, extroversion measures features such as sociability, assertiveness, enthusiasm and adventurousness; agreeableness is conceptualized as encompassing forgiveness, altruistic behaviours and sympathy; conscientiousness includes orderliness, efficiency and thoroughness; emotional stability/neuroticism encompasses anxiety, anger, self-consciousness and moodiness; and openness to experience

includes curiosity, imaginativeness, unconventionality and artistic traits.

Although the five-factor model (FFM) of personality appears appropriate for adult research, there is some evidence to suggest that in childhood personality structure may be somewhat more differentiated. Two independent studies have suggested that seven factors (the Big Five plus an additional two) are the most appropriate model for this age group (John *et al.* 1994; Van Lieshout & Haselager 1994). It is argued that the additional two factors of irritability and activity may become integrated into the Big Five adult personality structure over the course of adolescence (John *et al.* 1994). With the increasing consensus on the FFM of personality, there has been a resurgence of interest in the ways in which personality traits combine in individuals who share the same personality profile. Such type theories suggest that human personality variation can fit into a limited number of discrete categories. Several studies in children and adolescents have demonstrated evidence for three replicable personality types which have been generally labelled 'resilients', 'overcontrollers' and 'undercontrollers' (Van Lieshout & Haselager 1994; Caspi & Silva 1995; Robins *et al.* 1996; Hart *et al.* 1997). The resilient personality type demonstrates effective functioning on all five of the Big Five factors. Overcontrollers typically have high scores on the agreeableness and conscientiousness factors but score low on extraversion. Undercontrollers, on the other hand, have low scores on agreeableness and conscientiousness while scoring low on emotional stability. There is evidence for the validity of these personality categories in that they have been shown to be predictive of psychological adjustment, with the resilients generally demonstrating a high level of psychological adjustment.

Genetic and environmental influences on personality

Throughout the early part of the twentieth century the aetiology of both healthy and pathological psychological development was predominantly attributed to environmental forces, primarily the influence of the mother or primary caregiver. More recently, however, behavioural genetics, although confirming the importance of environmental factors, has also highlighted the importance of genetic influences. Twin studies using both self-report measures of personality (Loehlin & Nicholls 1976) and peer ratings (Riemann *et al.* 1997) have yielded consistent evidence for moderate genetic influence in most personality traits. The most extensively studied traits of extroversion and neuroticism have been investigated using a variety of behavioural genetic designs. Mathematical model fitting across studies produce heritability estimates of about 49% for extroversion and 41% for neuroticism (Loehlin 1992). In general, the net effect of genetic influences in most adult personality traits is typically in the range of 30–50%. The remainder of the variance in such studies is attributed to environmental factors, which are divided into that which is shared between family members (shared environment) and that which is uniquely experienced by individuals (non-shared environment). Research in adults has also

shown that it is the non-shared environment that is the most important contribution to the variance in personality measures (Plomin & Caspi 1999). It is important to stress that this may include family experiences common to all members, such as parenting, parental separation or divorce (Hetherington & Clingempeel 1992), as these may be experienced differently by different family members.

Similarly, the relationship between personality traits and mental illness may be mediated by genetic risk factors. Kendler *et al.* (1993a) explored the relationship between neuroticism and depression using a genetic study design. The study assessed 1733 female (same sex) twins from the Virginia Twin Registry and concluded that approximately 55% of the genetic liability to major depression appeared to be shared with neuroticism, suggesting that at least part of the genetic predisposition to depression is mediated via neurotic personality traits.

Research into childhood personality and temperament, which has traditionally relied on parental ratings, often produces somewhat unusual results. Despite yielding correlations for identical twins that are typically high, fraternal twin correlations are often low or negative. These findings have been attributed to sibling competition or contrast effects (Eaves 1976; Carey 1986). Such effects may be caused by the behaviour of one twin having an inhibitory effect on the behaviour of the other (Thapar *et al.* 1995). Alternatively, parental ratings may be biased by the parent's perception that one sibling exhibits a trait to a greater degree than is the case, because he or she does so relative to his or her sibling (Neale & Stevenson 1989; Simonoff *et al.* 1998). It is also of interest that some measures of 'environment' may show genetic influence. For example, parenting style can show genetic influence as a result of the genetic characteristics of the parents, or alternatively it may reflect genetic characteristics of the children (Plomin & Caspi 1999). There is evidence from work with children and adolescents that the genetic influence on some measures of environment appears to be mediated via personality as well as other psychological factors (Pike *et al.* 1996; Saudino & Plomin 1997).

Several associations between specific genes and particular personality traits have been described. The first of these, reported by Cloninger *et al.* (1996), described an association between the D₄ dopamine receptor on chromosome 11 and novelty seeking. Alleles at this locus are associated with a varying number of trinucleotide and dinucleotide repeats. The repeat length is associated with a reduction in receptor efficiency *in vitro* as well as reduced intracellular response to dopamine (Asghari *et al.* 1994). It has been suggested that individuals with such DRD4 alleles are dopamine-deficient and seek novelty to enhance dopamine release. Despite several attempted replications of this finding (Tomitaka *et al.* 1999) the results have not been consistent (Bau *et al.* 1999).

Another allelic association has been described between neurotic traits and a functional polymorphism in the promoter region of the serotonin transporter gene on chromosome 17 (Heils *et al.* 1996; Lesch *et al.* 1996; Katsuragi *et al.* 1999).

Again, there have been inconsistent replication findings (Deary *et al.* 1999; Gustavsson *et al.* 1999; Hamer *et al.* 1999).

Change and stability of personality over the life span

In a longitudinal study of 1000 children (Caspi & Roberts 1999), first observed at the age of 3 years and followed up at the age of 18 years, moderate continuity in several temperamental styles was observed. In particular, children who exhibited restless impulsive emotional labile behaviour at 3 years tended to score highly on measures of negative emotion and low on traits reflecting constraint at 18 years. Similarly, children who were 'inhibited' at initial interview reported cautious behaviour and a preference for safe activities at follow-up; this was associated with low scores on aggression and social potency (Caspi & Silva 1995).

In contrast to this longitudinal study, the continuity between behavioural characteristics noted in infancy and those found later in the preschool years has been shown to be quite low (Caspi & Roberts 1999). To explain this apparent anomaly, the authors suggested that much of the observed variation in infant behaviour prior to the second year of life is caused by transient situational factors. However, during the second year, cognitive changes enable the child to master object permanence and begin to develop self-conscious emotions, which may be important for the development of persisting behavioural responses and the prediction of later personality differences. Although it appears that personality characteristics become increasingly stable with age (Roberts & Friend-Delvecchio 2000), there is still the possibility of change even in old age.

Although these findings suggest that there is some stability of personality across the life span, the original concept assumed that temperament was highly immutable. However, recent research evidence suggests that the stability of temperament is much more modest than originally thought and that alterations in personality can occur in response to life changes (Stewart 1996). Furthermore, it has been postulated that such changes may be influenced by genetic factors (Matheny 1984, 1989; Plomin *et al.* 1993; Cherny *et al.* 1994). For example, accentuation of already existing personality characteristics may occur during periods of social discontinuity, and personal disposition may influence behaviour most when individuals are exposed to new situations or assume new roles (Caspi 1991; Caspi & Moffitt 1991). Also, individuals select situations and companions that are compatible with their disposition, e.g. choice of spouse (Caspi & Herbener 1990). Consequently, processes of social interchange may be developed that sustain an individual's dispositional characteristics across time and circumstances. Similarly, as we will describe below, both physical and mental illnesses may also modify aspects of personality.

One explanation for the finding of only modest stability of personality characteristics over time could be measurement error. It is possible that physiological measures (e.g. pupil size, cortisol level), such as those used by Kagan *et al.* (1988; Kagan 1994; see above) to evaluate shyness in childhood, may prove to be more reliable, valid and closer to personality endophenotypes

than more traditional longitudinal studies based on questionnaire measures.

Relationships between personality and illness

At the beginning of this chapter we described the links made between personality and illness, both physical and mental, throughout history. More recently, there have been many attempts to relate aspects of personality to the development of illness. Here we present the main areas of recent enquiry. First, we consider personality as a predisposing or vulnerability factor for the development of mental disorder. Secondly, we discuss personality and the symptomatology associated with mental disorders (psychopathology) as different parts of a common spectrum. Thirdly, we present recent research examining the relationships between personality and physical health and, fourthly, how aspects of personality may act as a protective factor against the development of both physical and mental illness. Fifthly, we consider evidence for a bidirectional relationship between personality and illness, and how illness may result in an alteration in personality functioning. Lastly, we speculate about future research directions.

Personality as a risk factor for psychopathology

A variety of associations between personality characteristics and psychopathology have been demonstrated, using both cross-sectional and longitudinal approaches. For example, it has been shown that high neuroticism scores are associated with a wide range of mental disorders including anxiety, major depression (Roberts & Kendler 1999; Jorm *et al.* 2000) and somatoform disorder (Kirmayer *et al.* 1994). Similarly, antisocial traits are related to the development of substance abuse (Trull & Sher 1994; Krueger *et al.* 1996; Gabel *et al.* 1999) and borderline personality traits contribute to disorders of eating, mood and impulse control (Widiger & Trull 1993). As well as neuroticism, several other personality dimensions have been consistently associated with depressive disorder. These include dependency, self-criticism, obsessionality and perfectionism (Enns & Cox 1997), traits often also seen in individuals with eating disorders. There is empirical evidence for an association between restricting anorexia and constricted, conforming and obsessional personality traits, while affective instability and impulsiveness have been described in patients with bulimia nervosa (Vitousek & Manke 1994). It has been noted that virtually all of the five main traits accounted for by the FFM are related to at least some type of mental disorder and similarly that most disorders studied are associated with at least one prominent trait of normal personality. However, as illustrated above, these relationships are generally non-specific with no one-to-one correspondence between any particular personality trait and a mental disorder. This is likely to be, at least partially, a reflection of the broad general nature of many of the traits studied, but may also be accounted for by the considerable co-occurrences among

mental disorders themselves (Watson *et al.* 1994). Differentiating broader personality traits according to their various facets may improve the specificity of the relationship.

Considerable attention has been focused on the relationship of neuroticism and extroversion to mental disorders, while fewer studies have explored the relationships between psychopathology and the other three factors (openness, agreeableness and conscientiousness) of the FFM (Widiger & Trull 1992). However, in one such study of adolescents, low scores on agreeableness and conscientiousness predicted juvenile delinquency; high neuroticism and low conscientiousness scores predicted internalizing disorders; while high conscientiousness and openness scores predicted school performance (John & Srivastava 1999). Children who consistently demonstrate behavioural inhibition on follow-up (stable inhibited) have been shown to suffer from significantly higher rates of anxiety disorder, while their parents have been shown to have both higher rates of childhood and continuing anxiety disorder. Further prospective studies have suggested the importance of the 'social avoidance' component of childhood behavioural inhibition in the later development of social phobia and the importance of the 'fearfulness' component for development of both social phobia and depression (Hayward *et al.* 1998). Evidence for the link between childhood inhibition and depressive disorder has further been provided by Caspi *et al.* (1996), who showed that examiner observed behavioural differences rated at 3 years were associated with adult psychiatric disorders on follow-up at 21 years. Inhibited children who were shy, fearful and easily upset were more likely to meet criteria for depression. Children rated as undercontrolled, impulsive, restless and distractible were more likely to meet criteria for antisocial personality disorder (in keeping with John & Srivastava 1999). In addition, both inhibited and undercontrolled groups had a greater risk of attempted suicide, and boys from both groups showed a greater vulnerability to alcohol-related problems (Caspi *et al.* 1996).

It is also possible that personality characteristics can influence the development of mental disorder indirectly. For example, certain types of severe and threatening life events are well-known risk factors for the development of major depression (Brown *et al.* 1973; Paykel 1978) and it has been shown that experiencing an excess of such events also runs in families (McGuffin *et al.* 1988; Kendler *et al.* 1993b). It has been postulated (McGuffin *et al.* 1988) that this increased familial rate of experiencing such events may be related to risk-taking, hazard-prone behaviour or threat-perceiving personality characteristics. Risk-taking is the type of behaviour associated with high scores on measures of extroversion, sensation or novelty seeking, while those who score highly on neuroticism tend to be highly threat-perceiving. Having a risk-taking personality may lead to an excess of life events that in turn could lead to the development of depression. On the other hand, it is possible that highly neurotic individuals will tend to 'make mountains out of molehills' and exaggerate the impact of life events. In a sib-pair study of life events and depression in adults, it has been shown that it is neuroticism rather than sensation-seeking behaviour that is associated with excess life

events and the development of depression (Farmer *et al.* 2000, 2001).

Personality and psychopathology as parts of a common spectrum

The close relationship between psychopathology and personality traits noted above has led to speculation that personality and psychopathology are not distinct but form part of a common spectrum. Consequently, they may represent different phenotypic expressions of the same underlying aetiology. It has also been suggested that there are disease spectra that range from ‘normal’ personality trait, via the more extreme and ‘abnormal’ personality disorders, through to frank mental illness, the differences being quantitative not qualitative. Where ‘personality disorder’ and ‘mental illness’ are defined along this spectrum is somewhat arbitrary (Moore *et al.*, 2000) and this calls into question whether a categorical approach to psychiatric classification is appropriate. Some authors have suggested that categorical approaches to psychiatric classifications are merely diagnostic conventions imposed on continua of symptoms (Kendler & Gardner 1998) and that a dimensional approach would be more appropriate.

In order to demonstrate that personality traits differed only quantitatively from personality disorder, Widiger *et al.* (1994) compared ratings on the FFM (Costa & McCrae 1992) of personality traits with the definitions of personality disorders described in DSM-IV (American Psychiatric Association 2000). The results suggested that the latter can be conceptualized as maladaptive or extreme forms of normal personality traits. Similarly, the relationship between personality disorder and psychiatric illness has also been established in relation to schizophrenia. Using a twin study approach, the maximum monozygotic (MZ) to dizygotic (DZ) concordance ratio was used as a method for exploring the ‘most genetic’ combination of disorders within the schizophrenic spectrum (Farmer *et al.* 1984). The authors showed that by including ‘affected’ twins with a diagnosis of schizotypal personality disorder as well as schizophrenia improved the MZ:DZ concordance ratio, while adding in all twins with any type of Axis I mental disorder led to a reduction in the ratio. These results suggested that schizotypal personality disorder shares the same genetic diathesis as schizophrenia. Consequently, this, together with other studies, has led to schizotypal personality disorder being accepted as part of the schizophrenia spectrum (Kendler *et al.* 1995; Battaglia & Torgersen, 1996) and this personality disorder is now usually classified as a form of schizophrenia (American Psychiatric Association 1994; World Health Organization 1992).

Personality and physical illness

‘Personality can be studied in relation to physical disorders, processes that culminate in physical disorders, or factors that influence health care utilization’ (Contrada *et al.* 1999). In general, research has focused on two main mechanisms thought

to underlie the relationship between personality and physical health: first, processes operating via direct psychophysiological pathways, and influenced by stress and, secondly, those operating at the level of specific behaviours which in turn may influence the risk of disease. It has been suggested that personality characteristics influence the frequency, intensity and duration of physiological stress responses via a variety of pathways that culminate in the development of illness (Smith & Williams 1992). It has been known for some time that psychological factors and stressful conditions can influence neuroendocrine and metabolic processes via activation of the hypothalamic–pituitary–adrenal axis (Arbuthnott 1998) and the sympathetic nervous system (Mason 1972). Both these systems direct the immune response and there is accumulating evidence that stress (Herbert & Cohen 1993), psychological states such as depression (Olf 1999), and personality factors (Borella *et al.* 1999; Miller *et al.* 1999) can influence the immune system. In particular, stress is associated with a decrease in functional immune responses, such as natural killer cell activity. It has also been noted that the immune changes are related to the duration and nature of the stressor (Herbert & Cohen 1993).

Personality can also influence health by predisposing an individual to carry out certain health-related behaviours, which may confer vulnerability to, or alternatively protection from, various disease processes. Behaviours such as smoking, a sedentary lifestyle or a poor diet have been shown to be important in the development of disorders including cancers, diabetes and CAD.

Other personality constructs suggested as having relevance for health outcomes are hardiness, dispositional optimism (both discussed in the next section), explanatory style (proposed by Peterson & Seligman 1987), emotional expressiveness (Jorgensen *et al.* 1996) and health locus of control (Wallston *et al.* 1976). Explanatory style refers to the characteristic causal attributions individuals make for life events both positive and negative. A pessimistic explanatory style is characterized by stable internal attributions for negative outcomes and external unstable attributions for positive events. It has been shown to be associated with greater reports of ill-health and visits to a doctor (Smith & Williams 1992). Personality styles that tend towards reduced emotional expressiveness, such as seen in alexithymic individuals, may also be at increased risk of physical illness. Under the health locus of control model, individuals who believe that their health is controllable are more likely to seek and comply with treatment.

As regards the FFM, there is evidence that individuals who score highly on conscientiousness lead more structured lives and that this results in better health, while individuals with low agreeableness who manifest hostility and high neuroticism appear to be at risk of poor health outcomes (John & Srivastava 1999). It is important to note, however, that although there is substantial evidence for a positive association between neuroticism and self-reports of physical illness and symptoms, there appears to be less support for a true association with actual objectively diagnosed disease. This suggests that neuroticism is associated with a reporting bias, possibly related to an increased concern about normal physical sensations (Smith & Williams

1992). Studies of adverse health behaviours, such as poor diet, smoking, drug abuse and unprotected sex in adolescents, have often highlighted the protective influence of high self-esteem and perceived self-efficacy (Breakwell & Millward 1997; Adih & Alexander 1999; Glendinning & Inglis 1999).

Caspi *et al.* (1997) explored the relationship between personality characteristics and four health-risk behaviours in young adults: alcohol dependence, violent crime, unsafe sex and dangerous driving. Adolescents who demonstrated low scores on traditionalism, harm avoidance, control and social closeness and high scores on alienation and aggression at aged 18 were significantly more likely to be involved in all four health risk behaviours at 21 years. Some personality traits were uniquely associated with specific health-risk behaviours; for example, those who scored highly on alienation were significantly more likely to be involved in violent crime and problematic alcohol use.

It is also important to note that personality and psychological factors may have an important role in the utilization of health care provision, which can affect disease course and ultimately outcome. Similarly, it has been suggested that certain personality traits may influence the diagnostic process, with physicians being more likely to label disagreeable patients as hypochondriacs (Kirmayer *et al.* 1994).

Personality as a protective factor against illness

Resilience refers to the idea that some individuals are able to withstand or rebound from adversity, and can be conceptualized as a dynamic process in which protective factors interact with risk factors to mitigate the occurrence of a negative outcome, such as becoming ill. Psychological resources deemed to have such mitigating effects can be identified in behavioural, cognitive and affective domains and include characteristics such as optimism, a sense of mastery or personal control, and certain coping styles. For example, it has been shown that belief in one's abilities and efficacy within a social or political system, in male adolescents from deprived urban areas, is associated with better self-esteem and mental health (Zimmerman *et al.* 1999). Similarly, high self-esteem in adolescents is associated with a decreased likelihood to engage in health-endangering behaviours (Gordon Rouse *et al.* 1998). However, the evidence suggests that, overall, a sense of self-efficacy, the belief that one can cope with life's challenges, may be more important than a general sense of well-being (Bandura 1995, 1997). Several studies have shown the protective effect of a positive style of planning as a reflection of a feeling of being able to control what happens to one (Quinton & Rutter 1988; Clausen 1991, 1993; Quinton *et al.* 1993; Shanahan *et al.* 1997). A style of active coping is probably important (Compas *et al.* 2001). In addition, children with chronic and disabling conditions who exhibit greater sociability and flexibility in their interactions have less emotional problems and better academic outcomes (Patterson & Blum 1996), while preschool-age children with 'easy' temperaments demonstrate fewer internalizing or externalizing behaviours when exposed to familial conflict (Tschann *et al.* 1996).

Hardiness, a personality construct first proposed by Kobasa (1979) and Kobasa *et al.* (1982), has been examined in a range of studies, including an investigation of coping in individuals with AIDS (Farber *et al.* 2000), and the factors that protect war veterans from post-traumatic stress disorder (King *et al.* 1998). In this model, hardy or stress-resistant individuals are typified by a strong sense of belief in the importance and meaningfulness of their activities and experiences (*commitment*), they believe that life events are predictable consequences of one's actions (*control*), and that change is normal and represents an opportunity (*challenge*). In general, these studies have shown that individuals with high hardiness scores tend to exhibit less psychological distress and have a better quality of life. It is likely that this influence is mediated via less threatening cognitive appraisals of the stressor and the adoption of more adaptive coping strategies. In terms of the FFM, hardy individuals score more highly on openness, conscientiousness and positive emotionality scales (Ramanaiah *et al.* 1999).

Scheier & Carver (1985) proposed that individual differences in dispositional optimism (a general and stable expectation that good things will happen) explained differences in adjustment to stressors. There is evidence that optimists, believing that positive outcomes are more likely, show more active coping strategies in the face of adversity and are less likely to respond with passive strategies, such as avoidance and denial (Scheier *et al.* 1986). Dispositional optimism also appeared to protect against a heightened physiological response to stress (Raikonen *et al.* 1999), that may be related to better immunity (Segerstrom *et al.* 1998). It may also lead to the adoption of particular health-related behaviours such as safe sexual practices and positive behavioural changes in cardiac patients (Contrada *et al.* 1999). However, the fact that hardiness and dispositional optimism scores are both highly correlated with neuroticism has given rise to the suggestion that associations between these concepts and health outcomes might be artefactual and may in fact reflect the well-documented association between neuroticism and health discussed previously.

Whether a personality characteristic is protective or increases risk to later psychopathology may depend on the adverse situation in which the individual finds themselves, on the presence of other factors of influence and on the outcome of interest. For example, we have seen that behavioural inhibition in childhood is a risk factor for anxiety disorder; however, there is also evidence that in the children of alcoholic fathers this trait may be protective against the later development of adolescent alcohol or drug problems (Vitaro *et al.* 1999). Interestingly, it has been suggested that the well-documented relationship between socioeconomic status and health may be partially mediated by protective psychological factors, such as a sense of mastery or control. There is evidence that such factors are differentially distributed by social class, as well as being related to health outcomes. This has led to the suggestion that adverse environments which undermine personal control may have an impact on chronic arousal and thereby contribute to the development of disorders such as cardiovascular disease (Taylor & Seeman 1999). It is

also of note that personality attributes that contribute to resilience are often not those that are believed to do so by the public. In a study of adolescents, it was generally held that being resilient was to be disconnected from others and isolated (Hunter & Chandler 1999).

The nature of resilience represents an important area for future research. If it becomes possible to understand what makes certain individuals resilient to the effects of adversity, it may lead to the development of strategies that promote better outcomes for the more vulnerable.

Influence of illness on personality measurement and personality on illness outcome

It is well recognized that episodes of mental disorder can distort the appearance of personality (Kerr *et al.* 1970), and this is particularly evident when self-report questionnaires are used to measure personality dimensions. However, the problem remains even when semistructured interviews are used as the assessment tool (Widiger *et al.* 1999). Difficulties in investigating the relationship between personality and physical illness can arise because of disease symptoms and treatment distorting measures of personality. Even prospective studies, which aim to assess personality before the development of disorder, may potentially be influenced by prodromal symptoms of the disease.

Conversely, there is evidence that personality can exert an influence on the presentation and course of illness. In Alzheimer disease there is evidence that premorbid personality predicts the level of personality change as rated by informants (Dawson *et al.* 2000) as well as other non-cognitive behavioural symptoms (Meins *et al.* 1998). The co-occurrence of borderline personality disorder and major depressive disorder results in a significantly higher suicide attempt rate, compared to the rates in individuals with either diagnosis alone (Lesage *et al.* 1994). It has also been suggested that personality dimensions can exert an influence on the outcome of schizophrenic illness through their capacity to promote adaptive mechanisms (Jorgensen & Parnas 1990). Similarly, negative affectivity (neuroticism) has been shown to be indicative of a poorer prognosis in anxiety and depressive disorders (Clark *et al.* 1994).

The role of personality factors in influencing response to treatment has also been explored. Cloninger *et al.* have suggested that depressed patients' response to antidepressant medication can be predicted from their temperament and character inventory (TCI) scores (Joyce *et al.* 1994; Nelson & Cloninger 1997; Tome *et al.* 1997). The presence of a personality disorder has been shown to detrimentally affect the outcome of cognitive-behavioural therapy in the treatment of panic disorder (Mennin & Heimberg 2000) and substance abuse (Pettinati *et al.* 1999). Personality change resulting from the use of medication, such as noradrenergic and serotonergic antidepressants, has also been reported (Bagby *et al.* 1999).

Illness resulting in a lasting alteration in personality

The 'scar hypothesis'—the possibility that episodes of mental ill-

ness result in lasting personality changes which persist beyond recovery from the disorder—has not been subjected to much study. Several investigations that have explored this possibility in relation to depressive illness have had predominantly negative (Rohde *et al.* 1990) or inconclusive results. Kendler *et al.* (1993a) found some evidence for an elevation in neuroticism scores in female twins who developed an episode of depressive illness during a 15-month follow-up period, which they suggested was related to a 'scar effect'. However, analysis of data collected as part of the National Institute of Mental Health Collaborative Program on the Psychobiology of Depression found no evidence of personality change for subjects with a prospectively observed first episode of major depression during a 6-year follow-up period (Shea *et al.* 1996). The results suggested a possible association between increase in emotional reliance with number of episodes, and increased introversion with length of episode. However, the findings were somewhat inconclusive, which prompted the authors to suggest the need for further research.

There is some evidence that childhood psychopathology is associated with a later diagnosis of adult personality disorder. In a follow-up of 551 youths aged 9–16 years over a 10-year period, prior disruptive disorders, anxiety disorders and major depression all significantly increased the odds of the later development of personality disorder (Kasen *et al.* 1999).

Both brain damage and dementia can also result in permanent changes in the manner in which individuals behave or interact with others. Typically, control of emotions, impulses, motivation and social judgement are predominantly affected (Lishman 1997).

Conclusions

It is important to appreciate that individuals can change their patterns of behaviour, thoughts and ways of interrelating as a result of intervention (Heatherton & Weinberger 1994). Consequently, although we commenced this chapter by stating that personality is largely constant throughout the life span, this is only true in a very general sense. Learning, experiences and illnesses can all modify personality characteristics. Better understanding of the nature and underlying mechanisms of personality and health relationships may well present the potential for prevention and treatment of a variety of disorders. Until relatively recently, personality and health research has been little influenced by developments in more general personality research. Many of the personality measures used have been derived with specific theoretical models in mind and, as well as issues of validity and reliability, there has been some concern about the possibility of researchers reinventing 'constructs under new labels' (Holroyd & Coyne 1987). With the general adoption of the FFM there exists an opportunity for a more integrated and ultimately applicable study of this area. Similarly, adoption of novel methods for evaluating the behavioural concomitants of personality may improve measurement and remove some of the errors associated with the questionnaire method.

Kagan's inhibition research may prove to be more productive in the future, as it avoids ratings and uses observations by trained observers in carefully described and controlled situations. This, combined with the joint study of personality concepts from different levels of personality organization, such as personal goals and cognitive processes with temperamental traits, will provide the most coherent strategy for future research.

Introduction

The concept of personality disorder in adult life is important and elusive. It is important because it is a major cause of burden to sufferers, to the adults and children with whom they have relationships, and to society; and because of its association with the majority of non-psychotic episodic psychiatric disorders. It is elusive because there is relatively little agreement on basic issues, such as whether there is one overarching disorder or many, and what are the core defining features of a personality disorder. Nevertheless, there is broad agreement that the concept must include stability of behaviour over substantial periods of time, and extensive or pervasive dysfunction encompassing a range of psychological, behavioural and interpersonal capacities. *Prima facie*, it seems likely that such stable and severe problems will have started before adult life, and there is evidence that in many instances analogous disorders or their antecedents do start in childhood, and that childhood experiences may affect risk for subsequent personality disorder. Accordingly, it seems crucial to consider what is known about personality disorders, with special reference to two key questions for child psychiatrists and child mental health practitioners more widely, of the extent to which there is continuity in personality disturbance between childhood and adult life, and whether it is useful to apply the diagnosis in childhood and adolescence.

Concepts of personality disorder

Attempts to classify personality types and dimensions go back to antiquity but concepts of personality disorder are of much more recent origin (Frances & Widiger 1986; Rutter 1987; Tyrer *et al.* 1991). Although there are numerous variations on the specifics, the unifying notion is the idea that there are pervasive and persistent abnormalities of overall personality functioning that cause social impairment and/or subjective distress, and that are not caused by episodic disorders of mental state. The basic assumption is that, personality disorders are different in some way from other more episodic psychiatric conditions such as schizophrenia, depression or anxiety states.

Having broadly characterized personality disorder in terms of persistent dysfunction that is not accounted for by episodic disorder, the question arises as to whether a unified concept for personality disorder (implying one set of underlying causal processes) is adequate. Several attempts to provide a unified

concept have been made, notably using the idea that personality disorder represents an extreme of normal personality. One approach, based on the proposal that there are five major domains of personality, the five-factor model (Widiger & Costa 1994), argues that 'Personality disorders are not qualitatively distinct from normal personality functioning. They are simply maladaptive, extreme variants of common personality traits.' In Cloninger's (1987) tridimensional model, personality disorder is seen to arise from a combination of extremes of temperament, each of which is thought to be influenced by different neurotransmitter systems. Some empirical support from animal and human studies for such associations have been demonstrated, and contributions of behaviour reflecting Cloninger's three dimensions of harm avoidance, novelty seeking and reward dependence have been shown to be predictive of persistence of aggression in adolescence (Kerr *et al.* 1997).

Although these frameworks are promising, it should be borne in mind that the concept of personality disorder did not originate from a model of normal personality, and indeed descriptions of different personality disorder types have come about through several contrasting routes. There are those that derive from the clinical observation that there are individuals who show enduring patterns of inflexible and seriously maladaptive behaviour that seem to fall outside the traditional criteria for mental illness or psychiatric syndrome. The need to have a term to describe these patterns of abnormal behaviour led to the concepts of psychopathy put forward by writers such as Hare (1970), Henderson (1939) and Cleckley (1941). These are the categories of personality disorder that identify individuals who are thought to be most prone to suffer from episodic mental disorders. Schneider's (1923, 1950) notion of psychopathic personality (defined quite differently from the psychopathy formulations of Hare, Henderson and Cleckley) provides the main historic notion of this approach. Many of the ICD-10 specific personality disorder categories (e.g. paranoid, anankastic and anxious) represent this tradition (World Health Organization 1992). Some categories have their origins in empirical observations of the continuities between psychopathological disorders in childhood, and pervasive social malfunction in adult lifestyle. The DSM-IV (American Psychiatric Association 1994) diagnosis of antisocial personality disorder is the obvious example of this type, with its starting point in the findings of the long-term longitudinal studies pioneered by Robins (1966, 1978) and replicated by others (see Earls & Mezzacappa, Chapter 26). Some categories stem fairly directly from theoretical, especially

psychoanalytic, notions. The concept of borderline personality organization (Kernberg 1967, 1975) underlies specification of the DSM-IV diagnosis of borderline personality disorder (Gunderson *et al.* 1981). A few categories have come, at least in part, from genetic findings. Meehl (1962) coined the term ‘schizotypy’ to describe the postulated characteristics of schizophrenia-prone individuals. The Danish adoption study showed that the biological families of adopted schizophrenic probands included a raised rate of personality disorders that seemed to exhibit some features reminiscent of schizophrenia (Kety *et al.* 1971). Spitzer *et al.* (1979) developed more explicit criteria for this type of personality syndrome which has come to be termed ‘schizotypal personality disorder’.

The differences in the origins of personality disorder have contributed to substantial heterogeneity in the balance between behaviours and psychological states that are included in the subtypes of personality disorder. DSM-IV antisocial personality disorder is based primarily on antisocial behaviours and interpersonal difficulties, and includes only one state of mind item, ‘lack of remorse’, which is closely tied to behaviour. By contrast, the borderline personality disorder category includes three items, ‘identity disturbance’, ‘chronic feelings of emptiness’ and ‘transient paranoid ideation’, referring solely to states of mind. Furthermore, within the DSM-IV framework only a subset of the total number of items is required for entry to a diagnosis, which means that criteria can be fulfilled in numerous ways.

Validation

Stability and separation from episodic disorders

It is assumed that the personality disorders should show substantial stability over time. However, there is surprisingly little evidence that this is the case. Several studies of referred adults have found low to moderate stability (Ferro *et al.* 1998). In a study of college students in the USA assessed at three time points over 4 years, Lenzenweger (1999) found moderate stability of DSM personality disorder dimensions, but the estimated prevalence of personality disorder fell from 7.6 to 2.8%.

The distinction between episodic disorders and personality disorder is enshrined in the DSM distinction between Axis I and Axis II. Axis II disorders should show persistence over a period in which there is either recovery from, or onset of, Axis I disorder. In view of this, remarkably few studies have been carried out to test the stability of personality disorder after accounting for episodic disorders. Loranger *et al.* (1991) undertook one of the few pertinent tests in their test–retest study of changes in the diagnosis of personality disorder (on a standardized interview) in a series of 84 psychiatric patients. The investigation was limited by the fact that the interval between assessments was only 1 week to 6 months, but there were major changes in mental state during this period. The key finding was that there was no effect of change in mental state on the diagnosis of personality disorder, supporting the personality disorder–episodic disorder dis-

inction. Nevertheless, remission was associated with some fall in personality disorder symptoms and the diagnosis of personality disorder showed only moderate temporal stability ($\kappa = 0.55$). Rutter (1977) and Rutter & Quinton (1984) tackled the issue over a longer time span by testing whether personality disorder predicted the course of handicapping symptoms in patients over a 4-year period. The results showed that personality disorder was a strong predictor of course (59% marked persistence vs. 18% in those without personality disorder), whereas duration of symptoms was unrelated to outcome in the absence of personality disorder. More recently, Quinton *et al.* (1995) examined the course of disorder in the same group of patients over a 15–20-year period. Persistent social role impairment was much more frequent in those diagnosed as showing personality disorder initially (61 vs. 17%); moreover, this difference was not accounted for by either the length or clinical severity of the initial associated episodic condition.

Although these findings support the distinction between episodic and personality disorders, the two are strongly associated. There are very high rates of personality disorder in patients with episodic disorders: nearly half in inpatient samples and 20–40% in outpatient groups (Docherty *et al.* 1986; Tyrer *et al.* 1991). These figures are much higher than the rates of 6–13% that are typical of general population samples (Casey & Tyrer 1986; Merikangas & Weissman 1986). In a study of outpatients with personality disorder referred to a private practice, the mean number of current DSM-IV Axis I disorders (mainly anxiety and depression) was 2.2, and of lifetime disorders 3.0 (Zimmerman & Mattia 1999); Zanarini *et al.* (1998a) found similarly elevated rates. The meaning of these associations is not clear. It is likely that to a certain extent they are artefacts arising from difficulties in distinguishing Axis I and Axis II items. In clinical and research practice it is often difficult to disentangle symptoms associated with episodes and those that reflect personality disorder. Furthermore, the same clinical phenomena, occurring over different time periods, can contribute either to episodic or to personality diagnoses. For instance, episodes of dysphoria lasting up to a few days contribute to the diagnosis of borderline personality disorder, while somewhat longer episodes contribute to the diagnosis of major depression.

This is unlikely to be the whole explanation. There are three main ways in which the associations may arise. First, personality disorder may constitute a risk factor for episodic conditions. This could occur through direct mechanisms whereby a feature of the disorder, such as poor coping (Vollrath *et al.* 1994), leads to helplessness and hence depression, or through indirect mechanisms in which the personality disorder increases the likelihood of psychosocial stressors which in turn are associated with a disorder such as depression (Daley *et al.* 1998). Second, episodic conditions may create the conditions in which personality disorders develop because a chain of maladaptive behaviours and adverse environmental responses is set in motion that fosters more persistent psychopathology (Kasen *et al.* 1999). Third, both the personality disorder and the episodic disorder could reflect one underlying liability.

Most studies of comorbidity between episodic and personality disorder have been cross-sectional and therefore not well suited to distinguishing between these possibilities, and findings from prospective longitudinal studies have not provided unequivocal answers. On the one hand, there is evidence that personality disorder increases the risk of episodic disorders. In a 2-year prospective study of adolescents, personality disorder symptoms were predictive of subsequent interpersonal chronic stress which in turn increased vulnerability to depression (Daley *et al.* 1998). In a community-based longitudinal study, Johnson *et al.* (1999) found that personality disorder ascertained in adolescence predicted episodic disorders in early adult life. After controlling for episodic disorders in adolescence, the presence of personality disorder more than doubled the likelihood. By contrast, findings from the same community study indicated that the influences may run the other way. Disruptive disorders, anxiety and depression ascertained between ages 9 and 16 were all associated with personality disorder in early adult life after controlling for prior personality disorder. There could be several interpretations of these findings. In the case of disruptive disorders, they could be a function of the convention whereby antisocial behaviours in childhood are seen as indicative of an episodic disorder, but the constellation of antisocial problems seen in adult life is assessed as an antisocial personality disorder. Alternatively, different subgroups may take different routes, some starting with episodic disorders and some with personality disorder. Equally, it could be that episodic and personality disorders are so strongly associated from late childhood and early adolescence that the attempt to give causal priority to one or the other will not prove fruitful.

It might be expected that, whatever the relationship between episodic disorders and personality disorder, the combination should in some sense reflect a more severe variant, with implications for treatment outcome. However, the evidence has been mixed. Several studies have found that personality disorders are associated with a worse immediate response to treatment and a worse overall outcome for episodic mental disturbances (Docherty *et al.* 1986; Shea *et al.* 1990; Reich & Green 1991). Tyrer *et al.* (1994) found that a community-based early intervention for psychiatric emergencies had better outcomes than a hospital-based service only for patients who did not have a personality disorder. In a study of response to ECT among inpatients, personality disorder was associated with slower social recovery, but personality status was not associated with recovery from depressive symptoms (Casey *et al.* 1996). In a study of 298 psychiatric outpatients re-evaluated after 6 years, relapse of depression was predicted by the presence of borderline and dependent personality disorders (Alnaes & Torgersen 1997). However, the evidence that the presence of personality disorder predicts poorer treatment outcome has not been consistent. Studies of the effectiveness of cognitive therapy (Patience *et al.* 1995) and of fluoxetine (Nierenberg *et al.* 1999) for depression did not find associations between personality disorder and outcomes. The inconsistencies in the findings are likely to have arisen from a wide range of factors including variations in sam-

ple sizes, types of clinical problems, treatments and outcomes. Where there is an effect of personality disorder very little is known about possible mechanisms. Personality disorder may be associated with poor treatment compliance, or with greater severity of overall psychopathology, or with a greater number of psychosocial adversities and fewer interpersonal resources or with maladaptive beliefs (Kuyken *et al.* 2001).

The conceptual distinction between personality disorders and chronic psychiatric conditions raises other difficult questions. Usually it has been assumed that the latter are more episodic in their course, do not reflect a basic characterological defect, are more amenable to change, and are ego-dystonic in the sense that they represent a difference from the person's ordinary functioning that is a source of distress to the individual and which the person wishes to change. In relation to each of these we find a blurring of the distinction. In many cases, episodic conditions such as schizophrenia and depression pursue a course in which there is relatively little evidence of discrete episodes. The idea that episodic disorders, whether chronic or acute, are not related to aspects of personality has been challenged in a number of ways. Proneness to depression is associated with the personality characteristics of neuroticism and sociotropy—a need for approval from others (Ormel & Wohlfarth 1991; Robins *et al.* 1994). The distinction does not apply with regard to genetic and biological contributions. There are substantial genetic contributions to schizophrenia, depression and personality disorder (McGuffin & Thapar 1992), and no evidence that the extent of genetic influences differs systematically between the episodic and personality disorders. Similarly, there is evidence of structural brain abnormalities in chronic episodic conditions, notably schizophrenia, and in personality disorder (Raine *et al.* 2000).

Differentiations among personality disorders

The World Health Organization (1992) classification, ICD-10, makes a basic differentiation between organic personality disorders (meaning those resulting from severe head injury, encephalitis and other forms of overt brain damage); enduring personality changes deriving from some catastrophic experience, personality abnormalities that reflect the residue of some mental illness (e.g. residual schizophrenia); and what they term personality disorders. The American Psychiatric Association (1994) scheme, DSM-IV, makes broadly comparable distinctions. This chapter is concerned with this last group of specific personality disorders because the others have only an extremely limited application in childhood and adolescence.

The ICD classification specifies nine personality disorder types, and the DSM system eleven. To a certain extent the different categories reflect the different origins referred to earlier. The DSM classification has received a lot of attention, and in spite of the operational definitions of each of the categories, the evidence for their discriminant validity is not strong. Studies have consistently shown that individuals who receive one DSM Axis II diagnosis generally receive several (Pfohl *et al.* 1986; Morey 1988; Oldham *et al.* 1992). Although there is evidence that the DSM

categories cluster into three broad bands of the odd/eccentric, the dramatic/emotional/erratic and the anxious/fearful (Kass *et al.* 1985), combinations of personality disorders that cross these bands are common (Oldham *et al.* 1992).

Support for the discriminant validity of particular personality disorders would be provided if it were possible to show differential association with other psychiatric conditions, family clustering, or associations with genetic or environmental influences. Studies of the association of borderline personality disorder with other episodic and personality disorders have provided some support for its discriminant validity. Zanarini *et al.* (1998b) compared patients with borderline personality disorder and patients with other personality disorders. Those with borderline disorder had higher rates of associated paranoid, avoidant and dependent personality disorders, and higher rates of mood, anxiety and eating disorders. Zimmerman & Mattia (1999) found higher mean totals of associated episodic disorders in patients with borderline personality disorder, and increased rates of particular Axis I disorders.

The most clear-cut finding from family studies is the association between schizophrenia and a loading of schizotypal personality disorders in the biological relatives (Kendler *et al.* 1981, 1984). The evidence for a link between schizotypal personality disorder and schizophrenia is further supported by findings of similarities in magnetic resonance imaging (MRI) (Dickey *et al.* 2000) and in deficits of attention and information processing (Cadenhead *et al.* 2000). A significant but weaker association with schizophrenia has been found with paranoid personality disorders (Kendler & Gruenberg 1982; Kendler *et al.* 1985).

There are very few family and genetic data on other personality disorders (McGuffin & Thapar 1992; Maier *et al.* 1998). There is some evidence that borderline personality disorders cluster in families and also are associated with affective disorders in other family members, but it remains quite uncertain whether the family loading has a genetic basis. There is consistent evidence for genetic influences on adult antisocial behaviours (Langbehn *et al.* 1998), but not adult violence (Carey & Goldman 1997). There seems to be a genetic component to antisocial personality disorder but there is limited evidence on its strength. Most studies of the association between adverse childhood experiences and personality disorders have reported associations with a wide range of episodic and personality disorders (Johnson *et al.* 1999). There may also be more specific effects. Bezirgianian *et al.* (1993) found that the combination of maternal inconsistency and high maternal overinvolvement assessed in adolescence was associated with the persistence or emergence of borderline personality disorder, and no other episodic or personality disorders. Parker *et al.* (1999) reported that dysfunctional parenting in childhood was associated with the dramatic and anxious DSM clusters, but not the odd/eccentric cluster.

In contrast to the rather sparse support for the distinctions between the majority of the different personality disorder cate-

gories, recent work identifying the relevant dimensions of personality functioning has produced more consistent findings. There has been broad support for at least four factors—emotional dysregulation, dissocial behaviour, inhibitedness and compulsivity—which are identifiable in clinical as well as non-clinical samples. Distinctive genetic and environmental factors associated with these broad factors, and also with lower level more specific traits, have been identified (Livesley *et al.* 1998). This implies that there may be ‘a large number of genetic building blocks each having a relatively specific effect in isolation, but also with the potential to combine to produce an almost infinite variety of configurations of personality traits and able to be expressed as “personality disorder”’ (Parker & Barrett 2000).

Specific personality disorders

In view of the lack of good discriminant validity among the many specific personality disorders, only a few of the key categories that may be particularly relevant in childhood and adolescence will be discussed.

Antisocial personality disorders

Although the adjective ‘antisocial’ might seem to imply that the personality disorder necessarily implies criminal behaviour, it is apparent from the DSM-IV (American Psychiatric Association 1994) that this is not so. The diagnostic criteria include an inability to sustain consistent work behaviour, antisocial acts, aggression, failure to honour financial obligations, failure to plan ahead, disregard for the truth, recklessness, and a lack of remorse.

Most adults with antisocial personality disorder have shown marked conduct problems in early childhood. Conduct problems starting early in childhood carry a high risk of persistence into adolescence and adult life (Moffitt *et al.* 1996). These life-course-persistent difficulties are associated with temperamental lack of control (quick to show negative emotions when frustrated, poor impulse control), hyperactivity, lower IQ, and peer problems and adverse family backgrounds (Henry *et al.* 1996; Moffitt *et al.* 1996). Although this is a high-risk group, around one-half do not go on to become antisocial adults and so identifying the predictors of persistence of conduct problems is central to understanding the causes of antisocial personality disorder. However, relatively little is known of factors and processes that predict within this vulnerable group. On the basis of retrospective reports within a large epidemiological study, Robins *et al.* (1991) found that the number of childhood antisocial problems was associated with risk of antisocial personality disorder. Studies within childhood provide some further clues regarding risk of persistence. Loeber *et al.* (1995) found that early fighting and hyperactivity predicted persistence of antisocial behaviours over a 6-year period among boys referred for conduct problems.

In a prospective study of a representative general population sample from ages 7–9 years to 14–16 years, persisters had the highest levels of family adversity, lower IQ and self-esteem; those with early conduct problems that did not persist had levels of these risk factors that were intermediate between persisters and children who lacked early behaviour problems (Fergusson *et al.* 1996). Persisters were more likely than those whose early antisocial behaviours had remitted to have a deviant peer group in adolescence. Whether this was a reflection, or a cause, of persistence is not clear; however, it is consistent with Sampson & Laub's (1993) argument that a key factor in determining persistence may be the presence or absence of social bonds and controls.

Conduct disorder in childhood leads to criminal behaviour in adult life, not so much because this is inevitable — although there are important individual influences — but rather because antisocial behaviour in childhood is likely to predispose to weak social commitments in work, friendship and marriage, and that these in turn make crime in adult life more likely. By the same token, if there are sufficiently powerful salient life events and socialization experiences of the right kind in adult life this strong indirect chain can be broken. Studies of the risk of deviant partners and the effects of quality of cohabiting relationships illustrate the point. Children who have been in care have high rates of conduct problems and have adult psychosocial difficulties typical of antisocial personality disorder. However, the risk of poor adult outcome is reduced among those who establish supportive cohabiting relationships (Rutter *et al.* 1990). Acquiring a non-deviant partner is crucial to this more benign outcome. Among individuals with conduct problems in childhood the likelihood of having a non-deviant partner was increased where they had shown evidence of planning for work before leaving school and had a non-deviant peer group in adolescence (Quinton *et al.* 1993).

Adequacy of antisocial personality disorder as a diagnosis

In common with all DSM categories, the diagnosis requires a subset of the criteria for antisocial personality disorder to be present, which means that there are numerous ways in which individuals may be identified as having the disorder. This is likely to limit precision in identifying mechanisms. Furthermore, antisocial personality disorder is no more immune from problems of multiple diagnoses than other personality disorders. A focus on particular features of the category may prove useful. Broadly speaking, it refers to antisocial behaviours, deficits in social role performance and lack of remorse. Findings from longitudinal studies in the UK have indicated that the continuity from conduct disorder in childhood to pervasive social dysfunction, affecting relationships and work, may be stronger than that of conduct disorder to antisocial behaviours (Zoccolillo *et al.* 1992), and that monozygotic twins who showed conduct disorder in childhood have greater concordance, compared with dizygotic twins, for adult social dysfunction than for anti-

social personality disorder (Simonoff 2001). It is therefore possible that difficulties in establishing and gaining from effective interpersonal, educational and work functioning not only contribute to persistence of childhood conduct problems but also constitute the core of the adult difficulties. These would, under some circumstances and in combination with additional individual vulnerabilities, be associated with antisocial behaviours, but also with a wider range of psychosocial problems.

Psychobiological mechanisms in antisocial personality disorder

It may be that conduct disorder persisters have particular biological or psychological profiles that pick them out from those who will remit. For example, a low heart rate has consistently been found to be associated with antisocial behaviours in children and adults (Farrington 1997). In a study comparing volunteer adults with antisocial personality disorder and psychiatric and normal controls, the antisocial group had lower mean prefrontal volumes and reduced autonomic activity (Raine *et al.* 2000). However, there were inconsistent associations between prefrontal volumes and autonomic measures. If these associations can be substantiated it will be important to ascertain whether remitters and persisters differ on these parameters, or whether they have the same biological vulnerabilities accompanied by other biological or social protective factors.

The role of temperament in relation to conduct disorders is reviewed by Moore & Farmer (Chapter 42) and by Earls & Mezzacappa (Chapter 26). The effects of lack of control in early childhood, as evidenced by an inability to modulate impulse expression, impersistence in problem-solving, and emotionally negative responses to stress and challenge, may be very persistent. In their prospective study of a New Zealand birth cohort, Henry *et al.* (1996) found that temperamental lack of control at ages 3 and 5 distinguished, among those who were convicted by age 18, between those with violent offences and those with non-violent offending histories.

Psychopathic disorder

Insensitivity to the feelings of others, as reflected in lack of guilt or remorse, is included as an item in DSM-IV antisocial personality disorder category. However, antisocial personality disorder and psychopathy are different concepts with different histories. Antisocial personality disorder is predominantly a behavioural description and, as many commentators have pointed out, it has substantial overlap with criminality. The concept of psychopathy, particularly as described by Cleckley (1941) and as assessed in the Psychopathy Checklist (PCL, Hare 1971), has more emphasis on inferred interpersonal and affective traits such as grandiosity, callousness, deceitfulness, shallow affect and lack of remorse. Psychopathy defines a narrower group of offenders than antisocial personality disorder. Between 50 and 80% of offenders meet DSM criteria for antisocial personality

disorder, whereas the rate of psychopathy is around 15–30% (Hare *et al.* 1991; Robins *et al.* 1991). The psychopathic group is probably a subgroup of those with antisocial personality disorder. Most criminals who meet criteria for psychopathy also meet those for antisocial personality disorder, and around 30% of those with antisocial personality disorder meet criteria for psychopathy (Hart & Hare 1989). Compared with other offenders, psychopathic individuals have a lower average age of first arrest, have a higher rate of offending and are somewhat more likely to have committed violent crimes (Hare & McPherson 1984; Cooke 1995). Scores on the PCL assessment of psychopathy predict recidivism following release from prison including violent recidivism (Serin & Amos 1995).

Lack of interpersonal emotional responsiveness may be the key deficit in psychopathy. In a comparison of psychopathic and non-psychopathic prisoners, the groups did not differ in their ability to attribute correctly happiness, sadness and embarrassment to protagonists in short stories. However, in response to guilt stories, the psychopaths were more likely to attribute happiness or indifference to the protagonists (Blair *et al.* 1995). Blair *et al.* (1997) have proposed that psychopathy is associated with a failure to inhibit aggression in response to signs of distress in others, arising from a deficit in processing behavioural evidence of that distress. There is supportive evidence that, compared with other offenders, psychopathic individuals have reduced autonomic responses to distress cues (Chaplin *et al.* 1995; Blair *et al.* 1997). Several functional imaging studies have reported increased activation of the left amygdala on presentation of fearful expressions, which raises the possibility that psychopathic individuals have specific deficits in the functioning of the amygdala (Blair *et al.* 1999). It could be that psychopathy arises directly from a structural deficit, with other factors playing relatively little part. Equally, functional deficits in responsiveness to others' emotions may arise in interactions of vulnerable individuals with psychosocial adversities in childhood. In a study using a standardized investigator-based interview measure of recalled childhood experiences, psychopathic offenders reported higher rates of family adversities, such as neglect and antipathy, than non-psychopathic criminals (Marshall & Cooke 1999).

Borderline personality disorder

The overall concept of borderline personality disorder is of a pervasive pattern of instability of interpersonal relationships, self-image, affects and control over impulses. The operationalization of this concept has varied somewhat over the years, but the criteria have usually included a pattern of unstable and intense interpersonal relationships with alternating idealization and devaluation, frantic efforts to avoid real or imagined abandonment, an unstable or distorted self-image, impulsiveness, recurrent suicidal behaviour, affective instability with intense episodic dysphoria, chronic feelings of emptiness, and a lack of control over anger.

Many theories of the origins of borderline personality disorder have proposed a central role for adverse and, in particular,

traumatic experiences in childhood. If this were the case there would be a particularly important preventative role for child care and mental health professionals. Among referred individuals with borderline personality disorder, the rate of recalled sexual abuse and neglect is very high; above 90% in a study of 467 inpatients with personality disorders (Zanarini *et al.* 1997). In a comparison of borderline patients and those with other personality disorder, those in the borderline group were more likely to have been abused by a male non-caregiver, to have experienced denial of their thoughts and feelings by a male caregiver and to have experienced inconsistent treatment by a female caregiver. As we saw earlier, in a general population study of adolescents, particular patterns of mother–child interaction were associated with subsequent borderline personality disorder (Bezirgianian *et al.* 1993). By contrast, in the same study, documented child sexual abuse was associated with increased symptom scores, not only for borderline functioning but also histrionic and depressive personality disorder, and neglect with a wide range of personality disorders (Johnson *et al.* 1999), suggesting a rather non-specific effect.

Although it is likely that childhood trauma and neglect have a role in the development of borderline personality disorder, very little is known regarding their importance compared with other risk factors, nor of possible causal mechanisms. In their meta-analysis covering 21 studies into possible associations between child sexual abuse and borderline personality disorder, Fossati *et al.* (1999) found there was only a moderate pooled effect size. Childhood sexual abuse and neglect are experienced by at least 20% of girls before the age of 16 (Fergusson *et al.* 2000; Hill *et al.*, 2001) and, although prevalence estimates of borderline personality disorder are lacking, it is clear that they do not come anywhere near to that level. Therefore, even if abusive or neglectful experiences were necessary for borderline personality disorder, they would not be sufficient, and it is likely that more specific aspects of childhood adversities together with other vulnerability factors need to be identified.

Identification of the role of specific aspects of childhood adversity is likely to require more precise specification of the phenomena to be explained. For example, individuals with borderline personality disorder also report more dissociative experiences (Jones *et al.* 1999). In a study of dissociative experiences among patients with borderline personality disorder, Zanarini *et al.* (2000) found that dissociative experiences were associated with particular experiences that included inconsistent behaviour by a caregiver and sexual abuse by a caregiver. There is currently no consensus on psychological mechanisms in borderline personality disorder that might provide a link with adverse experiences in childhood; however, emotional dysregulation (Linehan 1993) and failure of reflective function (Fonagy *et al.* 2000) are both promising candidates. The findings that the combination of intrusive and inconsistent mother–child interactions was associated specifically with borderline personality disorder (Bezirgianian *et al.* 1993) would be consistent with a role for both of these. Intrusive parenting is likely to lead to intense affect from which the child takes evasive action to reduce affect,

hence leading to the experience of extremes of emotional intensity. Inconsistent mother–child interactions are likely to inhibit the child’s capacity to read the intentions or states of mind of the parent, and hence limit his or her ability to think of others’ behaviours in mental state terms. If, as is often the case, the parent has also been abusive, and therefore conceiving of the parent’s motives includes understanding motives for abusive behaviour, the child is likely to inhibit reflection regarding the parent, with implications for reflectiveness more generally.

Repeated self-injury, cutting, burning or hitting, is frequently observed in individuals with severe personality disorders, and is one of the diagnostic items for borderline personality disorder. It is a serious and puzzling phenomenon. There is a wide range of theories concerning the motivation for self-injury, and themes that are common to most of them are of regulation of emotions, communication and social reinforcement (Kemperman *et al.* 1997). Linehan (1993) has proposed that self-injury directly relieves painful emotions, and is reinforced by the attention and care given by others. Several studies have supported the role of self-injury in reducing painful affect. In a study of volunteers who responded to a television programme about self-harm, 66% reported that they felt better immediately after injuring themselves (Favazza & Conterio 1989). Among female offenders, those who mutilated themselves regularly were characterized by high levels of affective symptoms, and the majority reported a build-up of painful emotions prior to self-injury that were relieved by self-mutilation (Coid 1993). Kemperman *et al.* (1997) asked female inpatients with borderline personality disorder to recall changes of mood prior to, during and following self-injury, and found decreases of negative, and increases of positive, mood following self-injury. Each of these studies was limited through the use of retrospective measures with samples that in different ways were unrepresentative; however, they were consistent in finding a mood-relieving role for self-injury. However, we are left with a paradox requiring explanation, that an act that disfigures, and often is painful, improves mood. Proposals have been made that there are effects on endogenous opioids or serotonin regulation but results from a small number of investigations have been inconsistent (Kemperman *et al.* 1997).

Dissociative identity disorder

The category multiple personality disorder (MPD), renamed dissociative identity disorder (DID) in DSM-IV, has provoked considerable controversy. The diagnosis is rarely made outside of the USA and Canada (Merskey 1995), and in the USA only a minority of psychiatrists believe that DID is supported by strong evidence of scientific validity (Pope *et al.* 1999). Nevertheless, the phenomenon has been described in a range of scientific and clinical publications, and the case has been made that the symptoms can be corroborated and that in offenders there is a strong association with documented severe abuse in childhood (Lewis *et al.* 1997). It is likely that this specific manifestation of personality disorder is culturally determined and to a certain extent ia-

trogenic, but possible that disorders of similar severity and with the same risk factors are seen more widely.

Schizotypal personality disorder

The general concept of schizotypal personality disorder is that of a pervasive pattern of social and interpersonal deficits marked by acute discomfort with, and reduced capacity for, close relationships, as well as by cognitive or perceptual distortions and eccentricities of behaviour, beginning by early adulthood. It is likely that the concept of a spectrum of schizophrenic disorders, including schizotypal personality disorder, applies in the pre-adult years, as well as later. However, there have been only a small number of attempts to apply the criteria in childhood. One study suggested an overlap with pervasive developmental disorders, although not autism as such (Nagy & Szatmari 1986); another suggested a course similar to that of schizophrenia arising in childhood (Asarnow & Ben-Meir 1988); and a third suggested that there was a pattern of communication deficits similar to, but milder than, those found in schizophrenia (Caplin & Guthrie 1992). Olin *et al.* (1997) gathered prospective questionnaire data from teachers on 15 year olds who subsequently developed schizotypal personality disorder. Compared with a range of other groups at varying levels of risk for psychiatric disorder other than schizophrenia, the schizotypal individuals as adolescents had been more passive and unengaged and more hypersensitive to criticism.

Schizoid personality disorder

The usual concept of schizoid personality disorder is of a pervasive pattern of detachment from social relationships and a restricted range of expression of emotions in interpersonal settings (American Psychiatric Association 1994). Thus, ICD-10 criteria (World Health Organization 1992) include a lack of pleasure in activities, emotional coldness, apparent indifference to praise or criticism, a limited capacity to express either positive or negative emotions, a lack of close friends, a preference for solitary activities, a marked insensitivity to prevailing social norms and an excessive preoccupation with fantasy and introspection. The literature on the syndrome is almost confined to adults. However, since the 1970s, Wolff has pressed the case for the application of the diagnosis in childhood (Wolff & Barlow 1979). Unfortunately for comparative purposes, her criteria differ in several key respects from those generally applied with adults. She has specified increased sensitivity and paranoid ideas, whereas ICD-10 and DSM-IV indicate marked insensitivity, and she has included an unusual or odd style of communicating which would ordinarily be part of schizotypal, not schizoid, personality disorders (Wolff & Chick 1980; Wolff 1991a,b). The initial findings in childhood suggested some similarities with autism (Wolff & Barlow 1979) and the follow-up showed substantial continuity with schizotypal personality disorder in adult life (Wolff *et al.* 1991; Wolff 1995). However, a study of psychophysiological responses of adults who in childhood met Wolff’s criteria for

schizoid disorder failed to find abnormalities previously documented in the relatives of schizophrenic patients and adults with schizotypal personality disorder (Blackwood *et al.* 1994).

Personality disorder, development and psychopathology

It is implicit in the ideas and the findings that have been reviewed here that the set of concepts referred to broadly as personality disorder is characterized by persistent and pervasive dysfunction that is not readily accounted for by episodic disorders. Equally, the limitations of existing approaches are very evident, and the subject of substantial debate (Parker & Barrett 2000). Several issues are in particular need of investigation.

Distinction between episodic disorders and personality disorders

This distinction may, in some instances, draw the line in the wrong place. Possible reasons for the strong association between episodic (Axis I) and personality (Axis II) disorders have been reviewed above. It may be that this does not represent an association between different conditions, rather that so-called episodic disorders accompanying personality disorders are part of the same condition. Zanarini *et al.* (1998a) found that the best 'episodic' discriminator of borderline and other personality disorders was the combination of a history of disorders of mood, such as depression or anxiety, and disorders of impulse such as eating disorders. The implication could be that individuals with this combination of Axis I disorders *also* suffer from borderline personality disorder, or that this 'combination' is a reflection of underlying difficulties in affect regulation and impulsivity, both of which are probably central to borderline functioning (Linehan 1993; Links *et al.* 1999).

Concept of personality disorder

It may also be that the concept of personality disorder is not sufficiently interpersonal or developmentally sensitive. The successful development of social capabilities and attachments early in childhood are associated with a wide range of subsequent competencies, and individual competence, or lack of it, needs to be understood in relation to developmental tasks. Most current concepts and measures of personality disorder do not provide systematic approaches to interpersonal functioning or to developmental demands and this may contribute to an apparent age dependence of some personality disorders. For example, rates of offending among males decline from their 20s onwards, as do rates of antisocial personality disorder (Cloninger *et al.* 1997). However, it is possible that the interpersonal difficulties persist and that less easily detectable forms of violent behaviour, such as domestic violence, replace those seen in younger men. There may be age-related differences in the way the same underlying deficits are manifest. A focus on personality difficulties as

deficits in adult social roles may help clarify the situation. Recently, Livesley *et al.* (1998) proposed that personality disorder could be seen as a failure involving the interrelated realms of self-system, intimate relationships, and wider social and occupational interactions. This opens up the possibility that such a failure may be evident in different ways in childhood, adolescence and over adult life. This is consistent with Hill's approach to personality functioning (Hill *et al.* 1989), in which dysfunction is assessed in six domains of social role performance. Individuals with pervasive dysfunction are also likely to be judged as having personality disorder using a trait-based measure (Tyrer 1988; Hill *et al.* 2000).

Interactional features

The concepts and measures of personality disorder may not be sufficiently interactional. It is well established that children's behaviour has a powerful effect in evoking and selecting environmental experiences (see Sandberg & Rutter, Chapter 17). Although these processes have not been studied much beyond childhood, it is very likely that they apply also to adults. Some types of stressful life events have a significant heritable component because some individuals have a stable tendency to select themselves into situations that have a high probability of generating such events (Kendler *et al.* 1999). Accordingly, difficulties such as marital separation or prosecution for debts may be either (or both) stressful life events or features of personality disorder. The interplay between disordered individuals and adverse environments merits attention.

Severity of disorder

As we have seen, multiple diagnoses of personality disorder are common. Oldham *et al.* (1992) recommended that the co-occurrence of supposedly distinct personality disorders should be seen to reflect 'extensive personality disorders' implying a more severe form of disorder. The implications of severity of personality disorder have received little attention; however, a recent study of risks for alcohol dependence illustrates the issues. Bucholz *et al.* (2000) examined the extent of risk for alcohol dependence associated with severity of antisocial personality disorder symptoms contrasted with subtypes of disorder in a family genetic study of 2834 females and 3488 males. Overall, findings from both men and women did not support the existence of subtypes of antisocial personality disorder, but rather indicated a disorder distributed on a severity spectrum.

Subclinical manifestations

Patterns of persistent dysfunction falling short of the criteria for personality disorder require study. Just as variations of severity above the personality disorder threshold may be important, so may those below it. Interpersonal difficulties, which rarely amount to personality disorder, are associated with increased risk of depression (Brown *et al.* 1990; Hill *et al.* 2001). These

may share childhood antecedents, and underlying biological and psychological processes, with the interpersonal difficulties seen in personality disorder.

Breadth of diagnostic category

Personality disorder may be too broad and heterogeneous a category for the investigation of some underlying causal processes. The effectiveness of the personality disorder diagnoses rests on their capacity to unify the causes, consequences or treatments of a wide range of behaviours, types of relationships and states of mind. This is clearly a possibility in some cases, but in others it may not be. For them, studies of more specific associations and processes may be needed. Examples referred to earlier include studies of the relationship between temperament and violence, neurocognitive deficits and psychopathy, and childhood experiences and dissociation.

Utility of personality disorder diagnosis in childhood and adolescence

In the light of these considerations is there an argument for applying the concept of personality disorder in adolescence or even in childhood? Given the probable heterogeneity of the personality disorders it is unlikely that there will be one answer to this question. Therefore the advantages and disadvantages will be considered in general and specific examples tested against these.

There would be a strong case if it could be shown that the category could unify diverse symptoms with a common cause, prognosis or response to treatment. It is, for example, clearly the case that the diagnosis of autism, which meets most of the requirements for personality disorder, provides an effective unifying diagnosis for diverse social and behavioural abnormalities.

Might we apply the same case in respect of conduct disorder in childhood? The case could be made that, given its strong association with poor peer relationships and educational failure, a childhood personality disorder equivalent to antisocial personality disorder in adult life should be proposed, comprising antisocial behaviours, peer problems and educational failure. There are indeed good reasons to support such a proposal. Childhood oppositional and conduct problems associated with poor peer relationships are more likely to persist (Vitaro *et al.* 2000), and adult antisocial outcomes are most common in children with multiple and diverse oppositional, social and educational difficulties (Stattin & Magnusson 1996).

On the other hand, the use of the personality disorder designation could introduce the limitations of the adult categories into childhood. Crucially, it would be likely to reduce our scope to investigate the links between different types of dysfunction. Vitaro *et al.* (2000) found that, in boys, although having a best friend who was deviant age 10 predicted delinquency at age 14, this was much less the case among those with warm relation-

ships with their parents. Such a specific mechanism could not be investigated if poor peer relationships was an item within a childhood antisocial personality disorder. Similarly, notwithstanding the strong association of conduct disorder and attention deficit hyperactivity disorder (ADHD) and evidence that ADHD in the presence of conduct disorder increases the likelihood of persistence (Loeber *et al.* 1995), important genetic and neuropsychological differences would not have been identified if they had been included in a hyperactivity-conduct personality disorder.

Psychopathy in childhood

Studies paralleling those of psychopathy in adult life have identified a subgroup of antisocial children who have a high level of reported callousness and emotional indifference in their peer relationships, using a scale with similar items to those on the PCL (Frick *et al.* 1999). A series of studies of referred children with conduct disorder have indicated that children who are characterized as callous and unemotional differ from other children with conduct disorder in that they have lower levels of anxiety, and the extent of their antisocial problems is not associated with the quality of the parenting they receive. A recent study has reported that children who score highly on the scale of callous/unemotional characteristics have reduced psychophysiological responsiveness to distress cues (Blair 1999). At this point the identification of psychopathy in children should be regarded as promising and in need of further investigation but it is not yet clear how this group should be identified. Lynam (1998) has proposed that children comorbid for conduct problems and hyperactivity-impulsivity-attention deficits are the 'fledgling psychopaths'; however, Frick *et al.* argued that further identification by callous/unemotional traits is necessary (Barry *et al.* 2000). Compared to the volume of research on conduct disorder and ADHD, little is known about the hypothesized psychopathic group, with respect to genetic and environmental influences, or the stability of this diagnosis and its long-term outcome.

Borderline personality disorder in adolescence

Many of the studies of personality disorder in adolescence have focused on borderline personality disorder. A substantial proportion of adolescent psychiatric inpatients in the USA and the UK can be diagnosed with the disorder using adult criteria. This resembles the adult diagnosis in that there is a strong association with episodic disorders, particularly depression, and its stability is low. In adolescents, the borderline personality disorder diagnosis picks out a group who, compared with other adolescent psychiatric patients, have experienced high levels of maternal neglect and rejection, grossly inappropriate parental behaviour and a number of parental surrogates, sexual abuse (Ludolph *et al.* 1990) and higher levels of angry, irritable interactions in the family (James *et al.* 1996). Associations of inconsistent and intrusive parenting with the emergence of borderline personal-

ity disorder were found in the longitudinal study of a general population sample (Bezirgianian *et al.* 1993) referred to earlier.

This study also yielded valuable findings on the relationship between episodic (Axis I) disorders and personality disorder in adolescence. Subjects with either an Axis I disorder or a personality disorder in adolescence were at increased risk for a personality disorder in adult life, but those with both were at greatly increased risk. There was evidence that the total number of episodic and personality disorders in adolescence reflected overall severity, in that the higher subjects scored on a scale of total disorders, the greater the likelihood of young adult disorder. There was some evidence that this applied particularly to the Cluster B (dramatic) disorders; however, all types were affected. These findings highlight the gains and the perils of the use of personality disorder concept in adolescence. The personality disorder assignment clearly identified dysfunction that was not reflected in the episodic disorder diagnoses. At the same time very little specificity was provided. It is possible that the episodic disorders, such as depression, contributed to social dysfunction that persisted beyond the episodes and hence increased the risk of adult personality disorder. Equally, depression may have reflected preceding family and peer difficulties, which in turn were predictive of the adult personality disorders.

Clinical implications

Clinical implications in many respects follow from these points. Children and adolescents with difficulties severe enough to merit referral frequently have multiple difficulties that go beyond the disorders currently diagnosed in childhood and early adolescence. Many of these are highly relevant to the origins, maintenance and therapeutic needs of the children's difficulties. Equally, there is a dynamic interplay between them, which blurs the edges of 'disorder'. Thus, it is important to gather information on peer and family relationships in relation to conduct problems, and yet both are likely to be consequences of the child's behaviours, and also contributors to them. In other words, the same behaviours or qualities could be seen as symptom or process, and as cause or consequence. The clinical task is to consider these various possibilities in the individual case, in order to identify areas for intervention. Similar considerations can be applied to outcome research in this area. Effectiveness must be judged not only in relation to symptomatic change, but also by whether the associated social and educational difficulties have improved.

There have not been any published studies of treatment effectiveness for personality disorders or personality dysfunction in adolescence. Studies of adult populations in relation to borderline personality disorder and chronic self-harm may provide some pointers. Perry *et al.* (1999) reviewed the results of 15 studies, and Bateman & Fonagy (2000) reviewed 25 reports of a range of psychotherapeutic approaches in adult personality disorders. Both reviews concluded that there was evidence for short- to medium-term effectiveness in a number of indices of disorder including depression and interpersonal problems, as

well as personality disorder diagnosis. However, there have been very few randomized controlled studies. Linehan *et al.* (1991) carried out a randomized controlled study of outpatient dialectical behaviour therapy, a structured approach combining techniques at the level of behaviour, cognition and support. Over the year of treatment, controls were more likely to make suicide attempts and spent longer as inpatients, although these differences were not evident at 1-year follow-up (Linehan *et al.* 1993). In a recent randomized controlled trial of psychoanalytically orientated therapy, partial hospitalization for borderline personality disorder, the treated group had a lower frequency of self-harm, suicide attempts, hospital admissions, use of medication and depression, and better social adjustment over an 18-month treatment period (Bateman & Fonagy 1999). Generally, studies of effectiveness of treatment of personality disorders have used outcomes, such as service utilization or depression levels, as proxies for measures of changes in personality functioning. Tackling the difficulties associated with the current conceptualization and measurement of personality disorder should lead to improved treatment and more refined measurement of outcomes.

Bateman & Fonagy (2000) have summarized the principal features of treatments for which there is some evidence of effectiveness. The approach is active and structured with a clear focus, in the context of a strong relationship between therapist and patient over a substantial period of time. The treatment is well integrated with other services available to the patient. Effective treatments for adolescents who have extensive dysfunction, paralleling that of the adult personality disorders, may well require an approach with these features, coupled with active involvement of the family and attention to educational or vocational needs.

Introduction

This chapter provides an overview of seven aspects of our knowledge about gender identity disorder (GID) in children and adolescents:

- 1 phenomenology;
- 2 epidemiology;
- 3 diagnosis and assessment;
- 4 associated psychopathology;
- 5 aetiology;
- 6 long-term follow-up; and
- 7 treatment.

Terminology

Six terms that will be used throughout are briefly described. These are:

- 1 sex;
- 2 gender;
- 3 gender identity;
- 4 gender role (masculinity–femininity);
- 5 sexual orientation; and
- 6 sexual identity.

Sex

Sex refers to attributes that collectively, and usually harmoniously, characterize biological maleness and femaleness. In humans, the most well-known attributes that constitute biological sex include the sex-determining genes, the sex chromosomes, the H-Y antigen, the gonads, sex hormones, the internal reproductive structures, and the external genitalia (Migeon & Wisniewski 1998). Over the past couple of decades, there has also been great interest in the possibility that the human brain has certain sex-dimorphic neuroanatomical structures which, perhaps, emerge during the process of prenatal physical sex differentiation (for recent developments in understanding aspects of biological sex, see Haqq & Donahoe 1998; Vilain & McCabe 1998).

Gender

Gender is often used to refer to psychological or behavioural characteristics associated with males and females (Ruble &

Martin 1998). The use of gender as a technical term is a recent phenomenon. As late as the mid-1950s, it was not even part of the professional literature that purported to study psychological similarities and differences between males and females. In fact, the first term introduced to the literature was that of *gender role*, not gender (Money 1955).

Over the past 40 years, three major developments have occurred with regard to the usage of the terms ‘sex’ and ‘gender’. First, there has been a tendency to conflate the use of the two terms, so that it is not always clear if one is referring to biological or psychological characteristics that distinguish males from females (Gentile 1993). Secondly, the use of the terms ‘sex’ and ‘gender’ has been related to assumptions about causality, in that the former is used to refer exclusively to biological processes and the latter is used to refer exclusively to psychological or sociological processes (for critiques of this division, see Money 1985; Maccoby 1988). As a result, some researchers who study humans employ such terms as *sex-typical*, *sex-dimorphic*, and *sex-typed* to characterize sex differences in behaviour, because terms of this kind are descriptively more neutral with regard to putative aetiology. The third development, as noted by Zucker & Bradley (1995), is that Money’s original use of the term ‘gender role’ has been decomposed into three conceptually distinct component parts that are identified by the terms ‘gender identity’, ‘gender role’ and ‘sexual orientation’.

Gender identity

Gender identity was introduced into the professional lexicon by Hooker and by Stoller in the early 1960s (Money 1985). Stoller (1964, p. 453) used the slightly different term *core gender identity* to describe a young child’s developing ‘fundamental sense of belonging to one sex’. This term was later adopted by cognitive-developmental psychologists, such as Kohlberg (1966), who defined gender identity as the child’s ability to discriminate accurately males from females and then to identify his or her own gender status correctly — a task considered by some to be the first ‘stage’ in ‘gender constancy’ development, the end state of which is the knowledge of gender invariance (Kohlberg 1966; Eaton & Von Bargen 1981).

Gender role

Gender role has been used extensively by developmental psychologists to refer to behaviours, attitudes and personality traits

that a society, in a given culture and historical period, designates as masculine or feminine, i.e. those more 'appropriate' to, or typical of, the male or female social role (Ruble & Martin 1998). It should be remembered that defining gender roles in this way assumes that they are completely arbitrary and social in origin, a view not universally shared by researchers in the field. In any case, from a descriptive point of view, the measurement of gender role behaviour in young children includes several easily observable phenomena, including affiliative preference for same-sex vs. opposite-sex peers, roles in fantasy play, toy interests, dress-up play, and interest in rough-and-tumble play. In older children, gender role has also been measured using personality attributes with stereotypic masculine or feminine connotations (Ruble & Martin 1998).

Sexual orientation

Sexual orientation is defined by a person's relative responsiveness to sexual stimuli. The most salient dimension of sexual orientation is probably the sex of the person to whom one is attracted sexually. This stimulus class is obviously how one defines a person's sexual orientation, or erotic partner preference, as heterosexual, bisexual or homosexual. In contemporary sexuality, sexual orientation is often assessed by psychophysiological techniques, such as penile plethysmography or vaginal photoplethysmography (Rosen & Beck 1988), although structured interview assessments have become increasingly common, particularly when respondents do not have a compelling reason to conceal their sexual orientation.

Sexual identity

It is important to uncouple the construct of sexual orientation from the construct of *sexual identity*. A person may, for example, be predominantly aroused by homosexual stimuli, yet not regard himself or herself as 'a homosexual', for whatever reason. Sociologists, particularly those of the 'social scripting' and 'social constructionist' schools, have articulated this notion most forcefully, arguing that the incorporation of sexual orientation into one's sense of identity is a relatively recent phenomenon, culturally variable, and the result of a complex interplay of sociohistorical events (Gagnon 1990; Weeks 1991). Anthropologists, such as Herdt (1981), who have described ritualized age-structured homosexual behaviour in non-Western cultures, note that such behaviour is not at all tied to a homosexual sexual identity, but rather is a rite of passage to mature adult heterosexuality.

In contemporary Western culture, there are many individuals who are primarily or exclusively sexually responsive to same-sex persons, yet do not adopt a homosexual or 'gay' identity (Ross 1983). Moreover, there are also individuals who engage in extensive homosexual behaviour, yet who are not predominantly aroused by homosexual stimuli or do not consider themselves to 'be' homosexual, such as among male adolescents who have

sex with men for money. Thus, one must pay attention to the empirical evidence regarding disjunctions between sexual orientation and sexual identity (for a detailed analysis see Laumann *et al.* 1994).

Phenomenology

Boys and girls diagnosed with GID as described in the fourth edition of the Diagnostic and Statistical Manual (DSM-IV) (American Psychiatric Association 2000), or in ICD-10 (World Health Organization 1992), display an array of sex-typed behaviour signalling a strong psychological identification with the opposite sex. These behaviours include:

- 1 identity statements;
- 2 dress-up play;
- 3 toy play;
- 4 roles in fantasy play;
- 5 peer relations;
- 6 motoric and speech characteristics;
- 7 statements about sexual anatomy; and
- 8 involvement in rough-and-tumble play.

In general, there is a strong preference for sex-typed behaviours more characteristic of the opposite sex and a rejection or avoidance of sex-typed behaviours more characteristic of one's own sex. There are also signs of distress and discomfort about one's status as a boy or a girl, including verbal expressions of dislike or disgust about one's genital anatomy. The behaviours that characterize GID in children occur in concert, not in isolation. It is this behavioural patterning that is of clinical significance, and recognition of the patterning is extremely important in conducting a diagnostic assessment.

The onset of most of the behaviours occurs during the preschool years (2–4 years), if not earlier. Clinical referral often occurs when parents begin to feel that the pattern of behaviour is no longer a 'phase', a common initial parental appraisal, that their child will 'grow out of' (Stoller 1967; Zucker 2000a). From a developmental perspective, the onset occurs during the same period that more typical sex-dimorphic behaviours can be observed in young children (Ruble & Martin 1998). For a more detailed account of phenomenology, see Green (1974) and Zucker & Bradley (1995).

Epidemiology

Prevalence

The prevalence of GID in children has not been formally studied by epidemiological methods. Nevertheless, Meyer-Bahlburg's (1985) characterization of GID as a 'rare phenomenon' is not unreasonable. Prevalence estimates of GID in adults suggest an occurrence of 1 in 24 000–37 000 men and 1 in 103 000–150 000 women (Meyer-Bahlburg 1985). Subsequently, Bakker

et al. (1993) inferred the prevalence of adult GID in the Netherlands from the number of persons receiving 'cross-gender' hormonal treatment at the main adult gender identity clinic in that country: 1 in 11 000 men and 1 in 30 400 women.

However, this approach suffers from at least three limitations. First, it relies on the number of persons who attend specialty clinics serving as gateways for surgical and hormonal sex reassignment, which may not see all gender-dysphoric adults. Secondly, unlike adult females with gender dysphoria, who are almost always attracted sexually to biological females, adult males with GID are about equally likely to be attracted sexually to biological males or females (Blanchard *et al.* 1987). A childhood history of GID, or its subclinical manifestation, occurs largely among gender-dysphoric adults with a homosexual sexual orientation. Estimates of the prevalence of GID in childhood inferred from the prevalence of GID in adult males should take this into account. Thirdly, the assumption that GID in children will persist into adulthood is not necessarily true (see below). It is likely therefore that the prevalence of GID is higher in children than it is in adults.

Another approach to the estimate of prevalence can borrow from normative studies of children in whom specific cross-gender behaviours were assessed (Zucker 1985, pp. 87–95). One source of information comes from the widely used Child Behavior Checklist (CBCL; Achenbach & Edelbrock 1983), a parent-report behaviour problem questionnaire with excellent psychometric properties. It includes two items (out of 118) that pertain to cross-gender identification: 'behaves like opposite sex' and 'wishes to be of opposite sex'. On the CBCL, ratings are made on a 3-point scale (0, not true; 1, somewhat or sometimes true; and 2, very true or often true). In the standardization study, endorsement of both items was more common for girls than for boys, regardless of age and clinical status (referred vs. non-referred).

As reported by Zucker *et al.* (1997a), among non-referred boys (ages 4–11 years), 3.8% received a rating of 1 and 1.0% a rating of 2 for the item 'behaves like opposite sex', but only 1.0% received a rating of 1 and 0.0% a rating of 2 for the item 'wishes to be of opposite sex.' The comparable percentages among non-referred girls was 8.3, 2.3, 2.5 and 1.0%, respectively. These findings suggest that there is a sex difference in the occurrence of mild displays of cross-gender behaviour, but not with regard to more extreme cross-gender behaviour. Similar results were obtained from the Achenbach, Connors, and Quay Behaviour Checklist (ACQ; Achenbach *et al.* 1991), which contains three items pertaining to cross-gender identification out of a total of 215 (two from the original CBCL and a third, 'Dresses like or plays at being opposite sex'; for details see Zucker *et al.* 1997a).

The main problem with such data is that they do not adequately identify patterns of cross-gender behaviour that would be of use in determining 'caseness.' Thus, such data may be best

viewed as screening devices for more intensive evaluation (Pleak *et al.* 1989; Sandberg *et al.* 1993).

Incidence

Lothstein (1983) speculated, on clinical grounds, that parents who had been influenced by the cultural *Zeitgeist* to use 'non-sexist' socialization techniques may have inadvertently induced gender identity conflict in their children. However, there are no systematic data regarding changes, or the lack thereof, in the incidence of GID over the past several decades.

Sex differences in referral rates

Consistently, it has been observed that boys are referred more often than girls for concerns regarding gender identity. This has been reflected in both research and clinical reports of treatment. In our own clinic, Zucker *et al.* (1997a) reported a referral ratio of 6.6:1 ($n=275$) of boys to girls.

How might this disparity be best understood? One possibility is that the sex difference in referral rates reflects a true sex difference in prevalence. Another possibility is that social factors have a role in accounting for the disparity. For example, it is well established that parents, teachers and peers are less tolerant of cross-gender behaviour in boys than in girls (Fagot 1985), which might result in a sex-differential in clinical referral (for review see Zucker & Bradley 1995). Weisz & Weiss (1991) devised a 'referability index' (RI) which reflected the frequency with which a child problem, adjusted for its prevalence in the general population, resulted in a clinic referral. All 118 items from the CBCL were analysed in a comparison of clinic-referred and non-referred children. Among parents in the USA, the 20 most referable problems (e.g. vandalism, poor schoolwork, attacks people) appeared to be relatively serious. In contrast, the 20 least referable problems (e.g. bragging, teases a lot, likes to be alone) appeared less so. Weiss (personal communication, March 4, 1992) indicated that, for boys, the CBCL item 'wishes to be of opposite sex' had an RI of 91/118 (in the upper quartile) and 'behaves like opposite sex' had an RI of 80/118. For girls, the RI was lower: 55/118 for 'wishes to be of opposite sex' and 14/118 for 'behaves like opposite sex'. Weisz & Weiss' (1991) study, together with studies from the normative literature, led us to predict that referred girls would display more extreme cross-gender behaviour than referred boys, which might account, at least in part, for the disparity by sex in referral rates. Zucker *et al.* (1997a) provided some data that supported this prediction, suggesting therefore that girls may need to display more cross-gender behaviour than boys before a referral is initiated. However, it is important to note that the sexes did not differ in the percentage who met the complete DSM criteria for GID; thus, there was no gross evidence for a sex difference in false-positive referrals.

Diagnosis and assessment

Diagnosis

DSM-IV diagnosis of gender identity disorder

In DSM-IV, there were some changes in the conceptualization of GID and in the diagnostic criteria; for example, there was a reduction of diagnostic categories from three to one between DSM-III-R (American Psychiatric Association 1987) and DSM-IV. The DSM-IV Subcommittee on Gender Identity Disorders (Bradley *et al.* 1991) took the position that the DSM-III-R diagnoses of gender identity disorder of childhood, transsexualism, and gender identity disorder of adolescence or adulthood, non-transsexual type were not qualitatively distinct disorders, but reflected differences in both developmental and severity parameters. As a result, the DSM-IV Subcommittee recommended one overarching diagnosis, gender identity disorder, that could be used, with appropriate variations in criteria, across the life cycle.

In DSM-IV, three criteria are required for the diagnosis, with one exclusion criterion. The first criterion (A) reflects the child's cross-gender identification, indexed by five behavioural characteristics, of which at least four must be present. The second criterion (B) reflects the child's rejection of his or her anatomic status and/or rejection of same-sex stereotypical activities and behaviours. The third criterion (D) specifies that the 'disturbance . . . causes clinically significant distress or impairment in social, occupational, or other important areas of functioning' (American Psychiatric Association 2000, p. 581). The exclusion criterion (C) pertains to the presence of a physical intersex condition (for discussion on this point see Meyer-Bahlburg 1994).

Reliability and validity

Can the DSM-IV diagnosis of GID be made reliably? Because the criteria have changed and because no field trials were conducted, this question cannot yet be answered; however, previous versions of the criteria have shown strong evidence for both reliability and validity (Zucker & Bradley 1995).

Distress and impairment

As noted by Zucker (1992), the DSM-III-R did not provide guidelines regarding the assessment of distress in the A criterion ('persistent and intense distress' about being a boy or a girl) or the ways in which it might be distinct from other operationalized components in the criteria (the 'desire' to be of the other sex). In the DSM-IV, this problem persists, except that it is now located in D, and there is the additional problem of defining impairment.

The inclusion of a distress/impairment criterion ('a clinical significance criterion'; American Psychiatric Association 2000, p. 8) is not unique to GID; in fact, this criterion now appears in most of the DSM-IV diagnoses. Very little empirical work pre-

ceded the introduction of the criterion (Spitzer & Wakefield 1999). Indeed, the DSM-IV states that assessment of distress and impairment 'is an inherently difficult clinical judgement' (American Psychiatric Association 2000, p. 8).

For children with GID, we need to ask two interrelated questions: are they distressed by their condition, and, if so, what is the source of the distress? Regarding these questions, there are two broad views. One view is that children with GID become distressed about their cross-gender behaviour only after it has been interfered with (Stoller 1975). Stoller argued that marked cross-gender identification (in boys) was ego-syntonic because the putative familial psychodynamics that produced it were systemically syntonic. The other view is that the distress is caused by psychopathology in the child and in the family. Coates & Person (1985) claimed that GID is a 'solution' to specific forms of psychopathology in the child, particularly separation anxiety and 'annihilation' anxiety, which were induced by familial psychopathology.

It is conceivable that both views are correct or that one or the other better fits individual cases. However, the latter view is more compatible with the notion of inherent distress, whereas the former is more compatible with the notion that social pathology creates individual pathology. Clinical experience suggests that many youngsters with GID feel a sense of discomfort regarding their status as boys or girls from a very early age, which matches nicely with the DSM notion of distress. Nevertheless, there are youngsters in whom the behavioural characteristics of GID appear to be ego-syntonic and who experience distress only when their cross-gender behaviour is interfered with. The exact manner in which we should measure the putative distress of children with GID has not been worked out (Zucker 1999a); this holds true not only for GID but also for all of the other childhood psychiatric conditions that include the distress/impairment criterion.

Regarding impairment, there are several domains that this might be manifest in children with GID. Such children seem to have more trouble than others with basic cognitive concepts concerning their gender. Zucker *et al.* (1993b) found that children with GID were more likely than controls to misclassify their own gender. Zucker *et al.* (1999b) provided additional evidence that children with GID appeared to have a 'developmental lag' in the acquisition of gender constancy. Given the ubiquity of gender as a social category, this may well lead to affective confusion in self-representation and in social interactions. There is also evidence that children with GID have poorer peer relations than controls and more general behavioural problems, possible indices of impairment (Zucker & Bradley 1995; Zucker *et al.* 1997a).

Assessment

Biomedical tests

There are no known biological markers that can identify children with GID. Gross parameters of biological sex, such as the

sex chromosomes and the appearance of the external genitalia, are invariably normal. Because gender identity conflict is overrepresented among specific physical intersex conditions, particularly congenital adrenal hyperplasia (CAH) in genetic females, partial androgen-insensitivity syndrome in genetic males reared as girls, and in genetic males with cloacal exstrophy reared as girls (for review see Meyer-Bahlburg 1994; Zucker 1999b), it is important to enquire about any physical signs of these conditions; however, it is rare that these conditions have not already been diagnosed prior to a clinical assessment for GID.

Psychological tests

A number of parent-report and behavioural measures can be used to assess sex-typed behaviour in children with GID (Zucker 1992; Zucker & Bradley 1995). No one test is a replacement for a diagnosis that is established by a clinical interview that covers the behavioural signs for GID. Nevertheless, these measures have strong discriminant validity and constitute one strong line of evidence that GID is, in fact, a distinct syndrome. As reviewed elsewhere, data from psychological tests show a consistent pattern in that the percentage of false-positives appears to be lower than the percentage of false-negatives (Zucker 1992; Zucker & Bradley 1995).

One useful clinical instrument is the Gender Identity Interview for Children, shown in Table 44.1. Based on factor analysis, Zucker *et al.* (1993b) identified two factors: Affective Gender Confusion (questions 6–12) and Cognitive Gender Confusion (questions 1–4). Cut-off scores of either three or four deviant responses yielded high specificity rates (88.8 and 93.9%, respectively), but lower sensitivity rates (54.1 and 65.8%, respectively).

Associated psychopathology

Comorbidity (the presence of two or more psychiatric disorders) occurs frequently among children referred for psychiatric evaluation. Assuming that the putative comorbid conditions actually represent distinct disorders, it is important to know, for various reasons (e.g. prevention and treatment planning), whether one condition increases the risk for the other condition or if the conditions are caused by distinct or overlapping factors (Caron & Rutter 1991).

Among children with GID, several measurement approaches have been employed to address this matter, including standardized behaviour problem questionnaires, ratings of social behaviour in structured situations and on questionnaires, assessment of personality functioning and structure on projective tests, assessment of quality of attachment with the mother, and ascertainment of other psychiatric disorders. Most of this work has focused on boys with GID, for which a detailed summary may be found elsewhere (Zucker & Bradley 1995).

The greatest amount of information on general behaviour

Table 44.1 Gender identity interview for children (boy version). (From Zucker *et al.* (1993b))

1	Are you a boy or a girl? BOY/GIRL
2	Are you a (opposite of first response)?
3	When you grow up, will you be a Mommy or a Daddy? MOMMY/DADDY
4	Could you ever grow up to be a (opposite of first response)? YES/NO
5	Are there any good things about being a boy? YES/NO If YES, say: Tell me some of the good things about being a boy (probe for a maximum of three responses)
6	Are there any things that you don't like about being a boy? YES/NO If YES, say: Tell me some of the things that you don't like about being a boy (probe for a maximum of three responses)
7	Do you think it is better to be a boy or a girl? YES/NO Why? (probe for a maximum of three responses)
8	In your mind, do you ever think that you would like to be a girl? YES/NO If YES, ask: Can you tell me why? (probe for a maximum of three responses)
9	In your mind, do you ever get mixed up and you're not sure if you are a boy or a girl? YES/NO If YES, say: Tell me more about that (probe until satisfied)
10	Do you ever feel more like a girl than like a boy? YES/NO If YES, say: Tell me more about that (probe until satisfied)
11	You know what dreams are, right? Well, when you dream at night, are you ever in the dream? If YES, ask: In your dreams, are you a boy, a girl, or sometimes a boy and sometimes a girl? BOY/GIRL/BOTH/NOT IN DREAMS (probe regarding content of dreams)
12	Do you ever think that you really are a girl? YES/NO If YES, say: Tell me more about that (probe until satisfied)

problems comes from parent-report data using the CBCL and the Teacher's Report Form (Achenbach & Edelbrock 1986). On these measures, clinic-referred boys and girls with GID show significantly more general behaviour problems than their siblings and non-referred ('normal') children. Given that the siblings and non-referred children do not engage, on average, in marked cross-gender role behaviour, this might be construed as evidence for a relation between cross-gender role behaviour and general behaviour problems. The situation is clearly more complicated than this because demographically matched clinical controls (who, on average, show typical gender role behaviour) show comparable levels of behaviour problems to the children with GID (Zucker & Bradley 1995).

On the CBCL, boys with GID have a predominance of emotional difficulties, whereas girls with GID do not (Zucker & Bradley 1995). Boys with GID have also been found to show high rates of separation anxiety traits (Coates & Person 1985; Zucker *et al.* 1996a; Birkenfeld-Adams 1999). At present, reasons for this associated psychopathology have been best studied

in boys with GID (Zucker & Bradley 1995). CBCL behaviour problems are positively associated with age, which may reflect the result of increasing social ostracism, particularly in the peer group. It is also associated with a composite index of maternal psychopathology, which may reflect generic, non-specific familial risk factors in producing behaviour problems in general. The predominance of emotional psychopathology may reflect familial risk for affective disorders and temperamental features of the boys. The extent to which aspects of the behavioural psychopathology may actually induce the emergence of the GID itself remains unresolved (see below).

Aetiological influences

Both biological and psychosocial factors have been proposed to account for the development of GID in children. In this section, I review some of the factors identified in the literature believed to be associated with an increased ‘risk’ for the development of GID.

Biological factors

Children with GID invariably do not show signs of a gross physical intersex condition, which would rule out a marked prenatal hormonal anomaly. Thus, the search for biological influences on the development of GID must focus on factors that are, perhaps, more subtle or at least on factors that do not affect the configuration of the external genitalia. In this regard, research strategies parallel those that have been used in the study of sexual orientation differentiation because, again, there is no evidence for the presence of gross hormonal abnormalities that would implicate the presence of a physical intersex condition (Meyer-Bahlburg 1984).

Activity level and rough-and-tumble play

Activity level (AL) is a commonly accepted dimension of temperament, with some evidence for a genetic basis (Willerman 1973; Saudino & Eaton 1991) and possibly prenatal hormonal influences (Ehrhardt & Baker 1974). Regarding children with GID, AL as a risk factor is a promising possibility, because it shows a rather strong sex difference, with boys having a higher AL than girls (Eaton & Enns 1986; Campbell & Eaton 1999). Rough-and-tumble (RT) play, another sex-dimorphic behaviour, bears some similarity to AL, in that it is often characterized by high energy expenditure; however, a distinguishing feature of RT is that it is a social interactive behaviour involving such sequences as ‘play fighting’ and ‘chasing’. Using parent-report measures of AL, two studies found that boys with GID had a lower AL than control boys (Bates *et al.* 1979; Zucker & Bradley 1995). Zucker & Bradley (1995) also found that girls with GID had a higher AL than control girls; indeed, the girls with GID had a higher AL than the boys with GID, whereas for the controls the typical sex difference was observed. It is possible there-

fore that a sex-atypical AL is a risk factor that predisposes to the development of GID. For example, a low-active boy with GID may find the typical play behaviour of other boys to be incompatible with his own behavioural style (Ruble & Martin 1998), which might make it difficult for him to integrate successfully into a male peer group.

Perhaps these within-sex variations in AL are related to subtle variations in patterns of prenatal hormonal secretion and converge with recent studies in the experimental animal literature. Among female rhesus monkey offspring, it has been possible, by varying the timing of exogenous administration of hormones during the pregnancy, to alter the normal patterning of sex-dimorphic behaviour but to keep normal genital differentiation intact (Goy *et al.* 1988). This animal model—which shows a *dissociation* between sex-dimorphic behavioural differentiation and genital differentiation—has the most direct relevance for explaining the marked cross-gender behaviour of children with GID.

Birth weight

On average, males weigh more than females at the time of birth (Arbuckle *et al.* 1993). There are, of course, many factors that influence variations in birth weight. One hypothesized factor is the sex difference in prenatal exposure to androgens. In one study, girls with CAH had a higher mean birth weight than unaffected girls (Qazi & Thompson 1971). In another study, genetic males with the complete form of the androgen insensitivity syndrome were comparable in birth weight to that of genetic females (de Zegher *et al.* 1998).

Zucker *et al.* (1999a) compared the birth weights of boys with GID and clinical control boys and girls. The clinical controls showed the expected sex difference in birth weight, with an effect size of 0.29 (Cohen’s *d*). The boys with GID had a significantly lower birth weight than the clinical control boys ($d=0.18$), but did not differ significantly from the clinical control girls. Although it is not clear what factor or set of factors account for the proband-control difference in birth weight, the results are consistent with the possible role of prenatal hypoandrogenization among the GID probands.

Handedness

Slightly more males than females show a preference for using the left hand in unimanual behavioural tasks, such as writing. There is no established consensus for understanding the basis of this sex difference but genetic factors clearly have a role in determining hand preference. Another line of research implicates adverse prenatal and/or perinatal events that result in an elevation in left-handedness above the approximate gold standard of 10% in the general population.

Zucker *et al.* (2001) found that boys with GID ($n=205$) had a significantly elevated rate of left-handedness (19.5%) when compared to three separate quasi-epidemiological samples of boys (11.8%, total $n=14\,253$) and with a diagnostically hetero-

generous sample of clinical control boys (8.3%, $n=205$). This finding parallels studies of adult males with GID, who also appear to have an elevated rate of left-handedness (Herman-Jeglinska *et al.* 1997), as well as studies of adult men with a homosexual sexual orientation (Lalumière *et al.* 2000). At present, the explanation for the elevation remains unclear, but candidate factors have centred on some type of perturbation in prenatal development that, in some way, affects sex-dimorphic behavioural differentiation.

Sibling sex ratio and birth order

Boys with GID have an excess of brothers:sisters (sibling sex ratio) and have a later birth order (Blanchard *et al.* 1995; Zucker *et al.* 1997b). Some additional evidence shows that boys with GID are born later, primarily in relation to the number of older brothers but not sisters. In the Blanchard *et al.* study, clinical control boys showed no evidence for an altered sibling sex ratio or a late birth order. One biological explanation to account for these results pertains to maternal immune reactions during pregnancy. The male fetus is experienced by the mother as more 'foreign' (antigenic) than the female fetus. Based on studies with lower animals, it has been suggested that one consequence of this is that the mother produces antibodies that have the effect of demasculinizing or feminizing the male fetus, but no corresponding masculinizing or defeminizing of the female fetus (Blanchard & Klassen 1997). This model would predict that males born later in a sib-line might be more affected, because the mother's antigenicity increases with each successive male pregnancy, which is consistent with the empirical evidence on sibling sex ratio and birth order among GID probands. At present, however, this proposed mechanism has not been formally tested in humans.

Summary

In summary, research over the past decade has begun to identify some characteristics of children with GID, particularly in boys, that may well have a biological basis. Corresponding studies of girls have been fewer in number, largely because of problems in sample size that limit statistical power. In many respects, it has been easier to rule out candidate biological explanations, such as the influence of gross anomalies in prenatal hormonal exposure, than it has been to identify the relevant biological mechanisms that are involved in affecting sex-dimorphic behavioural differentiation but not sex-dimorphic genital differentiation. However, the identification of new potential biological markers may open up avenues for further empirical inquiry.

Psychosocial factors

Psychosocial factors, to truly merit causal status, must be shown to influence the emergence of marked cross-gender behaviour in the first few years of life. Otherwise, such factors would be better conceptualized as perpetuating rather than predisposing.

Sex assignment at birth

Because most children with GID do not have a co-occurring physical intersex condition, sex assignment at birth is invariably in accordance with the external markers of biological sex. In some physical intersex conditions, sex assignment is delayed and, on occasion, changed from the initial sex assignment. It has been argued that prolonged delay or uncertainty about the child's 'true' sex can contribute to gender identity conflict in affected individuals (Money *et al.* 1957; Meyer-Bahlburg *et al.* 1996). This does not, however, appear to be the situation for children with GID.

Parents' sexual orientation

There is little evidence to suggest that the sexual orientation of parents is related to GID in children. Studies of lesbian mothers and gay fathers have not, to date, indicated an overrepresentation of GID among their offspring. In fact, the children of gay and lesbian parents appear to have fairly typical gender identity and gender role development when compared to the children of heterosexual parents (Golombok *et al.* 1983; Green *et al.* 1986; Tasker & Golombok 1997). In our own clinic, we have not detected any convincing evidence for an elevation in the rate of a homosexual sexual orientation among the parents of both children and adolescents with GID.

Prenatal gender preference

It is common for parents to express a prenatal gender preference. Other things being equal, parents will have a child of the non-preferred sex about 50% of the time. Are parents of children with GID more likely than control parents to report having had a desire for a child of the opposite sex? The simple answer appears to be no, at least with regard to the mothers of boys with GID (Zucker *et al.* 1994). We did find, however, that the maternal wish for a girl was significantly associated with the sex composition and birth order of the sibship. Among the GID boys with only older brothers, the percentage of mothers who recalled a desire for a daughter was significantly higher than among the probands with other sibship combinations; however, the same pattern was observed in a control group (Zucker *et al.* 1994).

Social reinforcement of cross-gender behaviour

Understanding the role of parent socialization in the genesis and/or perpetuation of GID (e.g. via reinforcement principles or modelling) has been influenced by the normative developmental literature on sex-dimorphic sex-typed behaviour (Ruble & Martin 1998). It has also been influenced by the seminal observations of Money *et al.* (1957) that the rearing environment was the predominant determinant of gender identity in children with physical intersex conditions.

It should be recognized that some critics are quite sceptical of

the role of parent socialization in inducing sex differences in sex-typed behaviour among ordinary children (Lytton & Romney 1991) or within-sex variations. In recent years, the importance of the rearing environment has also been questioned within the literature on physical intersex conditions (for review see Zucker 1999b). This literature has recently been discussed in relation to the long-term gender identity outcome of a normal boy whose penis was accidentally ablated during a routine circumcision at 7 months, and who was subsequently reassigned as a girl around the age of 2 years. A female gender identity was judged to have differentiated and was maintained to at least age 9 years (Money 1975). Longer term follow-up, however, revealed that the patient reverted to living as a male in early adolescence (Diamond & Sigmundson 1997), which has been interpreted by some to indicate a much stronger role for biological rather than psychosocial influences on gender identity differentiation. However, critics have pointed out that there are alternative interpretations to this case (Meyer-Bahlburg 1999a). Moreover, in another case of ablatio penis, in which a gender reassignment to female occurred at 7 months, the patient's gender identity was judged to be unequivocally female at age 26 (Bradley *et al.* 1998). It is against this backdrop of competing views on the role of socialization that the literature on GID must be appraised.

Clinicians of diverse theoretical persuasions have consistently reported that the parental response to early cross-gender behaviour in children with GID is typically neutral (tolerance) or even encouraging (for review see Zucker & Bradley 1995). Regarding boys with GID, Green (1974) assessed parental recall of such responses taken from clinical and structured interviews at the time of assessment and concluded that 'what comes closest so far to being a *necessary* variable is that, as any feminine behaviour begins to emerge, there is *no* discouragement of that behaviour by the child's principal caretaker' (p. 238, italics in original; see also Green 1987; Roberts *et al.* 1987). In our clinic, Mitchell (1991), in a structured interview study, found that mothers of GID boys were more likely to tolerate/encourage feminine behaviours and less likely to encourage masculine behaviours than were the mothers of both clinical and normal control boys. The following vignette of parents of a 4-year-old boy is illustrative.

Interviewer (I): What is the first memory that you have of Eric's interest in 'girls' things?

Mother (M): Well, when he was about 2, he started to wear my shoes. He would wear them every day.

I: What did you think about that?

M: I thought it was cute, the way he was clumping around in them.

I: What about you (to father)?

Father (F): I wasn't around much, working and all, so I didn't see much of it. She (his wife) told me about it and I said that I didn't like it, but what can you do?

I: What happened after that?

M: Well, then he got interested in my dresses (laughs) and he looked so cute, running around in the heels and my long dress. We even took pictures of him like that.

F: Yeah, right.

I: Anything else?

M: When I took him to the toddler group, he went immediately over to the girls and he got into the Barbie dolls. He seemed obsessed with their hair and we wound up buying him 3 or 4 of them. His favourite one is the Barbie with roller-blades. I asked his doctor about it when he was 3 and the doctor said that it was a phase and that he would grow out of it.

F: Yeah, and then he was pretending that he was a girl all the time and said that he would grow up and be a mommy, and then he said that he wanted to cut off his penis.

I: What happened when he said that?

M: Well, that's why we're here. I'm getting worried that he won't grow out of it...it's getting worse.

I: Before he said that he wanted to cut off his penis, how do you think you have reacted to his interest in the girls' things over the past couple of years?

M: Well, I've pretty well let him do what he wants and, anyways, the doctor told me not to worry. I thought that if he played with the Barbies, maybe he'd be a good father, but he doesn't want to be the father, he's only pretending to be me.

F: Yeah, I'm getting more worried myself, but my wife told me not to be so worried and, well, you know, she's kind of the boss when it comes to raising the kids.

Of course, the limitations of this kind of interview data need to be recognized. None the less, one aspect of these data deserves special comment. Clinicians of diverse theoretical persuasions have observed the apparent tolerance, or even encouragement, of feminine behaviour shown by parents of boys with GID. However, the fact that these parents have sought out a clinical assessment usually means that they are now concerned about their child's gender identity development (Zucker 2000a). From the standpoint of attribution theory (Weiner 1993), one might predict that parents would minimize their encouragement or tolerance of cross-gender behaviour, as it has such an obvious bearing on 'causality'. Yet a majority of the parents whom we have assessed do not recall systematic efforts to limit or redirect their child's cross-gender behaviour, particularly during the initial period of symptom onset and for various periods of time thereafter.

The reasons why parents might tolerate, if not encourage, early cross-gender behaviours appear to be quite diverse, suggesting that the antecedents to this 'end state' are multiple in origin. Some parents report being influenced by ideas regarding non-sexist child-rearing. In other parents, the antecedents seem to be rooted in pervasive conflict that revolves around gender issues. For example, a small subgroup of mothers (about 10%) of boys with GID appear to experience something akin to what we have termed *pathological gender mourning* (Zucker 1996). During the pregnancy, there is a strong desire for a girl; in all of the cases, the mother had already borne at least one other son, but no daughter—except in three instances in which the daughter was given up for adoption (one case) or had died in infancy (two cases). After the birth of the 'non-preferred' son, this wish seems to colour strongly the mother's perception and relation-

ship with her newborn, and there are strong signs of ambivalence about his gender status. Zucker (1996) identified at least 10 possible signs of pathological gender mourning, including severe post-partum depression related to the birth of a son, recurrent nightmares about being pregnant with a girl, delayed naming, and active cross-dressing of the boy (for further details see Zucker *et al.* 1993a; Zucker & Bradley 1995, 2000). In our clinical experience, the most common psychological trait associated with the strong wish for a daughter is the need to nurture and be nurtured by a female child, which often reflects compensatory needs originating in childhood (Gibson 1998).

Maternal emotional functioning

The role of maternal psychopathology in the genesis and perpetuation of GID has received a great deal of clinical and theoretical attention but, unfortunately, only limited empirical evaluation. At the outset, it should be noted that the available empirical studies have been delimited to the mothers of boys with GID—comparable studies are not available regarding the mothers of girls with GID (for descriptive data see Zucker & Bradley 1995, pp. 252–253).

Marantz & Coates (1991) found that the mothers of boys with GID showed more signs of psychopathology than did the mothers of demographically matched normal boys, including more pathological ratings on the Diagnostic Interview for Borderlines and more symptoms of depression on the Beck Depression Inventory.

Over the past several years, our group has collected systematic data on maternal psychopathology and marital discord, some of which was reported by Mitchell (1991) and Zucker & Bradley (1995). To date, our data show that, on average, mothers of boys with GID have levels of emotional distress and psychiatric impairment comparable to that of clinical control mothers, but higher than that of normal control mothers. We did not, however, detect between-group differences on a measure of marital discord.

On one measure—the Symptom Checklist 90–Revised—mothers of GID boys had higher scores on most of the subscales and the composites than did the mothers of the normal control boys, whereas the scores of the clinical control mothers fell in between the two other groups. The GID mothers had peak scores on the Obsessive-Compulsive, Depression, and Hostility subscales. On another measure, the Diagnostic Interview Schedule (DIS), 30% of the mothers (total $n = 140$) had two DIS diagnoses and 24% had three or more DIS diagnoses. The most common diagnoses were major depressive episode (39.6%) and recurrent major depression (32.1%). Overall, the rate of psychiatric impairment appears to be higher than our available data on mothers of both the clinical control and normal boys. Because more control group mother data are required, these results should be viewed cautiously. None the less, it is apparent by reference to epidemiological data that, on average, mothers of GID boys have a history of psychiatric disorder that is elevated.

The emerging data on emotional distress and psychiatric im-

pairment in the mothers of boys with GID indicate that it is more common than in the mothers of normal control boys and at least comparable to the mothers of clinical control boys. Still, we are left with the problem of specificity (Garber & Hollon 1991), in that these maternal characteristics are not unique to the mothers of GID boys, but common to the mothers of clinic-referred boys in general. Accordingly, maternal emotional distress/impairment functions, at best, only as a non-specific risk factor in the development of GID. If the mother's emotional state truly is involved in the genesis of GID, then there should be evidence of psychiatric impairment prior to and during the emergence of the child's symptoms. The data are suggestive that this is the case, and that the presence of emotional difficulties in the mothers is not simply a reaction to having a child with GID (Zucker & Bradley 1995, p. 123).

Coates has argued that the presence of psychopathology renders the mothers emotionally unavailable, which results in anxiety and insecurity in the son, and that it is this state of affairs that is partly responsible for symptom onset. Indeed, Coates & Person (1985) advanced a very specific hypothesis; that the erratic and uneven emotional availability of the mothers activated separation anxiety in the boys, which, in turn, activated the symptoms of GID: 'In imitating "Mommy" [the boy] confuse[s] "being Mommy" with "having Mommy". [Cross-gender behaviour] appears to allay, in part, the anxiety generated by the loss of the mother' (p. 708). Indeed, boys with GID appear to have high rates of separation anxiety traits, as judged by maternal report on a structured interview schedule (Zucker *et al.* 1996a) and their own responses on the Separation Anxiety Test (Birkenfeld-Adams 1999).

The possible role of separation anxiety in the genesis of GID raises more general questions about the quality of the mother-son relationship. Over the past few years, our group has examined the quality of attachment to the mother among young boys and girls with GID (ages 3–6 years). Among a sample of 22 boys, Birkenfeld-Adams (1999) found that the majority (73%) were classified as insecurely attached, a rate comparable to that of an internal clinical control group and of other studies of clinical populations (Greenberg *et al.* 1991).

Because insecure attachments and separation anxiety are likely to be non-specific risk factors (many boys who have these qualities do not have GID), the crucial question that remains is why only a small minority of boys develop the 'fantasy solution' of wanting to be a girl. Various predisposing factors have been implicated, including temperamental characteristics of the child, the premorbid relationship with the mother, the position of the father in the family system, that the family psychopathology must occur during the putative sensitive period for gender identity formation (Money *et al.* 1957), and so on. However, at present the question of specificity remains unanswered in any satisfactory manner.

One possible mediating variable might be the importance of the child's gender to the mother or her attitudes towards men and masculinity in general. In this regard, pathological gender mourning, as discussed earlier, may be a potential prototype.

Pathological gender mourning appears to be part of the family history in only a small minority of cases and thus other pathways are required to account for the role of maternal impairment in the genesis of GID.

It appears therefore that there are diverse pathways that lead to how parents respond to the child's early cross-gender behaviour, either by encouraging or tolerating it. Thus, from a clinical and therapeutic point of view, it is important to identify the putative motivations with regard to the selective reinforcement of sex-typed behaviours.

Paternal emotional functioning

The role of paternal influences in the genesis and perpetuation of GID has also received a great deal of clinical and theoretical attention but, again, only limited empirical evaluation, which has been delimited to the fathers of boys with GID.

One account implicates the father's role by virtue of his absence from the family matrix. Across 10 samples of boys with GID, the rate of father absence (e.g. because of separation or divorce) was 34.5% (summarized in Zucker & Bradley 1995). It is unlikely, however, that this rate would differ significantly from the rate found in clinical populations in general, if not the general population. Green (1987) found that paternal separations occurred earlier in the families of GID boys than in normal control boys, so it is possible that timing is an additional variable to consider. Green (1987) also found that the fathers of GID boys (both father-present and father-absent) recalled spending less time with their sons than did the fathers of control boys during the second year of life, years 3–5, and at the time of assessment. The inclusion of a clinical control group would be helpful in gauging the specificity of this finding.

Unfortunately, there is little in the way of systematic research on paternal psychopathology. Wolfe (1990) conducted a small but detailed study of 12 fathers, predominantly of an upper middle-class background, of boys with GID. On the Structured Clinical Interview for DSM-III, all of the fathers received an Axis I diagnosis for either a current or past disorder (most frequently substance abuse and depression) and eight also received at least one Axis II diagnosis. Unpublished DIS data from our own clinic on 90 fathers indicate that alcohol abuse (22.2%) has been the most common diagnosis. This percentage may underestimate the prevalence of alcohol abuse in fathers of GID boys, because we were not able to interview a substantial number of fathers who were no longer part of the family matrix. On the other hand, it should be noted that about half the fathers who were interviewed did not meet criteria for any DIS diagnosis. Whatever the exact patterning of paternal emotional functioning proves to be, the same issues of interpretation discussed earlier regarding mothers apply.

Summary

In summary, data on psychosocial influences have been able to rule out some hypothesized pathways and have lent some sup-

port for others. Social reinforcement of cross-gender behaviour when it first appears in the toddler and preschool years appears to be the most common psychosocial influence on the disorder's consolidation. The role of family influences, including parental psychiatric impairment and emotional distress, appears to be an important area for further empirical inquiry.

Long-term follow-up

Green (1987) has conducted the most extensive long-term follow-up of feminine boys, the majority of whom would likely have met DSM criteria for GID. This study can be used as a benchmark for the other published follow-up reports, which have been summarized in detail elsewhere (Zucker 1985, 1990). At the moment, insufficient numbers of girls with GID have been followed prospectively to draw conclusions about long-term outcome. Green's (1987) study contained 66 feminine and 56 control boys assessed initially at a mean age of 7.1 years (range, 4–12). Forty-four feminine boys and 30 control boys were available for follow-up at a mean age of 18.9 years (range, 14–24). The majority of the boys were not in therapy between assessment and follow-up.

Sexual orientation in fantasy and behaviour was assessed by means of a semistructured clinical interview. Kinsey ratings were made on a 7-point continuum, ranging from exclusive heterosexuality to exclusive homosexuality (Kinsey *et al.* 1948). Depending on the measure (fantasy or behaviour), 75–80% of the previously feminine boys were either bisexual or homosexual at follow-up vs. 0–4% of the control boys. Green also reported on the gender identity status of the 44 previously feminine boys. He found that one youngster, at the age of 18 years, was gender-dysphoric to the extent of considering sex-reassignment surgery.

In a more recent study, Cohen-Kettenis (2001) reported a persistence of gender dysphoria into adolescence that appears to be considerably higher than that reported on by Green (1987). Of 129 children referred between 4–12 years, 74 had now reached adolescence. Of these, Cohen-Kettenis reported that 17 (23%) had applied for sex-reassignment. Their mean age at assessment had been at 9 years (range, 6–12), which was a couple of years older than the mean age at assessment in Green's study. About half were reported to be living full-time in the cross-gender role, six were taking puberty-blocking medication and three were taking cross-sex hormones; however, none had of yet gone through any surgical procedure. From the Cohen-Kettenis report, it is not clear if any of these youngsters had had treatment for their GID during childhood.

The prospective data are consistent with retrospective studies of adults with a homosexual sexual orientation, which have repeatedly shown that homosexual men and women recall more cross-gender behaviour in childhood than heterosexual men and women (Bailey & Zucker 1995). Thus, there is now sufficient evidence, from both retrospective and prospective studies, to conclude that childhood sex-typed behaviour is strongly as-

sociated with later sexual orientation, which represents one of the more powerful illustrations of developmental continuity to emerge from research in developmental psychiatry. Recall interviews with both adolescents and adults with GID (with a homosexual sexual orientation) almost invariably document a childhood cross-gender history. The prospective studies of children, however, show that the disorder persists into adolescence or adulthood for only a small minority. Thus, there is a marked disjunction between the prospective and retrospective studies.

How might this disjunction be explained? In some respects, the situation is comparable to that which has been found for other child psychiatric disorders. Adults with antisocial personality disorder invariably will have had a childhood history of oppositional defiant disorder and conduct disorder. Yet, the vast majority of children with oppositional defiant disorder and the majority of children with conduct disorder followed prospectively will not be diagnosed with antisocial personality disorder in adulthood (Zoccolillo *et al.* 1992; Lahey *et al.* 2000).

Regarding children with GID, then, we need to understand why, for the majority, the disorder apparently remits by adolescence, if not earlier. One possible explanation concerns referral bias. Green (1974) argued that children with GID who are referred for clinical assessment (and then therapy) may come from families in which there is more concern than is the case for adolescents and adults, the majority of whom did not receive a clinical evaluation and treatment during childhood. Thus, a clinical evaluation and subsequent therapeutic intervention during childhood may alter the natural history of GID. This is only one account of the disjunction and there may well be additional factors that might distinguish those children who are more strongly at risk for the continuation of the disorder from those who are not. Another explanation is that the diagnostic criteria for GID, at least as they are currently formulated, simply are not sharp enough to distinguish children who are more likely to show a persistence in the disorder from those who are not.

To date, very little has been done in the way of assessing the more general psychosocial and psychiatric outcomes of children with GID. This is important for at least two reasons. First, children with GID show, on average, as much general behavioural psychopathology as do demographically matched clinical controls. Whether children with GID will continue to be at risk for more general disturbances in psychiatric functioning as they mature remains an understudied area of empirical inquiry. In a recent cross-sectional study, Zucker *et al.* (2001) compared children and adolescents with GID and found that the adolescents were substantially more disturbed on the CBCL than were the children, even after co-varying for various differences in demographic characteristics. Secondly, we now know that gay and lesbian adolescents, without known GID in childhood, are at increased risk for mental health problems although the reasons for this have been largely understudied (Remafedi *et al.* 1998; Fergusson *et al.* 1999; Garofalo *et al.* 1999a,b). Presumably, some of the variance is related to the stigma of a minority sexual orientation (Meyer 1995). It could be argued, for example, that

the severe social ostracism experienced by children with GID for their marked cross-gender behaviour increases the risk for general psychiatric problems (e.g. depression, suicidality), but this requires empirical verification.

Linkage between childhood sex-typed behaviour and sexual orientation

Because the linkage between GID in childhood and a later homosexual sexual orientation is so strong, understanding the connection is important, from both a theoretical and a clinical perspective. The most prominent biological explanation is that both sex-typed behaviour in childhood and sexual orientation in adolescence/adulthood are joined by some common factor or set of factors; for example, regarding genetic females with CAH, excessive prenatal exposure to androgens has been posited as the linkage factor that explains the higher rates of both behavioural masculinity during childhood (Berenbaum & Hines 1992) and bisexuality/homosexuality in adulthood (Zucker *et al.* 1996b).

Psychosocial perspectives have been varied. Green (1987) conjectured that, compared to control boys, a feminine boy's lack of close relationships with other boys and with his father might result in 'male affect starvation'. Thus, in adolescence and adulthood, homoerotic contact is used in some compensatory manner to achieve closeness with other males. This scenario is an example of accounting for a within-sex difference in a behavioural outcome (in this instance, sexual orientation); it is not clear if 'male affect starvation' during childhood would also account for a girl's later sexual attraction to males.

In Bem's (1996) developmental theory of sexual orientation, it is proposed that similar mechanisms are operative in the sexual object choice of feminine boys and feminine girls (and masculine boys and masculine girls). Bem's account is not so much a 'deficit' model, as is implied by the term 'affect starvation', but a 'difference' model. Bem proposed that variations in childhood 'temperaments' influence a child's preference for sex-typical or sex-atypical activities and peers:

These preferences lead children to feel different from opposite-sex or same-sex peers—to perceive them as dissimilar, unfamiliar, and exotic. This, in turn, produces heightened non-specific autonomic arousal that subsequently gets eroticized to that same class of dissimilar peers (Bem 1996, p. 320).

For feminine boys and feminine girls, males are 'exotic', whereas for masculine boys and masculine girls, females are 'exotic'. Bem's (1996) theory of sexual orientation represents a prototype in trying to unite typical and atypical development. However, there are many unanswered questions and alternative interpretations raised by the theory. Bem places great emphasis on temperamental factors that affect a child's preference for sex-typical or sex-atypical activities and friendships—an emphasis that might be disputed by some developmentalists (Ruble & Martin 1998). Empirical evidence for the emergence of specific erotic feelings following 'heightened non-specific autonomic

arousal' is scant, although it is quite likely that the relevant tests can be obtained through an analysis of emerging sexual interactions within the pre-adolescent peer group.

Bem's theory is intriguing in that it implies a greater potential for malleability in sexual orientation development than is apparent in some of the biological theories. If a feminine boy becomes more masculine in the course of his childhood, does this imply that the likelihood of later homoeroticism decreases? Conversely, if a feminine girl becomes more masculine in the course of her childhood, does this imply that the likelihood of later homoeroticism increases? Unfortunately, there is not much information available to answer these questions.

Green (1987) compared feminine boys who were subsequently classified as bisexual or homosexual with feminine boys who were subsequently classified as heterosexual. Although some feminine behaviours in childhood distinguished the two subgroups, a composite extent of femininity score only approached conventional levels of significance and only for the rating of sexual orientation in fantasy, not behaviour. The lack of a stronger correlation is somewhat surprising, because one might have expected an association between the degree of cross-gender identification and long-term outcome; however, Green (1987) did find that the continuation of certain feminine behaviours throughout childhood was associated with later homosexuality. Thus, it may be that the persistence of these feminine behaviours is more important than their extent during the early childhood years.

Treatment

In this section, I review some of the extant perspectives on treatment issues and what is known about the efficacy of various therapeutic interventions.

Ethical considerations

Any contemporary child clinician responsible for the therapeutic care of children and adolescents with GID will quickly be introduced to complex social and ethical issues pertaining to the politics of sex and gender in post-modern Western culture and have to think them through carefully. Is GID really a disorder or just a 'normal' variant of gendered behaviour? Is marked cross-gender behaviour inherently harmful or is it simply harmful because of social factors? If a teenager requests immediate cross-sex hormonal and surgical intervention as a therapeutic for gender dysphoria, should the clinician comply? If parents request treatment for their child with GID to divert the probability of a later homosexual sexual orientation, what is the appropriate clinical response? All of these questions force the clinician to think long and hard about theoretical and treatment issues.

Perhaps the most acute ethical issue concerns the relation between GID and a later homosexual sexual orientation. As noted earlier, follow-up studies of boys with GID, largely untreated, indicate that homosexuality is the most common long-term psy-

chosexual outcome. Some parents of children with GID request treatment, partly with an eye towards preventing subsequent homosexuality in their child, whether this is because of personal values, concerns about stigmatization, or for other reasons.

In the 1990s, this 'rationale' for treatment was subject to intense scrutiny (Sedgwick 1991; Minter 1999). Some critics have argued that clinicians, consciously or unconsciously, accept the prevention of homosexuality as a legitimate therapeutic goal (Pleak 1999). Minter (1999) has claimed, as have others (Scholinski 1997), that some adolescents in the USA are being hospitalized against their will because of their homosexual sexual orientation but under the guise of the GID diagnosis. These allegations have not been verified in any systematic manner and I know of no such case in which this has occurred (Meyer Bahlburg 1999b). Others have asserted, albeit without direct empirical documentation, that treatment of GID results in harm to children who are 'homosexual' or 'prehomosexual' (Isay 1997). Some clinicians have raised questions about differential diagnosis, arguing that there is not always an adequate distinction between children who are 'truly' GID vs. those who are merely prehomosexual (Corbett 1996; Richardson 1996, 1999).

The various issues regarding the relation between GID and homosexuality are complex—both clinically and ethically. Three points, albeit brief, can be made. First, until it has been shown that any form of treatment for GID during childhood affects later sexual orientation, the issue is moot. From an ethical standpoint, however, the clinician has an obligation to inform parents about the state of the empirical database. Secondly, I have argued elsewhere that some critics incorrectly conflate gender identity and sexual orientation, regarding them as isomorphic phenomena (Zucker 1999c), as do some parents. Psychoeducational work with parents can review the various explanatory models regarding the statistical linkage between gender identity and sexual orientation (Bailey & Zucker 1995; Bem 1996), but also discuss their distinctness as psychological constructs. Thirdly, many contemporary clinicians emphasize that the primary goal of treatment of children with GID is to resolve the conflicts that are associated with the disorder *per se*, regardless of the child's eventual sexual orientation. Most clinicians who have worked with children and adolescents with GID believe that they experience a great deal of suffering: many such youngsters are preoccupied with gender identity issues, they experience increased social ostracism and alienation as they get older, and show evidence of other behavioural and psychiatric difficulties. Most clinicians therefore take the position that therapeutics designed to reduce the gender dysphoria, lessen the degree of social ostracism, and to reduce the degree of psychiatric comorbidity constitute legitimate goals of intervention. How, then, might one go about reaching these therapeutic goals?

Developmental considerations

One aspect of the clinical literature suggests that there are important developmental considerations to bear in mind. For example, there is some evidence to suggest that GID is less re-

sponsive to psychosocial interventions during adolescence, and certainly by young adulthood, than it is during childhood. Thus, the lessening of malleability and plasticity over time in gender identity differentiation is an important clinical consideration.

Treatment of children

For children with GID, clinical experience suggests that psychosocial treatments can be relatively effective in reducing the gender dysphoria. Therapeutic approaches have included the most commonly used interventions for children in general, including behaviour therapy, psychodynamic therapy, parent counselling, and group therapy (for detailed reviews see Zucker 1985, 1990, 2001). In considering these various therapeutic approaches, there is one important sobering fact to contemplate: apart from a series of intrasubject behaviour therapy case reports from the 1970s, one will find not a single randomized controlled treatment trial in the literature (Zucker, 2001). Thus, the treating clinician must rely largely on the 'clinical wisdom' that has accumulated in the case report literature and the conceptual underpinnings that inform the various approaches to intervention.

Treatment for children with GID often proceeds on two fronts:

- 1 individual therapy with the child, in which efforts are made to understand the factors that seem to fuel the fantasy of wanting to become a member of the opposite sex and then to resolve them; and
- 2 parent counselling, in which efforts are made to help the child, in the naturalistic environment, to feel more comfortable about being a boy or a girl.

Treatment can address several issues. For youngsters who are quite confused about their gender identity, one can focus on the mastery of basic cognitive concepts of gender, including correct identification of the self as a boy or a girl; encouragement in the development of same-sex friendships, in which areas of mutual interest can be identified; and exploration of factors within the family that might be contributing to the gender identity conflict.

With parents, treatment issues include the following:

- 1 limit-setting of cross-gender behaviour and encouragement of gender-neutral or sex-typical activities;
- 2 factors within the family matrix that may be contributing to the child's gender identity conflict; and
- 3 parent factors, including psychiatric impairment, that may be compromising functioning in the parental role in general.

Here, I will focus on some technical aspects of limit-setting that are often misunderstood in the clinical literature and which thus require further explication. A common error committed by some clinicians is to simply recommend to parents that they impose limits on their child's cross-gender behaviour without attention to context. This kind of authoritarian approach is likely to fail, just as it will with regard to any behaviour, as it does not take into account systemic factors, both in the parents and in the child, that fuel the 'symptom'. At the very least, a psychoeducational approach is required, but, in many cases, limit-setting

needs to occur within the context of a more global treatment plan.

From a psychoeducational point of view, one rationale for limit-setting is that if parents allow their child to continue to engage in cross-gender behaviour, the GID is, in effect, being tolerated, if not reinforced. Thus, such an approach would contribute to the perpetuation of the condition. Another rationale for limit-setting is that it is, in effect, an effort to alter the GID from the 'outside in', while individual therapy for the child can explore the factors that have contributed to the GID from the 'inside out'. At the same time that one attempts to set limits, parents also need to help their child with alternative activities that might help consolidate a more comfortable same-gender identification. Encouragement of same-sex peer group relations can be an important part of such alternatives; for example, some boys with GID develop an avoidance of male playmates because they are anxious about rough-and-tumble play and fantasy aggression. Such anxiety may be fuelled by parent factors (e.g. where mothers conflate real aggression with fantasy aggression), but may also be fuelled by temperamental characteristics of the child (Zucker 2000b). Efforts on the part of parents to be more sensitive to their child's temperamental characteristics may be quite helpful in planning peer group encounters that are not experienced by the child as threatening and overwhelming. It is not unusual to encounter boys with GID who have a genuine longing to interact with other boys, but because of their shy and avoidant temperament do not know how to integrate themselves with other boys, particularly if they experience the contextual situation as threatening. Over time, with the appropriate therapeutic support, such boys are able to develop same-sex peer group relationships and begin to identify more with other boys as a result.

Another important contextual aspect of limit-setting is to explore with parents their initial encouragement or tolerance of the cross-gender behaviour. Some parents will tolerate the behaviour initially because they have been told, or believe themselves, that the behaviour is 'only a phase' that their child will grow out of. Such parents become concerned about their child once they begin to recognize that the behaviour is not merely a phase (Zucker 2000a). For other parents, the tolerance or encouragement of cross-gender behaviour can be linked to some of the systemic and dynamic factors described earlier. In these more complex clinical situations, one must attend to the underlying issues and work them through. Otherwise, it is quite likely that parents will not be comfortable in shifting their position.

Although many contemporary clinicians have stressed the important role of working with the parents of children with GID, one can ask if there is any empirical evidence that this is effective. Again, systematic information on the question is scanty. The most relevant study (Zucker *et al.* 1985) found some evidence that parental involvement in therapy was significantly correlated with a greater degree of behavioural change in the child at 1-year follow-up, but this study did not make random assignment to different treatment protocols, so one has to interpret the findings with caution.

Treatment of adolescents

If GID in adolescence is not responsive to psychosocial treatment, should the clinician recommend the same kinds of physical interventions that are used with adults (Harry Benjamin International Gender Dysphoria Association 1998)? Prior to such a recommendation, many clinicians usually encourage adolescents with GID to consider alternatives to this invasive and expensive treatment. One area of inquiry can therefore explore the meaning behind the adolescent's desire for sex reassignment and if there are viable alternative lifestyle adaptations. In this regard, the most common area of exploration pertains to the patient's sexual orientation. Almost all adolescents with GID recall that they always felt uncomfortable growing up as boys or as girls, but that the idea of 'sex change' did not occur until they became aware of homoerotic attractions. For some of these youngsters, the idea that they might be gay or homosexual is abhorrent. For some such adolescents, psychoeducational work can explore their attitudes and feelings about homosexuality. Group therapy, in which such youngsters have the opportunity to meet gay adolescents, can be a useful adjunct in such cases. In some cases, the gender dysphoria will resolve and a homosexual adaptation ensues (Zucker & Bradley 1995). For others, however, a homosexual adaptation is not possible and the gender dysphoria does not abate.

For adolescents in which the gender dysphoria appears chronic, the clinician can consider two main options:

1 management until the adolescent turns 18 and can be referred to an adult gender identity clinic; or

2 'early' institution of contra-sex hormonal treatment.

Regarding the latter, Gooren & Delemarre-van de Waal (1996) recommended that one option with gender-dysphoric adolescents is to prescribe puberty-blocking luteinizing hormone-releasing agonists (e.g. depot leuprolide or depot triptorelin) that facilitate more successful passing as the opposite sex. Thus, in male adolescents, such medication can suppress the development of secondary sex characteristics, such as facial hair growth and voice deepening, which makes it more difficult to pass in the female social role. Cohen-Kettenis & van Goozen (1997, 1998) reported that early cross-sex hormone treatment for adolescents under the age of 18 years, judged free of gross psychiatric comorbidity, facilitates the complex psychosexual and psychosocial transition to living as a member of the opposite sex and results in a lessening of the gender dysphoria.

Although such early hormonal treatment is controversial (Cohen-Kettenis 1994, 1995; Meyenburg 1994), it may well be the treatment of choice once the clinician is confident that other options have been exhausted. One issue that is not yet resolved concerns who are the best candidates for early hormonal treatments. Cohen-Kettenis & van Goozen (1997) have suggested that the least risky subgroup of adolescents with GID are those who show little evidence of psychiatric impairment. In my own clinic, the vast majority of adolescents with GID would not qualify on this basis (Zucker *et al.* in press). However, by adolescence, the issue is a tricky one because it is not clear to

what extent the psychiatric impairment is a consequence of the chronic gender dysphoria (Newman 1970). A randomized controlled trial would be useful in resolving the matter.

Future directions

In this chapter, I have provided an overview of the literature on GID in children and adolescents. Since GID first appeared in the DSM-III in 1980, considerable advances have been made in some areas. The phenomenology of GID is now well described and extant assessment procedures are available to conduct a thorough and competent diagnostic evaluation. Like other psychiatric disorders of childhood, it is apparent that complexity, not simplicity, is the guiding rule-of-thumb in any effort to make sense of the origins of GID. It appears that both biological and psychosocial factors contribute to the disorder's genesis and we are making some progress in identifying specific markers of both processes. From an aetiological standpoint, perhaps the most vexing issue is to make progress in solving the problem of specificity. A fair bit has been learned about the 'natural history' of GID and it appears to be the case that the prospects for therapeutic intervention are more optimistic during childhood than in adolescence, perhaps not a surprising observation to developmental psychiatrists. Much remains to be learned, however, about the most efficacious forms of treatment and perhaps this will be a goal to be reached in the first decade of the new millennium.

Introduction

Feeding and sleeping are two areas of functioning that not only occupy a great deal of time in the young child's life but also present significant challenges to parents and children. Together, feeding and sleeping serve biological function: feeding is important in terms of basic nutrition, to survive, to thrive and to develop both physically and mentally, while sleeping serves restorative functions.

Much of early parent and infant social interaction occurs around feeding and sleeping. During mealtimes infants often learn for the first time about some of their own emerging capacities, while in sleep the infant learns about separation from carers. Through these processes the infant develops its earliest self-regulation, so critical for later development and interaction with the social world.

Although sleeping and feeding are the context for much satisfaction and pleasure for both child and caregiver, they can also be the source of much distress. Some children have physiological attributes that mitigate against the smooth developmental progression of self-regulation required for sleep, whereas others may be unable to cope with the biological processes inherent in establishing feeding. Many parents and children find that these activities then become associated with stressful, conflictual and maladaptive relationships when either parent or child does not meet with the expectations of the other. It is not surprising therefore that studies of young children's behaviour problems consistently demonstrate that disruptions in sleeping, inability to remain asleep, reluctance to feed, refusal of foods or consumption of too much food are high on the list of the most commonly reported problems.

Feeding disorders

Introduction to feeding, growth and development

Infants and young children rely on caregivers to provide their nutritional requirements. Weight gain and the proportion of energy used for growth during the first 6 months is more rapid than at any other period of development (Whitehead 1985). The social importance of feeding is also greatest in the first few months when much of a child's waking time and social contacts will be taken up with ensuring adequate intake of nutrients (Bunton *et al.* 1987). This has led to a focus on mother–infant feeding in

the psychological study of interactions (Wolke 1991). Developmental changes in feeding during the first 2 years may have a powerful influence on the development of some kinds of feeding difficulty. During that time the infant moves from a completely liquid diet, through the acceptance of smooth thickened food, then roughly chopped mixtures, to an acceptance of an approximation to adult food. Thus, classification and diagnosis of feeding and eating problems in young children and plans for their treatment need to incorporate somatic, developmental and social or behavioural factors (Budd *et al.* 1992; Chatoor 1997).

The provision of nutrition is conducted in the context of the infant's emerging social relationships, in conjunction with the development of a number of biological regulatory systems. The newborn infant has reflexes (rooting, sucking) designed to seek out and ingest food, and soon learns to signal need through crying and other forms of communication, and also learns to what extent those signals are responded to, and in what manner. This process is guided and regulated by the brain structures and physiology involved in the development of oral-motor control, taste perception, hunger, appetite, food preferences and gastric regulation (Wolke 1994).

There are three main kinds of feeding problem in infancy and childhood:

- 1 too little intake;
- 2 too much intake; and
- 3 highly restricted or extremely idiosyncratic diet.

Some feeding problems may be closely associated with biological rhythmicity in hunger, or biological immaturity leading to reflux. Others derive from the context of the caregiver–child relationship. Health problems can also be linked with parental feeding strategies. The early introduction of solids was found in a large Scottish sample of infants to be associated with an increased risk for respiratory illness and coughs, after adjusting for factors such as parental smoking (Forsyth *et al.* 1993).

Historical trends in infant feeding

One of the most consistent findings is the way in which patterns of feeding have changed over the twentieth century, more often reflecting the social norms of the time than any definitive knowledge about the relative impact of any type of feeding. Recently, there has been a focus on ecological intergenerational influences. Thus, among African-American adolescent mothers it is the cultural norm to introduce cereal in the bottle within the first month of life and to use other semisolid foods, contrary to most

medical opinion and advice from child care books (Bentley *et al.* 1999). Grandmothers were influential in guiding feeding patterns, having extensive physical access to the infants in the context of their daughters being dependent on them for child care. The extent of a society's overall economic and social development is also relevant to the level of breastfeeding. In developing countries, mothers in rural areas are more likely to breastfeed than those in urban areas, and the more highly educated women are less likely to breastfeed, contrary to findings from many developed nations (Rogers *et al.* 1997). The wider cultural and social context is also important for understanding the development of feeding problems (Black 1999).

Epidemiology of breastfeeding

The trend in rates of breastfeeding was downwards for most of the twentieth century. In 1910, approximately 70% of mothers chose breastfeeding in the first instance (Hendershot 1984). A UK survey just after the Second World War showed that 60% of mothers breastfed when their child was 1 month of age, with the rate falling to 42% by 3 months. A study in Nottingham in the late 1950s found that the rate had dropped to 54 and 29% at 1 and 3 months, respectively. At that time the 'modern' and 'convenient' aspects of bottle-feeding were promoted at the same time that families had a higher standard of living and were thus able to afford equipment such as sterilizing units, bottles and teats (Newson & Newson 1963). Response to perceived medical wisdom is also a factor. Mothers revealed their knowledge that professionals such as health visitors preferred breastfeeding by differential responses: at 1 month 54% of mothers reported breastfeeding to their health visitor, but only 40% of the same women described breastfeeding to a university researcher (Newson & Newson 1963).

Rates of breastfeeding dropped through the 1960s to a low of 24–28% in the early 1970s, then gradually rose during the 1980s as natural childbirth became more popular. In the USA there was a similar decline from the 1950s to the 1970s, with fluctuations until the late 1990s, when the rate once again was >60% (Ryan 1997). However, by 6 months, the rate has dropped to 25%. European rates, with the exception of Ireland and Malta, are similar to or well above the UK and USA, ranging from 98% (Denmark, Sweden) to 60% (Belgium) (Meiklejohn, unpublished report, 2000). A recent community study in south-west England found that 77% of mothers intended to breastfeed at 1 month, and 58% planned to continue until at least 4 months (Barnes *et al.* 1997). National surveys have been conducted in the UK every 5 years since 1975. The two most recent surveys, completed in 1990 and 1995, found that the reported incidence of breastfeeding in the first weeks of life in England and Wales had risen slightly in those 5 years from 64 to 68% (White *et al.* 1992; Foster *et al.* 1997). There were similar rises in Scotland and Northern Ireland, but within much lower rates (Scotland 50 and 55%; Northern Ireland 36 and 45%).

Factors associated with lower rates in the UK include lower social class, living without a husband or partner, fewer years of

maternal education, younger maternal age, maternal smoking, and second or later births. Among primiparous mothers aged 30 or over, 85% breastfed compared with 44% of those under 20 years; of the mothers who completed their education over the age of 18, 89% breastfed compared with 59% of those whose education was completed at 16 or younger.

Current social class differences are reversed from the pattern prior to the 1970s. Until then, breastfeeding had been more common for working class than middle class mothers, but currently it is more often the method of choice for mothers in higher social classes. A shorter duration is found in each successive social class group: in the most recent UK survey 90% of mothers in social class I breastfed at birth, compared with 57% in social class IV and 50% in social class V. By the age of 6 weeks, 73% of social class I mothers were still breastfeeding, compared with 33% in social class IV and 23% in social class V. In the USA, mothers who opt for extended nursing of their children are also likely to be from middle class backgrounds (Sugarman & Kendall-Tackett 1995).

Breastfeeding has been strongly encouraged by health professionals (Standing Committee on Nutrition of the British Paediatric Society 1994), supported by recent evidence of a variety of benefits: protection from gastrointestinal disease (Howie *et al.* 1990); less respiratory tract illness (Wright *et al.* 1989); and enhanced neurological and intellectual development throughout childhood (Lanting *et al.* 1994; Pollock 1994a; Florey *et al.* 1995; Johnson *et al.* 1996), with particular cognitive benefits for pre-term infants (Lucas *et al.* 1990, 1992, 1998). There have been suggestions that the enhanced intellectual development associated with breastfeeding is an artefact of social class (Malloy & Berendes 1998). However, a recent meta-analysis concluded that, controlling for social class and maternal education, and including both low birth weight and full-term infants, breastfeeding was associated with significantly higher scores for cognitive development than bottle-feeding (Anderson *et al.* 1999).

The reasons mothers of first babies gave in the 1995 UK survey for choosing to breastfeed reflect professional advice to a certain extent: 'best for baby' (89%); 'more convenient' (36%); 'cheaper' (23%); it helps to develop 'a closer bond between mother and baby' (21%); and for those having a second or subsequent child that it was their previous feeding method (33%). Choice of bottle-feeding was supported by reasons that include 'someone else can feed the baby' (36%), dislike of the idea of breastfeeding (27%), or embarrassment about breastfeeding (7%) (Foster *et al.* 1997).

Personal and cultural factors are also important in predicting feeding patterns, with higher rates for women who were breastfed themselves, whose friends breastfed and who did not smoke during pregnancy (Foster *et al.* 1997). Attitudes towards child-rearing reflecting a child-orientated approach (e.g. always picking up a crying baby or adapting life to a baby's needs) are associated with a greater likelihood of planning to breastfeed, while socioemotional difficulties (e.g. depression or preoccupation with body weight and shape) are contraindications to breastfeeding (Barnes *et al.* 1997). Maternal depression has also

been associated with early cessation of breastfeeding (Cooper *et al.* 1993). In the UK, if there was a delay of more than 12 h after the birth before mothers held their babies, they were also less likely to breastfeed (Foster *et al.* 1997). However, in some countries in Asia it is commonplace for a child not to be given the mother's colostrum, and therefore for the first feed to occur well after 24 h (Rogers *et al.* 1997). In most societies the presence of conflicting advice from health professionals and the availability of (sometimes free samples of) powdered milk decrease the likelihood that mothers will establish breastfeeding.

Sucking/suckling, weaning and introduction of solids

It is recommended that, for most infants, solids should not be introduced before the age of 4 months (DOH 1994) but the UK 1995 survey found that 7% of mothers introduced solids by 6 weeks, 13% by 8 weeks and over half (55%) by 3 months (Foster *et al.* 1997). This was strongly associated with social class and maternal smoking. By 3 months more than two-thirds (68%) of mothers in social class V had introduced solids compared with one-third (35%) of those in social class I. Weaning was also associated with feeding method in that only 1% of breastfed infants had been given solids at 6 weeks compared with 9% of bottle-fed infants. By 3 months 30% of the breastfed group had been offered solids and 63% of those given a bottle. Studies have shown that early introduction of solids is a common source of conflict between professionals and mothers (Blaxter & Paterson 1982) and the knowledge that they are acting contrary to professional advice may be a reason for not attending child health clinics (McIntosh 1986). Mothers gave reasons for introducing solids related to encouraging their baby to sleep through the night or to ease fretfulness and crying (McIntosh 1986). It has been found that boys are given solids sooner. This may be related to sociocultural factors, such as wanting them to be large and strong, or to the fact that male infants are frequently fussier and less easy to soothe (Harris 1988).

A less common concern is the late introduction of solids. Basic oral-motor patterns are dependent on maturation but a necessary prerequisite is practice in mouth opening, lip movements, chewing and swallowing. Skills related to movement of food from one side of the mouth to the other during chewing, and coping with viscous foods in addition to solids, develop gradually up to at least 8 years of age (Gisel 1988). The absence of early experiences of these actions because of late introduction of solids, highlighted by the prolonged feeding of gruel from bottles experienced by infants in Romanian orphanages, can lead to problems with feeding such as food refusal and, in extreme cases, even to failure to thrive (Skuse *et al.* 1992).

Feeding difficulties and disorders

Food refusal

Food refusal is the most common type of feeding difficulty

among infants and preschool-age children. The proportion of children refusing all but a few foods is high, with as many as 30% of infants' mothers reporting feeding difficulties (Jenkins *et al.* 1980) and faddy eating (defined as refusing many foods for at least half the meals offered) reported by 12% of parents of 3 year olds (Richman *et al.* 1982). For some children the problem of food refusal can be severe, with only two or three foods eaten. This kind of behaviour may lead to children being slow to grow or to be deficient in specific nutrients, with a particular tendency to iron deficiency (Harris *et al.* 1983; Aukett *et al.* 1986). Some children will have been poor feeders from birth, others may start to limit their intake at the introduction of solids foods, and for others food refusal has its origins in illness which may or may not be related to diminished appetite or gastrointestinal disease (Harris 2000). Parents can be responsible for limiting the range of foods eaten, as a consequence of presumed food allergy (Price *et al.* 1988), cultural variations in the age of weaning or the use of many sweetened foods rather than progressing to family foods (Jones 1987). This may itself be a response to early patterns in the infant. Quite often chronic food refusers will have been poor feeders from birth, either slow to feed, with poor sucking, or frequent vomiting. Parents with such an infant may delay the onset of introducing solid foods and the later use of solids can exacerbate food refusal.

Children with food refusal frequently have acceptable behaviour outside the feeding situation but sometimes food refusal is associated with other difficulties. Chatoor *et al.* (1985) described a clinical sample in which the food refusal was seen as a component of a separation disorder; part of a broader challenge for the development of the child's autonomy in the face of parental control. This may be intensified if the parent is particularly anxious about his or her child's weight or growth, despite the fact that most food refusers do not show growth faltering. Some medical conditions, such as cerebral palsy, are associated with higher rates of food refusal. For these children oral-motor dysfunction means that they cannot manage to chew or swallow various textures which would otherwise be appropriate for their age group, leading to discomfort, gagging and ultimately to food refusal (Gisel & Patrick 1988). Children who have experienced prolonged supplementary feeding following conditions that require oesophageal surgery or those with gastrointestinal abnormalities often exhibit food refusal and gagging when textured food is offered. This may also be the case for children with conditions such as congenital heart disease and cystic fibrosis (Salzer *et al.* 1989; Thommessen *et al.* 1992). In defining chronic food refusal, children whose behaviour can be related to a current or recent infection would be excluded.

A number of non-organic causes have also been proposed for food refusal or restriction to a narrow range of foods. Some children have small appetites, which parents may find confusing if they have had other children who were hearty eaters or if parental guidance material gives information that differs considerably from their own child's behaviour. Most children with a

small appetite eat a range of foods (Harris 1997) and their management requires only growth monitoring and reassuring parents about the range on which average appetite is based. A group of, predominantly, boys who may considerably restrict the range of foods eaten has been described (Harris *et al.* 2000). They may also react if food is not the normal brand or is cooked in a different manner and react strongly to the smell and texture of foods offered. They could be exhibiting the rule-bound behaviour that is associated with a subclinical form of the autistic spectrum, and children with Asperger syndrome and autism also commonly have feeding problems as part of their wider range of symptoms (Harris *et al.* 2000). If there are no growth problems, management should focus on reducing parental anxiety and encouraging parents not to put pressure on children to accept new foods until later in childhood.

Food aversion can also be the consequence of learning. If a certain food is associated with a particularly violent episode of vomiting, which may or may not have been caused by the food in question, the single experience may be followed by absolute refusal to take the food subsequently. Dietary exposure to different tastes also has cultural variations and it has been suggested that children should be exposed to a range of salty and other savoury tastes during the preschool years, to combat their natural preference for sweet tastes (Harris *et al.* 1990). Standard behavioural management techniques, such as modelling appropriate behaviour, shaping approximations to the desired behaviour, reinforcement of appropriate eating and time out when foods are refused, can be successful (O'Brien *et al.* 1991) and parents can help to overcome children's fear of certain foods by modelling positive enjoyment and allowing use of fingers rather than insisting on utensils. However, many children are very resistant to change and coercive patterns of interaction may result (Sanders *et al.* 1993). Parents may be overanxious about their capacity to set limits and need support to help them to deal with struggles with child management and to set boundaries (Chatoor 1997).

Faddiness and selective eating

Some children persist with extreme faddiness, eating a small number of foods throughout their childhood. In particular, this may be a feature of the behavioural repertoire of autistic children (see Lord & Bailey, Chapter 38). Typically, the main foods eaten are carbohydrates, such as pasta, potatoes or bread. While they may be brought to medical attention through concern from parents, it is often the case that they are as physically healthy as their peers, with height and weight in the normal range (Bryant-Waugh & Lask 1995). Many clinicians to whom these children are referred do not usually recommend ways to increase the range of foods but instead focus on how the behaviour will influence social interactions with peers, such as attendance at parties, going on trips or staying overnight with friends. Many of these children seem to negotiate these social situations adequately, and as they move into puberty they gradually increase the range of foods eaten.

Pervasive refusal syndrome

Pervasive refusal syndrome has recently been identified as a rare condition in which refusal to eat and drink is accompanied by a more generalized refusal to walk, talk or carry out any kind of self-care activities, and is sometimes misdiagnosed as early onset anorexia nervosa. First described by Lask *et al.* (1991), it has been seen in a small number of girls, usually between the ages of 8 and 14. The marked fearful avoidance was thought to be symptomatic of post-traumatic stress disorder (PTSD), possibly following physical or sexual abuse, although there is continuing debate about both the syndrome itself and its aetiology. Two phases were conceptualized: first the trauma of abuse followed by a second phase of fear induced by intimidation about the consequences of disclosure. There has been a case report of successful treatment following the discovery of abuse, providing some support for this viewpoint (McGowan & Green 1998). Others have linked the disorder with learned helplessness (Nunn & Thompson 1996), said to be a more helpful theoretical paradigm with which to conceptualize the phenomenology, aetiology and treatment of pervasive refusal syndrome. A multi-disciplinary approach has been used, taking the learned helplessness model, one particular issue of which is consent, which may very well be refused as part of the wider behavioural pattern (Nunn *et al.* 1998). However, more work needs to be conducted to allow for a fuller understanding of the condition, and its relevance to current diagnostic systems.

Non-organic failure to thrive

Failure to thrive has been given a variety of labels, including maternal deprivation syndrome, reactive attachment disorder and anorexia nervosa of infancy, and has been defined using clinical and behavioural criteria. However, there is now emerging consensus that it should be defined solely on the basis of growth (Wolke *et al.*, in press). Specifically, it has been proposed that when growth failure (defined as weight below the third percentile) in young children is identified, it will be seen as failure to thrive (FTT) and, if it cannot be attributed to organic factors or to inadequate food intake, it is referred to as non-organic failure to thrive (NOFT). Nevertheless, this definition has been criticized in that it describes a symptom rather than a disorder (Skuse 1985). A British community survey put the prevalence of FTT at 3–4% (Skuse *et al.* 1992) but problems with lack of consistency in anthropometric criteria have also been noted, such that the reported incidence may vary from 1.3 to 20.9% (Wilcox *et al.* 1989; Mayes & Volkmar 1993).

Although traditionally FTT has been thought of as caused by organic factors and NOFT by parenting that lacks nurturance, leading to poor growth despite adequate food intake, the distinction between organic and non-organic causes is not necessarily clear-cut. Oral-motor difficulties and neurological abnormalities have been found in children diagnosed as NOFT (Mathisen *et al.* 1989; Ramsey *et al.* 1993). It has been proposed more recently that, because many organic diseases including

congenital heart failure and cerebral palsy lead to FTT only in interaction with poor feeding, some cases should be considered 'mixed' and the label 'non-organic' may not be appropriate (Reilly *et al.*, in press).

Although NOFT is associated with parenting problems, difficulties with the caregiver–child relationship and even child abuse, there is ongoing debate about the relevance of the role of parents (Boddy & Skuse 1994). In the past, studies have emphasized the role of the mother (Fischhoff *et al.* 1971). It has been suggested that they provide insufficient nutrition either deliberately or because of financial problems, or that they are abusive, or that they are just misguided about children's nutritional requirements.

More recently, there has been a focus on the whole family and their circumstances within a multifactorial model of development in that NOFT children receive inadequate nutrition for a variety of reasons (Lieberman & Birch 1985; Drotar 1991). Family violence, environmental disorganization and social isolation have received particular attention (Bradley *et al.* 1984; Newberger *et al.* 1986; Crittenden 1987). Problems with family relationships are likely to have an adverse effect on maternal mental health and the capacity to be attentive to the infant's needs. Some clinicians have highlighted the particular impact of fathers in the development and outcome of NOFT through their participation in maladaptive patterns of parenting and/or conflicts with the child's mother (Drotar & Sturm 1987). A multidisciplinary approach to treatment is now thought to be the most beneficial, ideally including home visits, with a team of at least a child psychiatrist/paediatrician, a developmental psychologist, a speech therapist, dietician and social worker, because FTT is usually neither caused primarily by organic disease nor by the social environment (Wolke *et al.*, in press). Some infants may have insufficient diet because of disorganized meals, prolonged use of exclusive breastfeeding, errors in preparing formula, as a result of religious or cultural practices or as a consequence of distorted maternal perceptions about body weight or shape.

There is growing evidence that personal dietary choices can be relevant to children's growth if parents hold distorted beliefs about:

- 1 adequate nutritional requirements (Pugliese *et al.* 1987);
- 2 whether infants are gaining sufficient weight (Sturm & Drotar 1991); or
- 3 the need to reduce fat in a child's diet (Birch 1990).

This highlights the importance of providing educational supportive intervention to families in addition to clinical treatment.

Cultural attitudes to feeding should also be taken into consideration. A UK community study conducted in a London regional health authority found that whereas 3–5% of white UK, Chinese Asian, Caribbean and mixed race infants had NOFT, the incidence was 15% for Indian Asian children and zero for African infants (Skuse *et al.* 1992). It has been suggested that the late introduction of solid foods and social isolation of the Indian Asian population may have contributed to this difference (Fenton *et al.* 1989).

The team's activities include not only an oral-motor and developmental assessment of the infant but also a history of early temperament, detailed diary of food intake, investigation of parental eating patterns, direct observation of the parent and child and a detailed caregiver interview, including a psychiatric screening. In conjunction with these investigations, information about living conditions, income, extended family support and cultural influences needs to be collected. Subsequent interventions to improve living circumstances and reduce isolation should be accompanied by therapeutic intervention directed both at maternal symptoms, such as depression, and at discordant family relationships.

Colic

Colic in infancy is characterized by paroxysmal crying and tends to follow a characteristic pattern with an onset from about 2–3 weeks of age and usually resolving by 3–4 months. There is debate about its exact definition. Clinicians have traditionally followed the 'rule of three': fussing and crying for 3 h per day on at least 3 days per week for at least 3 weeks (Wessel *et al.* 1954). More recently it has been defined for research purposes as fussing or crying of at least 2 h per day for at least 5 days out of 7, a high-pitched and pain-sounding cry and maternal report of inconsolability (Pinyerd 1992). Longitudinal investigations indicate that although disruptive and upsetting to parents in the first few months, it appears to be a transitory condition, with no discernible difference between infants with and without colic by 5 months (Stifter & Braungart 1992).

Explanations of its aetiology fall into four main types: gastrointestinal dysfunction, allergenic reactions, immaturity of the central nervous system or parental anxiety and tension (Hewson *et al.* 1987; Keefe 1988; Sampson 1989). Although colic clearly elicits much stress in parents, anxiety about separation (Humphry & Hock 1989) and strong feelings of personal inadequacy and depression (Pinyerd 1992; Stifter & Bono 1998), colic is not seen to be secondary to parental behaviour. A specific allergic reaction to the protein content of milk has been proposed (Lothe *et al.* 1982; Jakobsson & Lindberg 1983), although elimination of cows' milk from the diet of the infant—or the mother in the case of breastfed infants—has had mixed results (Wolke & Meyer 1995). Treatment strategies should take as their starting point advice on the management of crying. If that is unsuccessful then cows' milk protein intolerance may be considered, but with the proviso to parents that this does not imply lifelong allergic difficulties (Bock 1987; Wolke & Meyer 1995).

Gastro-oesophageal reflux

The involuntary return of the gastric contents into the oesophagus is particularly common in the first year of life, and takes place occasionally in many children and adults, but becomes pathological when its frequency increases. Gastro-

oesophageal reflux (GOR) may also contribute to other feeding problems, such as faddiness and food refusal. The frequent reflux of the acidic gastric contents may lead to pain and skin irritation and to the infant refusing to open his or her mouth, which may persist into childhood even after the GOR has been treated.

GOR may be due to primary (anatomical or physiological) causes or to secondary causes, such as food allergy or metabolic disorders. Apart from feeding problems, many other consequences are likely: growth failure, irritability, iron-deficiency anaemia, recurrent respiratory infections, coughing and choking and, in the most severe cases, sudden infant death (Paton *et al.* 1988; Davies & Sandhu 1995). Infants with GOR may have laboured respiration and, in its most severe manifestation, an odd posture, holding their head on one side; the vomiting after feeds may resemble seizures with apnoea, cyanosis and stiffening (Bray *et al.* 1977).

Diagnosis involves 24-h pH monitoring by placing a small probe just below the oesophageal sphincter. The total number of reflux episodes can be assessed and the infant's ability to clear the reflux. Treatment includes giving thickened feeds, antacids, modifying the diet and postural adjustment, such as positioning the infant prone with their head elevated or, failing these strategies, surgical intervention (Davies & Sandhu 1995).

Rumination

Rumination is defined as the voluntary regurgitation of previously eaten food, which is then re-swallowed, persistent over at least 1 month and without any organic cause (American Psychiatric Association 1993). It appears to be pleasurable and usually self-induced through placing fingers in the mouth or contracting the tongue muscles, which distinguishes it from gastro-oesophageal reflux, which is involuntary. However, there are problems with its diagnosis in the absence of weight loss, if it is accompanied by vomiting, or in the presence of organic aetiology (Jackson & Tierney 1984). It is unrelated to acute illness or disease associated with nausea. The prevalence has been estimated at 0.7% in a sample of infants in acute paediatric hospital care and at 6–10% in children with learning disabilities, with a higher incidence in males than females (Mayes *et al.* 1988).

Some researchers have attributed its aetiology to family factors, specifically problems with the mother–infant relationship, such as neglect, leading the infant to develop strategies for internal gratification. For instance, a study of 20 cases aged 5–28 months suggests that psychosocial stressors, anxiety and/or depression in the primary caregiver and under- or over-stimulation were precipitating factors (Sauvage *et al.* 1985). Although rumination disorder, most commonly associated with developmental delay, may be long-lasting, there is evidence of 'self-limited' rumination as a reaction to situational stress during childhood (Reis 1994). Historically it was treated from a psychodynamic

perspective, by extended inpatient treatment with a surrogate mother (Lavigne *et al.* 1981). More recently, it has been proposed that the attention received because of the behaviour serves to perpetuate it by providing positive reinforcement and behavioural strategies have been shown effective (Winton 1984). In the past, aversive punishment techniques, such as spraying lemon juice on the tongue or even electric shock, have been used to control rumination (Cunningham & Linscheid 1976) but that would not be considered ethical now, nor would parents wish to use these methods. Instead, the most common behavioural treatment strategies rely on techniques such as time out and reinforcement of retaining food (Winton & Singh 1983).

Pica

Defined by DSM-IV (American Psychiatric Association 1993) as a childhood eating disorder characterized by developmentally inappropriate and persistent eating of non-food or non-nutritive substances (e.g. dirt, starch, clay, paint, plaster) for a period of at least 1 month, pica can have serious health consequences. If the substances ingested are poisonous (e.g. contain lead or parasites) it can have serious health consequences and be life-threatening. For families living in older residences, pica has been associated with the risk of lead poisoning as many children with pica ingest flakes of paint, resulting in blood lead levels higher than even children of lead mine employees (Chiaradia *et al.* 1997). While this kind of indiscriminate mouthing and eating can be common in infants (eating dirt for example), its incidence declines between 1 and 4 years from 35% to ≈6% (Robischon 1971). Rates for boys and girls do not differ significantly (Marchi & Cohen 1990). There are few longitudinal studies linking early childhood eating problems with later behaviour, but a study of over 800 children in the USA found that pica before the age of 11 was a significant predictor of bulimia nervosa — but not anorexia — in the adolescent years (Marchi & Cohen 1990).

A number of causes have been suggested including nutritional deficiencies (mainly iron or zinc), infant characteristics such as developmental delay, caregiver behaviours such as deprivation or neglect, or more general deprivation of the home environment (Walker *et al.* 1997). Whereas there is a normative stage when mouthing of all kinds of objects is commonplace, persistence of this behaviour beyond infancy and early childhood is considered abnormal. Education of health professionals about the risks, detailed interviewing and observation of children at risk (e.g. those living in older accommodation, those with caregivers who have limited competence) and close monitoring of children can go a long way to alleviating the risks posed by pica to children's physical development (Robischon 1971). More comprehensive environmental interventions are needed to remove many of the risks and to provide support and education for parents whose children persist with the behaviour beyond infancy.

Obesity

Obesity is becoming more common in childhood (Chinn & Rona 1994; Dietz 1998; World Health Organization Consultation on Obesity 1998), in association with a rise in sedentary pursuits and greater parental protectiveness (Andersen *et al.* 1998). There is good evidence that childhood obesity is associated with an increased risk of adult obesity (Epstein *et al.* 1985; Epstein & Wing 1987). The importance of intervention is highlighted by the fact that childhood obesity, in addition to the medical risks and likelihood of persistence to adulthood (Frühbeck 2000), is likely to occur in conjunction with socioemotional difficulties such as a greater risk for bullying and other peer relationship problems, social withdrawal, and depression (Israel & Shapiro 1985; Epstein *et al.* 1994).

Various explanations for obesity have been put forward, including child and family factors. There is good evidence from adoption and twin studies for a genetic tendency (Sorensen *et al.* 1989; Cardon 1994) and the best predictor of childhood obesity is obesity in the biological parents (Meyers *et al.* 1990; Gallaher *et al.* 1991). Although no differences between children of obese and non-obese mothers can be detected by birth weight, different trajectories emerge from around 6 months onwards (Rummler & Woit 1992) at around the time that solid foods are being introduced. Children at greater risk include those with difficult temperament (Carey *et al.* 1988), those who are breastfed for a shorter time (Kramer *et al.* 1985) and those overfed during infancy (Mogan 1986). Whether obese children have a clearly defined eating disorder with features such as distorted body image, false perception of meal size or poor regulation of appetite and eating patterns is as yet unresolved (Kissileff 1989).

Behavioural treatments have proven effectiveness, and intervention effects are strengthened by parental involvement and the incorporation of exercise into the behavioural plan (Epstein & Wing 1987). There are three key settings for intervention: the family, the school and primary care (Frühbeck 2000). Work with the family has documented success, with the additional benefit of improving health and well-being of parents and other family members (Epstein *et al.* 1990). Nevertheless, interventions in out-of-home settings such as school may have a broader impact on children's emotional well-being, with a focus on developing self-esteem while acknowledging emotional difficulties such as depression (Little 1983).

Parental eating disorders and children's eating

Eating disorders occur commonly among women of child-bearing age (Szmukler 1985; Fairburn & Beglin 1990; Hoek 1993) and the prevalence seems to be rising (Treasure *et al.* 1996). A concern has been that mothers' attitudes and behaviours regarding food and body shape could influence the children's feeding and eating, and ultimately their attitudes to body shape and eating. Children are particularly vulnerable during infancy, given that feeding and mealtimes take up a significant

part of the day during the first months of life, and allow for close communication between parents and children. The attitudes, preoccupations and behaviours that people with eating disorders manifest may interfere with their ability to prepare meals, to sit patiently feeding their infants and, in particular, to respond appropriately to hunger and satiety cues. Their attitudes may even influence choice of infant feeding prior to the birth. A large community study found that women with the highest levels of body shape concern during pregnancy were least likely to plan breastfeeding. This relationship held even after adjustment for a wide range of factors known to influence breastfeeding preferences (Barnes *et al.* 1997).

Investigations of women with eating disorders who have young children have concentrated on mothers' difficulties over children's mealtimes and concerns about children's size. A Scandinavian study (Brinch *et al.* 1988) found that 17% of the children of women with a history of anorexia nervosa failed to thrive in the first year of life. A controlled study using direct observation of the 1-year-old children of mothers with eating disorders (Stein *et al.* 1994) found that, when compared with controls, the index mothers were more intrusive with their infants during both mealtimes and play, and they expressed more negative emotion (critical and derogatory remarks) during mealtimes. There was considerably more conflict between index infants and their mothers during mealtimes, and maternal responses were found to be associated with this conflict. In particular, conflict was more likely when mothers did not acknowledge their infants' signals or did not allow them to express age-appropriate needs for autonomy through self-feeding and experimentation with food (Stein *et al.* 1999). Furthermore, the index infants weighed less than the control infants, and infant weight was found to be independently and inversely related to the amount of conflict during mealtimes. Similar growth problems were not evident in comparison samples of mothers with postnatal depression, indicating that growth faltering was specific to the infants of mothers with eating disorders (Stein *et al.* 1996).

The strength and specificity of the association between maternal eating disorder psychopathology and child feeding was examined in a study using the child's feeding as the starting point. Thus, the mothers of a consecutive series of young children referred to child psychiatric clinics with feeding disorders were compared with a matched group of children with behavioural disorders and an unselected control group. Only the children with feeding disorders (defined as severe food refusal or extreme faddiness) had mothers with significantly disturbed eating habits and attitudes (Stein *et al.* 1995). This association has recently been confirmed in a community preschool sample (Whelan & Cooper 2000).

Although it should be emphasized that the children of parents with eating disorders are not invariably adversely affected, it is important to find out about parental characteristics, such as excessive concern about body shape and weight, as part of a thorough family assessment when a child presents with feeding problems or growth failure.

Sleep disorders

Physiological processes in sleep

Sleep is a reversible behavioural state of perceptual disengagement from, and reduced responsiveness to, the environment. This complex amalgam of physiological and behavioural processes is accompanied by characteristic electroencephalogram (EEG) changes (Carskadon & Dement 1989). A neuronal system that governs cyclic alteration between waking and sleep is situated in the core of the brain extending from the medulla through the brainstem and hypothalamus into the forebrain (Jones 1989). Within sleep, there are two different states: the non-rapid eye movement (NREM) state and the rapid eye movement (REM) state (Rechtschaffen & Kales 1968), defined on the basis of physiological parameters including EEG, muscle tone and eye movements. NREM sleep is divided into four stages: stages 1 and 2 are light sleep stages, while stages 3 and 4 represent deep sleep with a high arousal threshold. REM sleep, also called active sleep or paradoxical sleep, is characterized by EEG activation not unlike the wake state, with muscle atonia (absence of muscle tone) and intermittent bursts of rapid eye movements, from which it gets its name. Dreaming only occurs during REM sleep. The arousal threshold in REM sleep is variable. The two sleep states are interrupted throughout the night by brief arousals characterized by EEG changes towards the wake state and an increase in muscle tone with accompanying movement. Arousals vary in duration from a few seconds to several minutes. Thus, sleep is not a uniform state but is constantly changing throughout the night.

From birth onwards NREM and REM sleep alternate cyclically throughout the night. Each cycle takes about 50–60 min in the newborn and gradually increases to 90 min in older children and adults (Carskadon & Dement 1989). Sleep is entered through NREM sleep. NREM sleep stages 3 and 4 dominate the sleep cycle in the early part of the night, with only short periods of REM. As the night progresses, stages 1 and 2 of NREM sleep, as well as REM sleep, take up proportionately greater periods of each cycle, so that morning awakening occurs from REM sleep or the light stages of NREM sleep. Stages 3 and 4 sleep are maximal in young children and decrease in favour of more stage 1 and 2 sleep with age. This explains why young children can be difficult to wake from the first sleep cycle.

Despite a great deal of research, the precise function of sleep remains unresolved. The two most popular theories suggest that sleep is essential for either cerebral restitution, focusing particularly on REM sleep because of its association with dreaming (Dement & Kleitman 1957), or body replenishment because sleep with its enforced rest puts a ceiling on energy expenditure (Zepelin & Rechtschaffen 1974).

Developmental progression of sleep patterns in neonates and infants

In the first year of life, development occurs rapidly and one of the primary functions is to synchronize physiological adaptation with the primary social relationships. Sleep regulation and consolidation are amongst the most important early developmental milestones which infants need to acquire in the first year. Regulation concerns the ability of infants to make the transition smoothly from wakefulness to sleep, and consolidation concerns the infant's ability to sustain sleep in a continuous fashion for an age-appropriate period of time before fully awakening (Sadeh & Anders 1993). The internal biological 'clock' that regulates the sleep–wake cycle begins to synchronize with other internal signals, such as hunger and satiety, and with scheduled periods of social interaction, as well as with other environmental cues such as the light–dark cycle and ambient temperature.

The survival of increasingly premature babies has provided insight into some aspects of the development and maturation of the immature brain, reflected in the infants' regulation of their sleep–wake pattern. It is likely that the fetus is never truly awake but alternates between quiet sleep (QS) and active sleep (AS) which are the precursors of the NREM–REM cycle. Neonates born prior to 30 weeks' gestation spend 90% of sleep time in REM sleep (AS) compared with 50% at term. There are striking changes in the pattern of sleeping and waking in the first 16 weeks of life. Parmelee *et al.* (1964) found that although there was a relatively small decrease in the total hours of sleep per 24 h over the first 16 weeks from 16.3 to 14.8 h, the average daily continuous sleep period increased from 4 to 8.5 h over the 16 weeks. In conjunction with this change, the average longest daily period of wakefulness increased from 2.4 to 3.6 h. In the first week there were almost equal amounts of sleep during day and night, but by 16 weeks infants slept double the amount at night compared to the day.

There is an important relationship between two central infant activities: sleeping and feeding. Before 1 month of age the sleep–waking pattern is organized around 3–4 hourly feed times. Between 1 and 3 months of age, as the diurnal pattern begins to be established, it is also influenced by environmental and maturational factors (Kleitman & Englemann 1953). At around this time a redistribution of the sleep state takes place so that NREM sleep begins to dominate the beginning of the night and REM sleep later on (Hoppenbrouwers *et al.* 1982). Infants regularly experience brief periods of waking during the night but usually settle themselves back to sleep. Anders (1979) found that 2-month-old infants spent approximately 9% of the night 'sleep' awake, and this was reduced to 6% by 9 months.

Assessment of the sleep–wake cycle and sleep problems

The cornerstone of assessment is a careful history. Stores (1999a) suggested that three key screening questions should be asked about any child. Does the child experience:

- 1 difficulty getting to sleep or staying asleep;
- 2 excessive sleepiness during the day; or
- 3 disturbing episodes at night.

If positive answers are given for any of these, a detailed sleep history should be obtained. Careful questioning should be made of the full 24-h sleep–wake cycle (Ferber 1995; see Rutter & Yule, Chapter 7). Ferber (1995) suggested the sequence and timing of events should be obtained through each phase of the child's day in relation to sleep, beginning with the evening meal, later evening, going to bed, when asleep, waking and day time. A full history of the child's physical, emotional, health and development is also necessary. A sleep diary kept for a period of 2 weeks will provide a great deal of information which may be helpful in arriving at a clear diagnosis and in treating the problem. An assessment of the family relationships as well as the emotional state of the parents and other family members should be undertaken.

In a small number of cases physiological sleep studies, known as polysomnography, are required. These are likely to be useful in cases of excessive daytime sleepiness, complicated parasomnias and sleep apnoea (Stores 1999b). Polysomnography includes EEG, eye movement and muscle tone recordings, and from these the different sleep stages can be recognized. In children, home polysomnography is often useful rather than bringing them into a laboratory setting. An actigraph, which records body movements, is sometimes used and this can provide some basic information on sleep–wake patterns (for a review of assessment methods see Wiggs & Stores 1995).

Classification of sleep disorders in children

Sleep problems can be grouped into three main categories (Stores 1999b).

- 1 Sleeplessness, principally settling and night waking problems.
- 2 Excessive daytime sleepiness, caused by insufficient sleep, disturbed overnight sleep or increased sleep requirements.
- 3 Episodic disturbances of behaviour associated with sleep, known as parasomnias.

An additional section considers other conditions associated with sleep disorders. Most attention will be paid to settling and waking problems in young children, which are very common.

A comprehensive classification known as the International Classification of Sleep Disorders–Revised (American Sleep Disorders Association 1997) has been published separately from DSM and ICD and includes over 80 different conditions. It provides a number of groupings.

- 1 Dysomnias are primary sleep disorders which cause either difficulty getting off to sleep or remaining asleep, or excessive sleepiness during the day.
- 2 Parasomnias, which are subdivided according to the stage of sleep with which they are usually associated.
- 3 Sleep disorders associated with mental, neurological and other medical disorders.
- 4 Proposed sleep disorders, or conditions which require further

evaluation before being considered as sleep disorders in their own right.

Sleeplessness

Settling and night waking problems in young children

Nature and prevalence

Sleep difficulties consist of a reluctance or an inability to settle to sleep at the required time, repeated waking in the night with demands for parental attention as well as waking early in the morning. Children make very strong demands for parents to be present and become distressed if they leave (Stores 1996).

Approximately 20% of children aged 1–3 years (Richman 1981; Zuckerman *et al.* 1987) and 10% of children aged 4–5 years (Bax 1980) have significant problems in settling to sleep and waking at night. There is a significant risk that early sleeping problems will persist, with many studies finding that the best predictor of later sleeping problems is early sleeping difficulties (Richman *et al.* 1982; Jenkins *et al.* 1984; Scott & Richards 1990a; Scher 1991). Furthermore, Richman *et al.* (1982) in their large community epidemiological study found that 40% of children who had sleep problems at 8 years of age had such problems dating back to at least 3 years old. However, it should be emphasized that although there is clearly a significant risk that early sleep problems will persist, the majority do not.

Sleep problems are sometimes associated with other behavioural or emotional disturbances. Zuckerman *et al.* (1987) found that children of 3 years of age with persistent sleeping problems, compared to those with transient sleeping problems, were more likely to exhibit tantrums and behaviour management problems. Pollock (1994b), in a large epidemiological study, found that sleeping problems were associated with stomach aches, eating difficulties, headaches and temper tantrums.

Aetiological factors in settling and night waking

Many authors, such as Sadeh & Anders (1993), use a transactional model to understand children's sleep patterns, assuming that symptoms are dynamic and that there is a bidirectionality of effects. The influences on children's sleep patterns (settling and night waking in particular) can be divided into extrinsic factors (sociodemographic, cultural and parental factors) and intrinsic child factors. These factors are in turn mediated by parental caregiving interactions and the parent–child relationship.

Most reports on children's sleep patterns come from parents, whose own well-being may have been influenced by their children's difficulties. Their accounts of night waking depend on whether they have been woken themselves. Minde *et al.* (1993) compared parental diary records to videotapes of 28 children with sleep disorders and 30 controls, and found that children regarded as 'good sleepers' woke as often as 'poor sleepers', but soothed themselves back to sleep without disturbing anyone. This indicated that the critical difference between the groups

was that the good sleepers had the capacity to soothe themselves back to sleep, rather than that they woke less. In addition, parents vary greatly as to whether they perceive night waking to be a problem (Scott & Richards 1990b).

Sociodemographic and cultural factors. Factors reflecting adverse living conditions, such as overcrowding and poor housing, have generally been shown to be associated with sleep problems (Chavin & Tinson 1980; Scott & Richards 1990b). However, there does not seem to be a relationship with maternal education, socioeconomic class or maternal age.

The issue of cosleeping is a rather complex one. It is not particularly sanctioned in Western countries, although it is probably relatively common, while in many communities in other countries cosleeping is probably the norm (Morelli *et al.* 1992). It appears that sleep problems are largely reported in relation to cosleeping in cultures where it is not the norm. However, as most of the data available are from developed countries it is difficult to make easy generalizable judgements. In the laboratory, cosleeping mother–infant pairs have been shown by McKenna *et al.* (1990) to have more frequent brief arousals when sleeping together than when sleeping apart. A number of studies have shown that cosleeping is associated with increased sleep problems, particularly in slightly older children (Lozoff *et al.* 1984; Schachter *et al.* 1989; Madansky & Edelbrock 1990). In a recent study comparing cosleeping patterns amongst Japanese and US families, Japanese families were more likely to cosleep (Latz *et al.* 1999). Cosleeping was strongly associated with a variety of sleep problems such as bedtime struggles and overall stressful sleep problems amongst the USA infants, but was not associated with increased sleep problems amongst Japanese infants. This study suggests that cultural factors are important in influencing whether cosleeping is related to reported sleep problems. In particular, cultural factors are likely to influence parents' expectations of infant behaviour.

There has also been considerable interest in the relationship between cosleeping and the risk of sudden infant death syndrome (see section below).

Family factors. The one family factor that has been consistently found to be important is the mother's mental state. A number of studies have reported an association between maternal mood and sleep problems (Richman 1981; Zuckerman *et al.* 1987). Zuckerman *et al.* (1987) found that maternal depression at 8 months was associated with the persistence of sleep problems from 8 months to 3 years. In a prospective study of postnatal depression, Murray (1992) found an association between maternal postnatal depression in the first few months of life and sleeping difficulties at 18 months, at which time many of the mothers were no longer depressed.

Child factors. Both Carey (1974) and Sadeh *et al.* (1992) found that infants with sleep problems had lower sensory thresholds than infants without sleep problems, and the latter study also found lower adaptability in younger children with severe night

waking problems compared to controls. Richman (1981) and Schaefer (1990) found difficult temperaments amongst children to be related to night awakenings in a community and clinical sample, respectively, and more recently Halpern *et al.* (1994) confirmed that infant sleep–wake patterns (assessed by videotape) were related to temperament. Only the study of Keener *et al.* (1988) differs in that they did not find temperamental differences between infants who cried when they woke during the night compared to those who did not. Thus, in general, infant temperament does seem to be related to sleep–wake regulation and sleep problems.

A number of other infant factors have been linked to sleep disturbance. Specific difficulties during the perinatal period as well as infant irritability in the early weeks have been found to be related to later sleep difficulties (Bernal 1973; Blurton-Jones *et al.* 1978; Richman 1981). Such difficulties include prolonged labour, poor infant state at birth (e.g. longer time to first breath and cry, poor muscle tone and reflex irritability) as well as increased frequency of crying bouts in the first 10 days. Two non-mutually exclusive mechanisms are suggested. First, infants who go on to be poorer sleepers are neurodevelopmentally more vulnerable and less adaptable and, secondly, these early perinatal difficulties may lead parents to be more attentive and responsive at night with increased handling, making the infants more susceptible to sleep difficulties (Bernal 1973).

Caregiving patterns and the parent–infant relationship. The above influences on sleep–wake patterns are mediated through the parent–infant relationship. These include interactive behaviours such as breast/bottle-feeding, parental presence at sleep time, parental cognitions and behaviours, attachment patterns and separation anxiety.

The balance of research indicates that breastfeeding has an impact on the sleep–wake cycle, with breastfed infants waking more frequently than artificially fed infants. Wright & Crow (1982), Elias *et al.* (1986) and Eaton-Evans & Dugdale (1988) all found that breastfed infants were more likely to wake at night, although some earlier studies did not find this relationship (Bernal 1973). Breastfed infants have also been found to have fewer total hours of sleep (per 24-h cycle) during the first 2 years of life (Wright *et al.* 1983; Keane *et al.* 1988). While at 2 months of age breastfed infants have large feeds early in the morning and smaller feeds at the end of the day, by 4 months this pattern changes with large meals at the end of the day (Wright & Crow 1982). This is apparently adaptive in order to allow the infant to manage the longer sleep periods without having to feed. Parents of bottle-fed infants often introduce this pattern earlier on in an attempt to reduce overnight feeds.

Both Adair *et al.* (1991) and Johnson (1991) found that parental presence when the infant goes off to sleep is associated with sleep difficulties, especially night waking. The latter study also found that active soothing at bedtime was associated with not sleeping through the night.

Parental cognitions and attitudes have also been implicated in infant sleep problems. Morrell (1999) found that certain

parental cognitions were related to sleep problems, including difficulties with limit setting, resisting infant demands, as well as anger with infant demands and doubt about parenting competence. Furthermore, Scher & Blumberg (1999) found that first-born infants (although not infants born subsequently) of mothers who were rated as ‘facilitators’—who feel that the baby knows best and that the environment should be adapted to the baby—had more night waking at 1 year, compared to infants of mothers who were rated as ‘regulators’—who believe that the baby must adapt him or herself to the environment.

A number of authors have argued that the quality of parent–infant attachment relationships is likely to have a bearing on night settling and night waking and the development of sleep problems in young infants (Moore 1989; Anders 1994). Falling asleep alone and settling after waking during the night are said to be important aspects of early separation and individuation whereby the infant develops an autonomous self and deals with separation anxiety. A recent study by Morrell (unpublished data) examined the relationship between attachment security and persistent sleep problems by studying 100 infants, 40 with sleep problems and 60 without at 15 months and following them up 12 months later. He found that ambivalent attachment at 15 months predicted persistent sleep problems. Benoit *et al.* (1992) found a relationship between maternal insecure adult attachment classification and sleep disorders in young children, while Scher & Blumberg (1999) found that maternal separation anxiety from the infant was related to night waking, suggesting that the mother’s own attachment status and her separation concerns have a role in infant sleep–wake regulation. Sadeh & Anders (1993), based on their clinical experience, reported that separation problems in both parent and infant are the most common relationship issues underlying persistent parent–infant difficulties in resolving sleep problems.

As mentioned above, parent–child influences are bidirectional and persistent sleep disturbance can have a considerable impact on the parents and family (Chavin & Tinson 1980), although it is often difficult to disentangle the direction of causal relationships. This complex interplay between child factors and parental factors is well illustrated in a study by Quine (1992) of mothers of children with learning difficulties who had sleep problems. These mothers were found to have particular parenting difficulties, being more irritable, using more physical punishment and being generally more negative towards their children, compared to control mothers of children with learning difficulties but without sleep problems.

Treatment

The principal aim of treatment is to help the child to fall asleep without the involvement of the parents, and, if a child wakes, to be able to soothe itself and settle back to sleep without the parents’ help.

Medication. Medication is sometimes used but is not usually a first-line treatment and tends to be confined to short-term use,

usually in a crisis, to allow parents and children a chance to settle before behavioural programmes are introduced. In trials evaluating the use of medication—usually antihistamine hypnotics such as trimeprazine—there were some positive effects in treating night wakings in the short term but these benefits did not seem to last once the drug was stopped (Ramchandani *et al.* 2000). Furthermore, there was a considerable drop-out in these drug trials.

Behavioural treatments. Generally, the procedure adopted is to encourage parents to put the child to bed awake and then left alone for progressively longer periods with repeated brief reassurances. Where night wakings occur, the same process should be followed. For further details see Douglas & Richman (1984) and France & Hudson (1993).

A number of behavioural treatments for settling problems and night waking in young children have been subjected to treatment trials (for a systematic review see Ramchandani *et al.* 2000).

1 Positive routines consist of a set of positive winding-down routines usually to deal with bedtime tantrums. These include enjoyable but relaxing activities for 20 minutes prior to bedtime, beginning at the time the child normally falls asleep then gradually brought forward 5–10 minutes per week, until the target bedtime is reached. After completion of the routine, any resistance from the child is dealt with by the parents saying ‘It’s time for sleep’ and placing the child back to sleep if necessary (Adams & Rickert 1989).

2 Extinction or systematic ignoring, where parents go to the child when they hear the first cry, check that the child is not ill, change the nappy if necessary but do not pick up the child, soothe or feed in any way. Once the parent is reassured the child is not ill the parent leaves the room and does not return for the duration of the crying episode.

3 Graduated extinction (removing any reinforcing response to the child’s waking behaviour) in which parents ignore bedtime tantrums for preset time intervals, the duration of which is increased each week. At the end of the interval the parents enter the room and put the child back to bed, if necessary, and tell them it is time for sleep before leaving the room again after a maximum of 15 seconds.

4 Modified extinction involves the parents ignoring the child for 20 minutes and then checking the child is not ill but not picking the child up, soothing or interacting, or feeding the child. Once reassured, the parents leave the room and only return after the child displays the settling problem, waiting for a further 20 minutes. Some parents find extinction programmes unacceptable and drop out of trials (Rickert & Johnson 1988). Support visits are often given to the parents in conjunction with modified extinction every 2 or 3 days during the first 2 or 3 weeks of treatment.

5 Scheduled wakes: following the collection of baseline data, parents are instructed to wake the child 15–60 minutes before the child usually wakes spontaneously and to resettle them in their usual manner. The number and timing of schedule wakes

are then modified on a twice-weekly basis, depending on the child's sleep pattern during the previous few nights.

6 Educational booklets have also been tried (Seymour *et al.* 1989) as have sleep programmes which consist of individually tailored behavioural programmes using a variety of techniques with daily supportive telephone calls, decreasing in frequency over time, accompanied by a behavioural advice booklet.

In general, trials have shown that these specific behavioural interventions lead to improvements, with the various forms of extinction and scheduled awakenings showing reductions in night waking (Ramchandani *et al.* 2000). Adams & Rickert (1989) evaluated the effect of settling problems of two treatments: positive routines and graduated extinction. They found that both types of treatment were more effective than controls. There was some evidence that a specific educational booklet could be useful in sleeping problems (Seymour *et al.* 1989). In the trials that followed up the children (at 6 weeks or 3 months following treatment) the beneficial effects had generally been maintained.

Positive reinforcement can be used with slightly older children (3 or 4 years and above). The appropriate sleeping behaviour to be reinforced needs to be clearly defined and initially relatively easy to achieve, such as settling to bed quietly. Once achieved, the task is increased gradually until the child goes through the night without demanding parental attention. The usual reinforcers such as star charts are used. Parents are often willing to use this technique but relapses are more common.

Brief psychodynamic psychotherapy. Morrell (1999) noted that some parents dislike behavioural therapy, especially extinction techniques. This might be as a result of attachment difficulties and maternal cognitions concerning difficulty in setting limits, resisting infant demands, anger at infant demands and doubts about parenting competence. Morrell (1999) argued that this necessitates an approach that takes account of the parents' perceptions and feelings and the parent–infant relationship.

Brief psychodynamic psychotherapy for parents and their young children attempts to take account of these issues and may be more acceptable to some parents. One outcome study has shown some positive benefits for a variety of infant difficulties including sleep problems using this form of psychotherapy (Cramer 1995). Daws (1989) used a particular form of brief psychodynamic psychotherapy for parents and infants when an infant has a sleep problem and reports considerable success; however, this remains to be formally evaluated. This form of treatment deals principally with emotional and attachment issues rather than behavioural issues in trying to help parents to understand their feelings about their infant and in managing the infant's sleep. The therapist takes account of the infant's daily patterns of sleep and waking, the parents' memories of pregnancy and birth, their own past experiences and their thoughts about their relationship with the infant. In essence, the treatment links the meaning of not sleeping to deeper issues of separation and individuation between mother and infant, incorporating past and present experiences and relationships.

Sadeh & Anders (1993) used a model in which the infant is viewed as part of a system and sleep–wake is a mode of 'transaction', with attachment separation and individuation being the central issue. Their intervention also takes account of parental beliefs and expectations and enquires carefully into the way the nature of the attachment between parents and infant might relate to sleeping and waking. They provide a more focused intervention with a number of components: educational, psychodynamic (understanding the meaning of symptoms) and behavioural. However, until these forms of psychodynamic psychotherapy are subjected to formal evaluation, it is not possible to judge them in relation to other more established behavioural treatments.

Routines. One important issue, relevant to all types of intervention but particularly behavioural strategies, is that of daytime napping (Stores 1996). Two naps a day is usual at 6 months and one nap by 1 year, each nap not usually lasting more than 2–2.5 h. These naps may be taken at times of the day that complicate the sleep–wake cycle, for example, too late in the afternoon, or children may take too many naps. This may be a particular issue for children who have more than one caregiver throughout the day. The promotion of sleep 'hygiene' for children and adolescents is an important part of prevention as well as treatment. In particular, children need a sleeping environment with a comfortable familiar setting, correct temperature, a dark and quiet room, and non-stimulating, non-punitive parental behaviour. Parents should encourage bedtime or nap routines with consistent sleep and waking up times (Stores 1996). Parents often report that infants will only go off to sleep, or return to sleep, after feeding, which in turn leads to a large overnight food consumption and very wet nappies which lead to more waking. This can often be overcome by the promotion of a circadian pattern of feeding during the day and sleeping at night. This is usually most easily achieved by the reduction of night-time feeding (Stores 1996).

Impact of improving sleep patterns

There have been a number of reports indicating that where parents have been helped with the sleep problems of their young children, it can lead to improvements in maternal state, mother–child interaction and child behaviour. Wolfson *et al.* (1992), who provided parent training for infant problems, found that this led to improvements in the mother's emotional state and in her general confidence in her parenting abilities. Minde *et al.* (1994) found marked improvements following treatment, not only in sleep disturbance but in toddlers' daytime behaviour and in feeding interactions with their mothers. Thus, help for families to manage sleep disturbances can generalize to other aspects of infant behaviour and mother–infant interaction.

Sleeplessness in older preschool and school-age children

Bedtime struggles and other settling difficulties often continue in

older preschool and school-aged children where children refuse or delay going to bed. The problem is often maintained by parents' continuing difficulty in establishing and consistently enforcing rules about bedtime and settling to sleep. Many of these parents find it difficult to set limits in a clear and non-punitive manner (Stores 1996).

Night-time fears are common in childhood and may be one of the causes of children's difficulty in getting off to sleep or disturbance during the night. The cause of night fears depend on children's stage of development. Children's fears include those of the dark, shadows and monsters and they require comfort and reassurance. Where severe anxiety complicates these fears, they may be associated with nightmares. If these persist a more serious cause may need to be considered, such as family disruptions and traumas, and more intensive help for the family provided.

Sometimes children are physiologically unable to go to sleep at the times the parents wish them to, as in the delayed sleep phase syndrome (DSPS). This can occur at all ages. Children and adults have a period later in the day when they are alert and tendency to sleep is at its lowest, and this is followed by a period of least alertness, ultimately leading to sleep onset. If the child's bedtime coincides with this alert period then it is likely to lead to struggles. If the child is put to bed later when obviously tired and goes off without a struggle, DSPS is the likely cause of the problem. DSPS is often associated with difficulties in waking for school or preschool because the child's sleep requirements have not been fully met. The management of this syndrome is usually to gradually advance the sleep phase by first bringing the wake time forward, then the bedtime, and this should be maintained at weekends. This is continued until the desired sleeptime is achieved (for further details see Ferber 1986).

Sleeplessness in adolescents

There are considerable changes in sleep and wakefulness and the sleep-wake cycle as adolescence is reached. The amount of slow wave sleep decreases with an apparent increase in sleep requirements and the sleep phase is delayed. These changes are a result principally of lifestyle changes, particularly going to sleep much later at night, but also because of postpubertal biological influences.

Problems of going off to sleep are very common and are often part of a DSPS, and this is associated with considerable daytime sleepiness because sleep needs have not been met. Rates of insomnia in adolescence have been described as particularly high and this may be associated with other psychological problems (Morrison *et al.* 1992). There are a variety of potential underlying causes of these sleep problems in adolescence and they should not simply be interpreted as normal adolescent lifestyle. These difficulties include psychological/psychiatric problems such as stress and depression, the effect of prescribed drugs, hypnotics as well as illicit drugs, some of which produce insomnia, as well as alcohol, caffeine and nicotine. In cases where adolescents have chronic sleep problems, a very careful history needs to be taken.

Excessive daytime sleepiness

Excessive daytime sleepiness is a common problem which is frequently misinterpreted as disinterest or lack of motivation on the part of the child (Stores 1999a). This sleepiness is often associated with yawning, stretching, head nodding and eye rubbing. Many children may have associated behavioural problems as well as underfunctioning educationally. In particular, in some cases, school and learning problems may be attributable to insufficient and disrupted sleep. Although children who are sleepy may have low energy levels, they are often irritable, restless and sometimes even manifest overactive behaviour (Stores 1992). Increased sleep during the day should be distinguished from fatigue or lack of energy which may be secondary to physical illnesses. There are three principal causes of such excessive daytime sleepiness.

- 1 Insufficient sleep, including disturbances in the sleep-wake cycle.
- 2 Disturbances of overnight sleep as a result of medical conditions, such as obstructive sleep apnoea or parasomnias, drugs and alcohol.
- 3 Increased sleep requirements including narcolepsy and the Kleine-Levin syndrome.

Insufficient sleep is the most common cause of excessive daytime sleepiness for all the reasons already described. Adolescents are particularly prone to complain of daytime sleepiness. On the one hand, there is probably a physiological postpubertal need for more sleep, yet largely for social reasons adolescents sleep less at night (Carskadon & Dement 1987; Carskadon 1990). Furthermore, DSPS may be a particular problem.

Disturbed overnight sleep occurs when both the timing and the length of sleep are sufficient but the quality of sleep is disrupted. This may be caused by a variety of medical conditions, such as obstructive sleep apnoea, nocturnal asthma and epilepsy, the parasomnias (see below) and the effects of drugs and alcohol and caffeine-containing drinks. Recent research has focused particularly on obstructive sleep apnoea (characterized by sleep-related breathing difficulties) because of the physical and psychological effects on children's functioning (Carroll & Loughlin 1995a,b). Upper airway obstruction of some degree occurs in about 1% of children (Stores 1999b). In many cases in the normal population it is secondary to enlarged tonsils and adenoids in young children, but it is also associated with a variety of conditions: Down syndrome (Silverman 1998), Prader-Willi syndrome (Clift *et al.* 1994), craniofacial syndromes and other conditions which affect the upper airway. Typical signs include snoring (although only 10–20% of children who snore have upper airways obstruction), other evidence of breathing difficulty during sleep, restlessness, profuse sweating and some mouth breathing. Where there is partial or complete upper airway obstruction, there is a reduction in blood oxygen levels and/or raised CO₂ levels, leading to disrupted sleep physiology and intermittent awakenings. This in turn results in daytime sleepiness and can have an impact on the child's cognitive and behavioural development and, in very severe

forms, even lead to failure to thrive. In all cases careful assessment is required. Sometimes the removal of enlarged tonsils and adenoids is the key to relieving the obstruction. Where the pathophysiology is more complicated, treatment is often more difficult.

There are a number of conditions in which increased sleep requirements are part of the core pathophysiology of the condition, rather than being secondary to some other condition. The two most important conditions are narcolepsy, in which the excessive sleepiness is persistent, and the Kleine–Levin syndrome in which excessive sleepiness is intermittent.

Narcolepsy has a prevalence of about 1 in 2000 (Dement *et al.* 1973). It has a genetic predisposition, although the precise nature of the genetic susceptibility remains to be determined. The risk of a first-degree relative developing narcolepsy is 1–2% which although low is a lot higher than the general population (for a review see Mignot 1998). The condition tends to be lifelong and usually starts in adolescence. In this condition, REM sleep phenomena intrude into the awake state leading to daytime sleep attacks and hypnagogic hallucinations as a result of the dream element of REM sleep. The muscle paralysis associated with REM sleep can lead to cataplexy, when the subject suddenly loses all muscle tone and falls to the ground, as well as to sleep paralysis. The episodes of sleep last from seconds to 30 min. Overnight sleep is also disrupted by awakenings. As a result of all these disruptions children often experience serious academic problems.

Narcolepsy is often difficult to recognize in the early stages of the disorder as the characteristic sleep attacks may not be present in their full form. Support and counselling is an important part of the treatment. Medical treatment includes the use of stimulants, with modafinil usually being the treatment of choice, although methylphenidate, pemoline and sometimes tricyclic antidepressants are also used. The stimulants in particular should be used with caution. Regular sleep and good sleep routines, including planned naps during the day together with time of activities in relation to symptoms can be very helpful (Stores 1996).

Kleine–Levin syndrome is rare and typically begins following infection or some other type of stressful experience or injury in adolescent males (Stores 1996). It tends to occur in periods which last hours to weeks at intervals of weeks or months, interspersed with episodes of normality. During the episodes the subject sleeps for excessively long periods, overeats and displays hypersexual behaviour, and sometimes exhibits disturbances suggestive of a mild organic confusional state. There is a tendency towards spontaneous resolution but this may take many years. Stimulant medication may be used during episodes and positive results have been reported with lithium (Pike & Stores 1994). There are a number of conditions which are associated with excessive sleepiness, such as depression and non-convulsive status epilepticus.

Parasomnias

The parasomnias consist of a group of disorders involving episodic disturbances of behaviour or experiences associated with sleep and are especially common in childhood. Some of the parasomnias can be very worrying to families who often believe that they indicate a serious underlying psychological problem. In childhood this is rarely the case, although there are exceptions (Stores 1999a). The parasomnias are divided into a number of types.

Partial arousal disorders

Partial arousal disorders include night terrors, sleep walking and confusional arousals. Partial arousal disorders receive their name because they occur when there is a sudden change from deep NREM sleep to a lighter stage of sleep. As the largest proportion of deep NREM occurs in the first third of the night, these disorders most commonly occur at this time. In these conditions children appear to be awake but are actually asleep.

1 During night terrors children appear particularly distressed. These tend to occur in older children and adolescents. Usually the child screams, appears terrified, sweats profusely with staring eyes. Sometimes the child jumps out of bed and rushes around. It lasts no longer than a few minutes and the episode ends abruptly with the child waking up. The child should not be woken during the episode and be guided gently back to bed when the episode is over (Stores 1996).

2 Sleep walking, another form of partial arousal disorder, is common with up to 30% of children having experienced one episode and is habitual in about 2.5% of the population (Klackenberg 1987; Handford *et al.* 1991). Sleep walking can last up to 10 min and a safe environment and protection is most important.

3 Confusional arousals usually occur in infants and toddlers and last 5–15 min. They usually begin with movements and moaning before progressing to agitation and sometimes crying. The child appears alert but does not respond to being talked to (Stores 1996). These arousals do not have a psychological significance and tend to resolve spontaneously.

The management of partial arousal disorders usually involves the need for reassurance; occasionally practical steps need to be taken to avoid any accidental injury as in sleep walking, as well as preventing overtiredness. The promotion of a relaxed attitude to bedtime and help with daytime worries can be useful. Very rarely medication is required for severe cases. Lask (1993) has described a useful intervention for night terrors: anticipatory waking 10–15 min before an episode or episodes that are consistent in their time of occurrence.

Nightmares

Nightmares are frightening dreams that arise in the course of REM sleep; they tend to occur in the later part of the night when REM is most common. In this condition children wake up and

can recall the content of their frightening dream but can be comforted. The content of a nightmare may provide an indication of some underlying stress. Nightmares are common, reported as occurring in 1 in 5 children of 6–12 years in one large survey (Vela-Bueno *et al.* 1985). Treatment may be necessary if the nightmares are persistent and the child cannot be comforted. The treatment is of the underlying cause, and is especially important if the nightmares occur as part of a more serious condition, such as PTSD.

Sleep-related movements

Sleep-related head banging or other rhythmic movements are quite common, especially in children with learning difficulties, are usually benign and usually resolve spontaneously by 3–4 years of age (Stores 1999a). They are often seen as a self-comforting way of getting to sleep. Protective measures are an important part of management and occasionally behavioural treatment is required. A variety of behavioural approaches have been suggested (Balaschak & Mostofsky 1980).

There are a number of other parasomnias, including nocturnal enuresis (see P. Hill, Chapter 31) and hypnagogic and hypnopompic imagery ('hallucinations' accompanying sleep starts and sleep waking, respectively), which are common and not usually associated with any other problems.

Sleep disturbances associated with other conditions

Learning disabilities and neurodegenerative conditions

There is now considerable evidence that children with learning disabilities and neurodegenerative conditions experience high rates of disturbance which frequently go unrecognized and are often severe and persistent (Stores 1992, 1996). The origins of these difficulties tend to fall into three categories, although once the sleep disturbance has become established maintaining factors tend to be multifactorial. These causes are:

- 1 behavioural;
- 2 physical causes involving upper airway obstruction (see section on disturbed overnight sleep); and
- 3 central (neurological in the case of neurodegenerative conditions).

As far as behavioural causes are concerned, these often reflect parenting practices but should be seen in the context of nocturnal challenging behaviour that is often a feature of children with learning disabilities. Sleep problems are well described in a number of neurodegenerative conditions including Rett syndrome (McArthur & Budden 1998) and Angelman syndrome (Zhdanova *et al.* 1999). Nocturnal seizures may disrupt sleep but the seizures themselves should be distinguished from a primary sleep disorder (Stores 1996). It should be emphasized that, as with other sleep disorders, once the sleep disturbance is established it is likely to have an effect on daytime behaviour by exacerbating learning problems and raising the risk of daytime behavioural difficulties.

Sleep disturbance and psychiatric disorders

Disturbed sleep is a clinical feature of many psychiatric disorders and in some cases is part of the core psychopathology. Sleep disturbance in depression in children is well documented (Ryan *et al.* 1987). The difficulties include getting off to sleep, interrupted sleep and early morning waking, while a proportion of adolescents also complain of hypersomnia. One of the key features of PTSD is nightmares. These occur during REM sleep and therefore are more prominent towards the end of the night. They can be extremely persistent and disturbing.

Sleep disturbances in attention deficit hyperactivity disorder (ADHD) have been of considerable interest particularly because of the potential causal relationships involved, in that disturbed overnight sleep might lead to significant inattention during the day and even overactivity. Conversely, extreme activity and restlessness might in itself interrupt sleep. Furthermore, stimulant medication might interfere with sleep patterns. Parental reports have consistently indicated that children with ADHD have disturbed sleep, including difficulty in getting off to sleep and night waking (for a review see Corkum *et al.* 1998), with approximately 25–50% of parents of children with ADHD reporting these difficulties compared to 7% of controls. However, objective sleep studies have failed to produce consistent findings, except that children with ADHD do not differ from controls in total sleep time but do experience increased body movements during sleep. Recently, Picchetti *et al.* (1998) confirmed the increase in limb movements in sleep (with a proportion of children fulfilling criteria for period limb movement disorder) amongst children with ADHD compared to controls. Stimulant medication does affect sleep patterns by prolonging sleep latency and the length of onset to the first REM cycle but this is not thought to be at a pathological level (Corkum *et al.* 1998).

A number of studies have described both quantitative and qualitative differences in sleep patterns amongst children with autism and Asperger syndrome compared to controls (Patzhold *et al.* 1998). Children with autism are likely to experience some form of sleep difficulty at some time, such as repeated night waking, shortened night sleep and early morning waking. Richdale & Prior (1995) argue that sleep difficulties are related to the children's severe social difficulties and the consequent inability of these children to use social cues to regulate their sleep-wake cycle (Richdale & Prior 1995). There has been considerable interest in sleep difficulties in children with Tourette syndrome where both sleeplessness and parasomnias have been reported (Allen *et al.* 1992). Insufficient sleep, largely caused by extensive bedtime rituals, has been reported in association with obsessive-compulsive disorder (Rapoport *et al.* 1981).

Sudden infant death syndrome

Sudden infant death syndrome (SIDS) is the dominant cause of post-neonatal mortality in the UK and other Western countries, occurs during sleep, and accounted for 0.56 deaths in 1000 live births in 2000 in the UK (FSID 2000). The majority of deaths

occur before the age of 6 months. It peaks between the ages of 2 and 4 months coinciding with a time of significant changes in sleep organization and central nervous system maturation. It is not a homogeneous condition and the diagnosis is largely by exclusion if the death cannot be explained on clinical or post-mortem grounds (CESDI 1996).

A genetic susceptibility which may interact with environmental factors is suggested by a 5.8-fold increase in recurrence of SIDS within families (Oyen *et al.* 1996). The genetic susceptibility is likely to derive from a failure to respond to cardiorespiratory challenges during sleep. Kinney *et al.* (1995) found that failure to respond to cardiorespiratory challenges during sleep may result from decreased binding muscarinic receptor in the arcuate nucleus of SIDS infants, a structure which is postulated to be involved in cardiorespiratory control. One large study of 33 000 infants found that a significant prolongation of the Q-T interval, the period of repolarization in the cardiac cycle, is strongly associated with SIDS (Schwartz *et al.* 1998). Passive smoking has also been found to be a significant modifiable risk factor in SIDS; this includes smoking during pregnancy. Interestingly, established SIDS risk factors of pre-term birth and low birth weight were found in one study to increase the risk 15-fold amongst smokers but not at all amongst non-smokers (Schellscheidt *et al.* 1997).

There is considerable evidence that SIDS is associated with some aspects of the infant's sleeping environment. In particular, it has been shown to be associated with sleeping prone, and the 'back to sleep campaign' has resulted in a significant decrease in the rate of SIDS (CESDI 1996). There has also been particular interest in the issue of cosleeping. However, because of the associated potentially confounding risk factors it has been difficult to draw firm conclusions. In a recent large population-based case-control study, using parental interview concerning sleep practices in relation to SIDS, Blair *et al.* (1999) found that infants who shared their parents' bed and were then put back in their own cot had no increased risk. There was an increased risk for infants below 14 weeks of age who shared the bed for the whole sleep or were taken to, or found in, the parental bed. The risk was particularly raised for infants who shared a sofa with a parent. Infants who slept in a separate room from their parents also had an increased risk. However, once a variety of confounding factors, including those of socioeconomic disadvantage, maternal alcohol consumption, use of duvets, parental tiredness and overcrowding, were accounted for, the risk associated with being found in the parental bed was no longer significant. This suggested that it was not bed-sharing *per se* but the circumstances in which bed-sharing occurs that carries the risk (Blair *et al.* 1999). In conclusion, whereas the aetiology of SIDS is complex and much remains to be resolved, infant sleep environment and physiology are likely to be relevant.

Conclusions

In conclusion, there are a wide range of childhood sleeping and feeding problems. At one end of the spectrum there are difficulties such as occasional night waking and refusal of some foods that could simply be construed as variations of normality, depending on the caregiver's perception. At the other end of the spectrum there are severe problems that are ultimately likely to interfere with the child's development. As many of the problems are common and treatable but are not often picked up, they represent considerable public health issues. Parents may need guidance and help in the early months of the child's life in establishing healthy patterns of feeding and sleeping, as well as with early feeding and sleeping problems. If feeding and sleeping are well managed these can be positive experiences for the child. On the other hand, if more serious problems arise specialist referral may be necessary.

Attachment Disorders of Infancy and Childhood

Thomas G. O'Connor

Introduction

The knowledge base and currency of attachment disorders in clinical and social care settings has increased substantially in recent years. When Zeanah & Emde (1994) wrote the preceding version of this chapter in the last edition of this volume, there were very few empirical papers on attachment disorder and related behaviours and only slightly more clinical reports. Fortunately, because the concept of attachment disorder is now attracting systematic attention, we are now in a better position to evaluate its conceptual and clinical basis.

This chapter has four goals:

- 1 to review the history and development of the attachment disorder construct;
- 2 to examine the links between attachment theory and attachment disorder, and especially to identify how these ideas converge and diverge;
- 3 to review the evidence supporting the reliability and validity of the attachment disorders; and
- 4 to evaluate the limited data on intervention and clinical management.

A note on terminology is given in order to reduce the confusion concerning the concepts covered. Throughout this chapter, the term 'attachment disorder' is used to denote the diagnostic label, whereas the term 'attachment disorder behaviour' is used to denote a more general disturbance that may or may not meet diagnostic requirements. Use of the more specific terms 'disinhibited' and 'inhibited' attachment disorder (behaviour) is reserved for the particular proposed subtypes of disturbance. Finally, 'attachment theory' refers to the principles outlined by Bowlby, Ainsworth and others, whereas 'attachment behaviour' refers to the range of behaviours that form the basis of individual differences in the child–parent attachment relationship (e.g. proximity-seeking, exploration; see below); 'attachment classification' is reserved specifically for the categories of secure and insecure attachment derived from standard assessments.

* The terms 'disinhibited' and 'inhibited' are used throughout the chapter to refer to the two forms of attachment disorder discussed by DSM-IV and ICD-10. These terms correspond to 'reactive attachment disorder, disinhibited type' and 'reactive attachment disorder, inhibited type', respectively, in the DSM-IV and 'disinhibited attachment disorder' and 'reactive attachment disorder', respectively, in ICD-10. A diagnostic condition (disorder) is not implied unless specifically mentioned.

History and development of the attachment disorder construct

Although the first diagnostic definition of attachment disorder appeared in 1980 (DSM-III), some of the core behavioural symptoms were evident in writings on institutionalized children dating back over half a century. Indeed, one of the most remarkable features of attachment disorder behaviour is how consistent select features of the disorder have been described, despite widely varying theoretical dispositions and methodological sophistication. A second key feature underscored by a historical review is that the patterns of behaviour described did not fit existing diagnostic terms.

The consistency across reports is most evident for what DSM-IV (American Psychiatric Association 1994) and ICD-10 (World Health Organization 1992) refer to as the 'disinhibited'* form of attachment disorder (see section on detachment disorder for a more detailed discussion of symptoms and diagnostic requirements). In one of the earliest descriptions of the atypical social behaviour of (ex-)institutionalized children, Levy (1937) used the term 'superficially affectionate' to describe the behaviour of children toward others. Goldfarb (1943, 1945) also highlighted high rates of indiscriminate behaviour toward unfamiliar persons based on his observations of a sample of children in institutions in New York; he added that some institutionalized children demonstrated an 'excessive need for adult attention' that persisted long after they were placed in foster families. In their volume, *Infants without Families*, Freud & Burlingham (1946/1973) provided extensive observations of children being reared in a residential nursery without a consistent and selective attachment figure. They used the term 'indiscriminate exhibition' to convey the way in which some children eagerly approached complete strangers to show off their clothes or other belongings. The key finding was that this behaviour was found only in children 'who are emotionally starved and unattached' (Freud & Burlingham 1946/1973, p. 616). Provence & Lipton (1962) reported similar observations of 'indiscriminately friendly' behaviour toward strangers in their assessment of institutionally reared children.

Somewhat more contemporary research studies also signalled disinhibited behaviour toward strangers as a likely consequence of early institutional care, and suggested further insights into the phenomenon. In his study of 'affectionless psychopathy', Wolkind (1974) found that of the three syndromes that were

linked with institutionalization, only disinhibition toward strangers was associated with *early* institutional care. A separate UK study illustrated the further point that severe and non-specific deprivation was not necessary for the development of attachment disorder behaviour. Thus, children who, apart from the lack of a consistent caregiver, received adequate care in a residential setting exhibited ‘indiscriminately friendly’ behaviour (Tizard & Rees 1975). This behaviour diminished by the time the children were aged 8 years, with the degree of persistence greater among children with poorer post-institutional care (Tizard & Hodges 1978).

Echoes of the above reports are evident in very recent research on children whose early experiences were characterized by severe deprivation. One of the most important sources of data on severe attachment disturbance is the investigation of children adopted into Canadian or UK families after severe and profound deprivation in institutions in Romania. Predictably, each of the three intensive studies of behavioural adjustment following adoption all reported disinhibition in a sizeable number of children (Goldberg 1997; Chisholm 1998; O’Connor *et al.* 1999). These three studies are noteworthy in several respects. First, the kinds of attachment disturbances match what was reported in prior studies. Secondly, the disturbance was apparent in observational, interview and questionnaire methods. The multi-method validation of the behavioural pattern was a new and important extension of prior studies. Thirdly, each study attempted to assess the links between attachment disorder behaviour and attachment theory. In addition, findings from these reports provide a major source of data on the reliability and validity of attachment disorder. The results of these investigations are therefore detailed in the sections on theoretical links with attachment theory and attachment disorder below.

In addition to the reports of disinhibited behaviour in Romanian adoptees, parallel reports of disinhibited behaviour or superficial friendliness toward strangers were made by investigators studying children living in comparably neglectful circumstances, such as orphans in war-torn countries such as Eritrea (Wolff & Fesseha 1999).

A second proposed form of attachment disorder according to both ICD-10 and DSM-IV, the inhibited variety, has a much less clear historical and clinical basis, and existing links are tenuous. Furthermore, no doubt because of the continuing uncertainty regarding the basic phenotype, it is not yet certain if the behaviours thought to characterize an inhibited attachment disturbance cannot be incorporated into existing diagnostic categories. A small number of children with a history of very severe maltreatment have been described as having extreme fear and even terror of strangers (Goldfarb 1943; Albus & Dozier 1999). Descriptions of children who responded with detachment, such as those reported by Bowlby *et al.* (1952) and Bowlby (1982) in their work with children separated from their parents, may also be relevant, although the source of the stress in the caregiving environment is far less severe. Also, it is likely significant that the children had already established a (presumed positive) relationship with the parent. Additionally, attempts to interpret previ-

ously reported syndromes in infancy (Spitz 1946) in attachment disorder terms has been suggested (Call 1987) although, as in the previous cases, the connection with inhibited attachment disorder is questionable.

Historically, samples of institutional children were the most common source of reports of attachment disorder behaviour. However, residential rearing of that sort is nowhere near as common as it once was. Instead, much of the current interest in the attachment disorders is based on the large and growing number of children in the adoption and foster care system. Experiences of early and severely disrupted relationships with caregivers—by which we mean the virtual absence of any consistent relationship with a caregiver rather than simply inadequate care—may put some of these children at risk for severe attachment disturbances (Howe 1995). Accordingly, it may be that the kinds of risks experienced by children in some of the more recent reports of attachment disorders differ in important respects from the earlier work in this field.

Partly because of the increased popularity and somewhat indiscriminate application of the diagnosis in diverse settings and by diverse professional and lay individuals, there is now considerable heterogeneity in the descriptions of attachment disorder behaviour—especially when considered in the context of the homogeneity of reports from several decades ago. Subsequent sections of the chapter seek to offset the increasing uncertainty about the appearance and meaning of the disturbance.

Explanations for attachment disorder behaviour

An effort to codify what was known about the effects of severely disturbed or non-existent attachment relationships, namely those behaviours described above as ‘disinhibited’ or ‘inhibited’, was made in DSM-III (American Psychiatric Association 1980). However, confusion about the manifestation of attachment disturbance(s) was apparent in the early diagnostic description. Thus, the initial definition of attachment disorder was something of a misnomer because it included symptoms separate from the child–parent attachment relationship (e.g. failure to thrive). In addition, proposed criteria were contrary to what was known about the development of child–parent relationships (e.g. the criterion that the disorder be apparent before 8 months). Further diagnostic revisions improved the face validity of the criteria (at least relative to earlier reports of institutionalized children) but, as discussed in the next section, serious problems remain in terms of the phenotypic description, general conceptualization and link with attachment theory.

Previous reports of attachment disorder behaviour have, by and large, avoided detailed discussions of the mechanisms responsible for the disturbance; neither have they proposed testable hypotheses for advancing our understanding of the meaning of attachment disorder behaviour. There is, to date, a ready acceptance that attachment theory provides an explanation (in terms of both causes and effects) for attachment disorder behaviour. It is, despite the relative lack of necessary research, the dominant and perhaps only proposed framework. An exclu-

sive focus on attachment theory is bolstered by research on non-human primates (Kraemer 1992; Suomi 1999) and, more recently, investigations of the biological bases for relationships and their effects (Insel 1997; Carter 1998), which also draws heavily from attachment theory. These alternative lines of research reinforce the dominant position played by attachment theory and, in addition, help to anchor the behavioural disturbances within a sociobiological–ethological framework that is a hallmark of attachment theory. Given the importance of this topic, it is addressed in detail below.

Summary

A historical survey of the literature on attachment disorder behaviours reveals a remarkable degree of consistency, at least with respect to the disinhibited disturbance, but also uncertainty concerning the meaning of the behaviour and its place in psychiatric nomenclature. Several lessons are also noteworthy from prior research. Perhaps the most important of these is the need for further research on attachment disorder to focus on institutionalized populations of children or, more generally, children who lacked a selective or consistent attachment relationship from early life. Because the findings reported to date are most consistent in these populations, they provide a natural starting point and ‘test case’ for further conceptual and methodological study. A brief historical overview highlights parallels between the history of the concept of attachment disorder and attachment theory. Both were derived from a careful and systematic observation of children in institutional care or children whose experiences with caregivers were severely disrupted (Bowlby 1951, 1982). In addition, clinical and child care policy were the initial contexts for much of the interest in attachment theory and attachment disorders. However, while studies testing attachment theory in normal and at-risk samples proliferated in developmental and clinical psychology, attachment disorder behaviours were largely ignored. Several decades after Bowlby’s initial observations, attachment theory is being reconnected to the study of development following deprivation.

Theoretical links with attachment theory

Despite the label ‘attachment disorder’, it is by no means a foregone conclusion that the attachment disorders represent disorders of the child–parent *attachment* relationship as defined by Bowlby and Ainsworth and elaborated in subsequent developmental research. There are several reasons for this. First, attachment disorder behaviour has not yet been adequately conceptualized in terms of attachment theory. In this regard, it is noteworthy that diagnostic formulations focus on ‘social relatedness’ (DSM-IV) or ‘social responses’ and ‘selective social attachments’ (ICD-10). These phrases are not easily translated into attachment theory. Assuming that a selective attachment relationship had been formed (a dubious assumption in many cases of institutionalized children), a further, more interesting

and perplexing challenge is that the prototypical ‘disinhibited’ or ‘inhibited’ behavioural patterns differ substantially from attachment theory expectations (see below). If attachment theory is to clarify the nature and meaning of attachment disorders, then it will be essential to revisit the basic principles of the theory and identify convergences and divergences between the concepts underlying attachment theory and those associated with attachment disorder.

Some rudiments of attachment theory relevant to attachment disorders

Rather than provide a detailed review of attachment theory and the research methods devised to test aspects of the theory, this chapter highlights only those features that are directly relevant to attachment disorder. Discussions of attachment theory are available from numerous sources (Marvin 1977; Sroufe & Waters 1977; Ainsworth *et al.* 1978; Bowlby 1982; Cicchetti *et al.* 1995; Rutter 1995; Thompson 1998; Cassidy & Shaver 1999).

A starting point for discussion is to note some core components of the theory and highlight what is unique about attachment relationships and attachment behaviour (Bowlby 1982; Ainsworth 1989). First, attachment is but one of several components of the child–parent relationship, and so it is important not to equate parent–child relationships with attachment relationships. The implication is that, at least in theory, there may be some positive features of the child–parent relationship in attachment disordered children (e.g. play and casual social interactions).

A second key feature is that it is essential to consider the meaning or function of the attachment behaviours according to the setting and the child’s development (Bretherton & Ainsworth 1974; Bowlby 1982; Cicchetti *et al.* 1990). Thus, the meaning—in terms of attachment theory—of a child’s willingness to approach a stranger will depend on such factors as the presence of the attachment figure and child’s age (Rajecki *et al.* 1978). One particular application of this is that the significance of the DSM-IV symptom of indiscriminate sociability would be far greater in the absence of a current primary caregiver.

Thirdly, the development of child–parent attachment and its implications for social and personality development were constructed within what Bowlby (1982) referred to as the ‘environment of evolutionary adaptedness’. Rearing environments that severely breach this condition, such as institutionalization (but perhaps not maltreatment; see Ainsworth 1978; Rajecki *et al.* 1978), may not provide the environmental input that promotes species-typical attachment. This serves to illustrate Bowlby’s point that attachment evolved in a specific environmental context and, although protected from perturbations in the environment, it can nevertheless be fundamentally and critically modified. If the caregiving environment is outside the expected environment so as to severely modify or, in extreme cases, pre-empt the development of normal early selective attachment relationships, then the theory (as well as its implications for

assessment and treatment) would not be expected to apply. This theme is revisited throughout the chapter.

A fourth consideration in the bridging of attachment theory with the attachment disorders concerns the ontogeny of attachment relationships. Four stages in the ontogeny of attachment were discussed by Bowlby (1982).

- 1 At the simplest and most immature level, the infant orientates and signals with only limited discrimination.
- 2 At the second stage, the infant's orientation and signals are directed towards one (or more) discriminated attachment figure(s).
- 3 The third stage involves the 'maintenance of proximity to a discriminated figure by means of locomotion as well as signals' (Bowlby 1982, p. 299).
- 4 Finally, in the preschool years, there is the formation of a 'goal-corrected partnership', which accompanies the child's emerging ability to understand, to a limited degree, the parent's feelings and motives, and is capable to attribute internal states to him or her.

This increasing differentiation and 'focusing on a figure' is what appears to be lacking in children with attachment disorder, especially in those children with the disinhibited form. In the special case of institutionally reared children this is hardly surprising because there is no one particular person towards whom the child could direct and receive interactions and attachment/caregiving behaviours. It might therefore be tempting to view disinhibited behaviour as a 'developmental delay' in the normal ontogeny of attachment, and to assume that the formation of a new attachment relationship post infancy would proceed through the above four stages. In that instance, 'indiscriminate sociability' may be viewed as a necessary precondition for the emergence of later selective attachment relationships. Although there are no data directly relevant to this question (Provence & Lipton 1962; Shaffer 1963; Ainsworth 1967), this seems an unlikely possibility, not least because the stages of attachment are partly governed and co-ordinated by normally developing social, motor and cognitive skills (Cicchetti *et al.* 1990). Moreover, it is not yet clear how the first early signs of selective attachment behaviour would appear in preschool-aged children. Alternatively, it may be that the ontogeny of attachment behaviour in children who did not receive expectable environment/caregiving input is different from what Bowlby outlined. What is needed are systematic studies following the establishment of new attachment relationships, especially in children who experienced an absence of early care or severe maltreatment (Stovall & Dozier 2000). In addition, more detailed information on the development of attachment behaviours of infants in institutional or other forms of pathogenic care would be valuable in tracing the aberrant ontogeny of attachment relationships, although such information is naturally difficult to obtain.

A fifth consideration concerns sensitive periods in the formation of selective attachment relationships. The issue here is not whether or not early attachment relationships, once formed, have deterministic lifelong prediction—they do not (Bowlby 1988)—but instead the degree to which the *formation* of normal

selective attachment relationships requires consistent responsiveness from caregivers in infancy. A somewhat related concept is developmental programming, or the notion that experiences in early life may persistently influence how the individual responds to later experiences (Ladd *et al.* 1996). Relevant data are again limited, but extant findings indicate that 'normal' secure or insecure attachment relationships with supportive adoptive parents are less likely with prolonged periods of severe early deprivation and, more importantly, that children with such disturbances show little improvement in the short term (Chisholm 1998; O'Connor *et al.* 2000). The significance of this finding in terms of developmental theory is yet to be determined, although it is broadly in line with a sensitive period or developmental programming hypothesis. There are too few data directly relevant to sensitive periods or developmental programming for forming attachment relationships, not least because virtually all studies of attachment include children who had been reared by a biological parent since birth. Increasing applications of attachment theory to non-traditional settings will therefore provide much needed information about some of the outstanding issues for attachment theory (Rutter & O'Connor 1999).

A further issue that will need to be resolved before attachment theory and attachment disorders can be reconciled involves the assessment of whether a relationship is an *attachment* relationship. This issue is hardly relevant when children are assessed with biological parents with whom they have always lived (Ainsworth 1978), but it becomes critical in the case of children placed in the care of alternate adults beyond infancy. Interestingly, both the diagnosis (implicitly) and attachment theory (explicitly) imply that a child with attachment disorder would not have had a selective attachment relationship. A related concern is whether or not the attachment disorder is conceptualized in terms of a current relationship or instead as an effect of prior relationship experiences or, more generally, in terms of an individual or a relationship. This issue is discussed subsequently in this section. It is therefore essential to be able to define what constitutes a selective attachment relationship. Some suggestions for addressing this issue are provided in the assessment component of the section on attachment disorder.

A final issue that is relevant to creating an attachment theory-informed definition of attachment disorder is the fact that attachment theory extends beyond the particular behaviours associated with gaining proximity to, and maintaining contact with, an attachment figure. Attachment theory is also fundamentally concerned with exploration of the environment and managing and coping with fear/wariness and threat (Bowlby 1982). Indeed, the ability to describe and explain children's need for contact with caregivers as well as their tendency to leave caregivers in order to explore the environment sets attachment theory apart from rival explanations for the child–parent bond (Rajecki *et al.* 1978; Bowlby 1982).

The distinct behaviours that have received the most attention from attachment theory include attachment (gaining proximity to, and maintaining contact with, an attachment figure), fear/wariness, sociability, and exploration (Ainsworth *et al.* 1971,

1978; Bowlby 1982; Greenberg & Marvin 1982). These behaviours are co-ordinated, such that they may inhibit or potentiate one another. Feedback mechanisms have been proposed to explain why there appears to be some degree of connection among these behaviours (Bowlby 1982). There is as yet no direct test of the feedback or 'behavioural systems' hypothesis as originally proposed, but it serves as a heuristic for defining the larger context for attachment behaviours.

The most obvious example of the links among attachment-related behaviours mentioned above is of a child who, while exploring his or her environment, perceives fear. The reaction is to curtail play and seek proximity to an attachment figure. Thus, fear inhibits exploration and leads to an increase in attachment behaviour. The experience of safety and security from the attachment figure (reduction in fear) then promotes the child's return to exploration. This behavioural pattern illustrates what is meant by the parent acting as a 'secure base' for the child's exploration, and demonstrates that an understanding of the child's attachment relationship with a caregiver requires a detailed assessment of a range of behaviours and their interrelatedness. The need to assess the interrelatedness of attachment-related behaviours may be especially important when assessing attachment disorder because it is in this area that a disturbance may be most evident.

Given that the child has (or had) formed a selective attachment relationship, then the inhibited and disinhibited patterns of behaviour present a paradox to attachment theory because they violate this basic biologically programmed patterning of behaviour. A child who wanders off with a stranger without checking back with the parent, or a child who seeks comfort from a stranger when distressed is puzzling because of the merging of apparently contradictory behaviours (e.g. fear and *lack of* attachment behaviour). In the above examples, the expected outcome is that the child would increase proximity to an attachment figure rather than to continue to wander off or seek out a stranger.

A consideration of the behaviour patterns that underlie normal attachment behaviour raises several possible explanations for attachment disorders. It may be that attachment disorder is a disorder limited to one of the attachment-related behaviours. In this regard it is noteworthy that clinical and anecdotal reports indicate that fear/wariness is often disrupted in children with attachment disturbances, such that children exhibit minimal evidence of fearfulness toward strangers, even when some degree of wariness would be developmentally appropriate. On the other hand, given that there is often a reference to problems in excessive sociability, it may be that disturbance may be confined to this behaviour. A further possibility is that there is a specific problem in attachment behaviour—seeking out of attachment figures when distressed—however, there are, at least for disinhibited children, normal instances of such behaviour (O'Connor *et al.* 2001).

It may be beneficial, both conceptually and clinically, to interpret attachment disorder behaviour according to the behaviours and behavioural patterns emphasized in attachment theory.

However, there is an obvious and important caveat to this approach; it could be a mistake to interpret behaviour in terms of a theory that may not be directly applicable. Attachment theory and its developmental and clinical implications presupposes that a child has developed an early selective attachment relationship. For those children for whom that is not the case, such as institutionalized children, there may be a danger in trying to fit attachment-related behaviour into a framework designed for children with more conventional (or species-typical) attachment histories. Accordingly, a parsimonious explanation for attachment disorder behaviour is that it is a consequence of an absence of a selective attachment relationship. Whether or not there is additive explanatory value in discussing attachment disorder behaviour in terms of the interrelatedness of behaviours remains to be seen, although there is little doubt that such a disturbance exists, as noted below.

There is substantial evidence that the patterns of behaviour found in children who did not develop an early selective attachment relationship differ radically from normal expectations. Most importantly, each of the three studies of Romanian adoptees mentioned above found that some children were classified as 'securely' attached to the main caregiver but still exhibited inappropriately friendly behaviour toward the stranger, based on either behaviour in the separation–reunion paradigm or other sources of data (Goldberg 1997; Chisholm 1998; O'Connor *et al.* 2001). In other words, several years of sensitive and responsive care from the adoptive parent may have provided the basis for the child's attachment behaviour to the adoptive parent, but the expression of apparently normal proximity-seeking and secure base behaviour may exist alongside continuing disturbance with respect to fear/wariness or sociability. On that basis, it would be a mistake, as Bowlby (1982) anticipated, to refer to these children as securely attached, not according to their behaviour toward parents *per se*, but because the organization of attachment-related behaviours is disturbed.

Although no data directly test the above explanations for attachment disorder, this approach does have some advantages over alternative proposals. It is sometimes proposed that the disinhibited behaviour of children is strategic—expressed with the intent of attracting care from potentially protective and caring adults. This explanation is possible, but has a number of drawbacks. Disinhibited behaviour is observed in very young children, including children whose cognitive capacity for such a strategic approach seems doubtful. Relatedly, many of the children with disordered behaviour exhibit marked deficits in social understanding—quite the opposite of what would be expected given the fairly sophisticated social understanding and perspective-taking that would be required to enlist strange adults to be prospective carers.

Individual or relationship disorder?

Both DSM-IV and ICD-10 require that the child's attachment disturbance be evident across social settings. Thus, the assump-

tion made by diagnostic systems is that an attachment disorder is not a disorder confined to a particular current relationship, although it may derive from a specific pathogenic relationship in the past. This requirement is in line with general assumptions about diagnoses (e.g. that they be characteristic of the individual), but presents particular problems for integrating attachment disorders with attachment theory in young children. That is because research on child–parent attachment in young children focuses on the relationship rather than the individual as the unit of analysis. Individual children are coded as ‘secure’ or ‘insecure’ according to research methods, but it is the relationship that is so described. The relationship-specific nature of children’s attachments is supported by findings indicating that a child develops different relationships with different caregivers (Anders 1989; Steele *et al.* 1996).

The relationship-specific focus of attachment theory is obviously important and has been beneficial for conceptualizing development and for designing treatments (Lieberman 1991). Both attachment-based research and clinical work with normal and at-risk populations emphasize the problems of assuming that a secure or insecure attachment can be ‘localized’ in the child. On the other hand, it is probably a mistake to adopt a strictly relationship-based approach to defining attachment disorder and to dismiss the diagnostic requirement that the child exhibit marked disturbances across social and relationship settings. In this context, it is important to distinguish between the qualities of the current relationship as such from the *effects* of earlier relationships on current relationships. For instance, an attachment disorder observed in a child with a foster or adoptive parent may have comparatively little to do with the current relationship and much more to do with the effects of prior experiences of deprivation or neglect. Further appreciation of the carrying forward of effects from prior relationships to current relationships must therefore figure in further diagnostic refinements. After all, one of the reasons secure or insecure attachment classifications are meaningful is that they have relevance to the child’s adaptation outside the specific child–caregiver relationship context (Sroufe 1983; Cassidy *et al.* 1996).

Underlying the question of whether the attachment disturbance lies within the individual or the relationship is the further question of what explains cross-setting and cross-relationship consistency and longitudinal stability in the child’s disturbed behaviour. One possibility is that the carrying forward of effects of earlier relationships (across setting or through time) is explained by an internal working model: the child’s internalized cognitive schema or set of expectations for predicting others’ behaviour and for making evaluations about the self and others (Bowlby 1982; Bretherton 1990). There is growing evidence for such a mechanism in normally developing and at-risk children (Bretherton & Munholland 1999). It remains for further clinical research to examine if the internal working model account provides the best explanation for cross-setting and cross-relationship disturbances found in children with attachment disorder. At present, the strongest rationale for maintaining the

cross-setting/relationship criterion is that it would clearly differentiate children with potential attachment disorders from those with a more ‘focused’ disturbance with a particular caregiver (who may be better described in terms of a parent–child relational problem, a ‘V’ code in DSM-IV). What is needed is an account of this continuity that lends itself to further study.

What is the connection between attachment disorders and attachment classifications?

Initially derived from a comparatively small longitudinal study of infants in the USA (Ainsworth *et al.* 1978), the distinction between ‘secure’ and ‘insecure-avoidant’ or ‘insecure-ambivalent’ classifications for describing individual differences in child–parent attachment have proved to be remarkably robust (van Ijzendoorn & Sagi 1999). Nevertheless, problems with the three-way classification scheme surfaced when attachment researchers turned their attention to high-risk samples, notably maltreated children and children of parents with severe psychopathology (Radke-Yarrow *et al.* 1985; Cicchetti & Barnett 1991). A sizeable number of high-risk children did not satisfy criteria for insecure-avoidant, insecure-ambivalent or secure classification, but instead demonstrated a mixed, confused or overtly disturbed pattern (Main & Solomon 1990). The response was to define a fourth classification: ‘insecure-disorganized’. A substantial literature has emerged in the past decade on this pattern in infancy and its aetiology, prevalence in high-risk samples and connection with psychopathology (Lyons-Ruth 1996; Carlson 1998; Vondra & Barnett 1999). Similarly, the preschool extension of the infant classification system (Cassidy & Marvin 1992) also makes allowances for more severe forms of insecurity, ‘insecure-controlling’ and ‘insecure-other’ classifications, in addition to ‘insecure-disorganized’.

Attachment researchers resist attempts to equate an insecure attachment classification with psychopathology or disorder by emphasizing the role of attachment vis-à-vis a developmental trajectory that may be more or less likely to lead to maladaptation and psychopathology (Bowlby 1988). Nevertheless, not all authors completely reject the notion that some severe forms of attachment insecurity might be tantamount to disorder (Zeanah *et al.* 1993). The contrast between these two positions may partly stem from the substantial difficulty in assimilating attachment classifications and attachment disorder.

Importantly, most investigations indicate that the existing insecure categories adequately account for the disturbed attachment relationships found in clinical samples, even in those with well-characterized forms of developmental delay (Barnett *et al.* 1999; Waters & Valenzuela 1999). Furthermore, there is no suggestion in these lines of investigation that attachment problems can be described in terms of the atypical patterns described in children with attachment disordered behaviour. Indeed, the fact that the traditional observational assessments and coding procedures are applied, albeit with some modifications, implies that the pattern among attachment, exploration, fear/wariness and sociability behaviours is thought to be normal. Nor is there

evidence yet reported that the most severe forms of insecure attachment ('disorganized' or 'controlling') are accompanied by 'indiscriminate sociability' or other hallmarks of attachment disordered children, although further research is needed to determine whether some of the atypical or 'contradictory' behaviours and sequences found in children classified as 'disorganized' are analogous to the symptoms included in DSM-IV or ICD-10. An implication of the above discussion is that insecure attachment is qualitatively different from the disturbance implied by attachment disorder. The possibility that the 'disorganized' insecure attachment might signal more severe disturbance and therefore command greater clinical and perhaps diagnostic attention is discussed in the next section.

Until recently, there were no data that directly examined the association between the standard secure and insecure classifications derived from separation–reunion procedures and attachment disorder behaviour. This gap has now been filled by findings from the three studies of Romanian adoptees referred to above. The similarities among studies, despite the different methods employed, suggest that some weight may be placed on the findings. In the current context, some of the key findings were that although some children exhibited apparently secure behaviour toward the parent, their excessively sociable and disinhibited behaviour toward the stranger undermined a secure classification; in addition, many children could not easily be classified into one of the existing categories (O'Connor *et al.* 2001). These findings support the previous view that there may be a qualitative difference between current attachment classifications and attachment disorder behaviour. In addition to raising obvious conceptual and clinical questions, these findings raise the equally important methodological point that very misleading conclusions might be drawn if children with attachment disorder are assessed using conventional observational assessments and coding procedures.

Summary

Considerable theoretical and empirical evidence indicates that child–parent attachment quality significantly influences the development of psychopathology (Bowlby 1977, 1988; Greenberg 1999). However, a clear distinction needs to be drawn between these research findings, derived almost entirely from children with conventional (species-typical) attachment histories, and the emerging interest in the much less well-understood concept of attachment disorder. The reason for this suggested disjunction is that the connection between attachment theory and attachment disorder is unresolved. There is the further concern that recent diagnostic formulations have explicitly attempted to resist a particular theoretical account of behaviour or a specific explanation for its origins. Trying to fit attachment disorder within the context of attachment theory—however successfully—runs counter to this approach. A key concern with the current state is that a connection between attachment theory and attachment disorder has been widely in-

ferred when, in fact, the actual fit between these concepts is weak. There is therefore a need to either reformulate attachment disorders according to attachment theory, which would require a near complete overhaul of the current diagnoses, or to make more explicit that the term 'attachment disorder' is not meant to imply any direct link with attachment theory. Given the information now available (reviewed in this and the following section), the latter approach may be preferable. Attachment theory may help elucidate the disturbed and puzzling behavioural pattern captured by attachment disorder, but for conceptual, methodological and clinical reasons it may be neither possible nor desirable to force an integration of attachment theory and the current definitions of attachment disorder. One important lesson for further research is the need for more cross-discipline research and a greater correspondence between academic attachment research and research in social work and applied settings (Rutter & O'Connor 1999).

Attachment disorder

Despite the long history of reports on disinhibited, inhibited and related disturbances and more than 20 years in the psychiatric nomenclature, we know very little about attachment disorder *per se*. Consequently, it is very difficult to review what is known about attachment disorder *qua* disorder because there are virtually no data on aetiology, comorbidity, prevalence or longitudinal course, and certainly not enough to justify a review. Accordingly, the research findings that are reviewed below are dominated by the somewhat more general disturbance of disinhibited behaviour. It remains to be established whether the findings regarding this general disturbance can be applied to the diagnosable disorder.

Phenotype and phenomenology

One notable point of agreement between DSM-IV and ICD-10 is that there are two forms of attachment disorder, although the labels used differ slightly between nosologies. As reviewed above, there is substantial support for the core behavioural element referred to as the 'disinhibited' form. In reports of institutionalized children this phenotype is most often described as 'indiscriminate friendliness', which conveys that it is not necessarily attachment behaviour that is expressed toward strangers but simply social, affectionate or excessively familiar (e.g. physical proximity-seeking) behaviour. However, the term 'indiscriminate friendliness' is misleading in other respects. The behaviour in question seems neither genuinely 'friendly' nor 'sociable', but instead superficial, impersonal, shallow and rarely reciprocal (Tizard & Rees 1975; O'Connor *et al.* 1999). Nor is the behaviour truly indiscriminate, although children may fail to demonstrate consistently discriminating attachment behaviour toward primary caregivers. Undoubtedly, one benefit of extending research in this area will be more precise symptom descriptions.

Diagnostic formulations of the disinhibited phenotype also require disturbed interactions with others (strangers), defined as ‘indiscriminate sociability’ (DSM-IV) or ‘indiscriminately friendly behaviour’ (ICD-10). Importantly, both DSM-IV and ICD-10 also make the additional specification that the phenotype also include disturbed *attachment behaviour* but, unfortunately, the meaning of attachment behaviour is not always clear (e.g. as noted above, behaviours as seemingly different as proximity-seeking and exploration can be viewed as attachment related). For example, in DSM-IV, evidence of ‘marked inability to exhibit appropriate selective attachment’ is potentially useful, but the notion of ‘diffuse attachments’ is not (and is an oxymoron).

The inhibited attachment disorder phenotype (or ‘reactive attachment disorder’ in ICD-10) is much less well developed than the disinhibited variety. Thus, the inhibited phenotype includes behaviour that ranges from ‘a persistent failure to initiate or respond . . . to most social interactions’ (DSM-IV) to highly ambivalent, avoidant or aggressive behaviour. The absence of relevant empirical data is hardly surprising given the diverse and contradictory ways in which this phenotype is defined. It is difficult to see how the imprecise diagnostic criteria will facilitate progress in describing and understanding the phenotype.

Both diagnostic systems are in agreement that the two attachment disorder phenotypes can be distinguished. Moreover, the almost mutually exclusive kinds of disturbance implied by the two phenotypes would suggest that there would be little overlap between the two forms. The UK study of Romanian adoptees (O’Connor *et al.* 2000) reported some of the only available data on this issue. That study supported a distinction between disinhibited and inhibited symptoms and between disinhibited and inhibited individuals, but there is a need for further research on other samples.

Several further points need to be made about the diagnostic phenotypes. First, both DSM-IV and ICD-10 specify an onset before age 5 years. Second, it must be established that the attachment disorder behaviour is not solely accounted for by developmental delay or pervasive developmental disorder. These points are generally accepted. Third, the criterion of cross-situational impairment was discussed above in the context of the debate about individual or relationship disorders. The need for modification in this instance depends on the degree of desired congruence with attachment theory. Fourth, present diagnostic proposals focus on the current behavioural abnormalities in the context of the current (presumed) attachment relationship. Symptoms not directly related to the current attachment relationship are not included. Nevertheless, consequences of early severe pathogenic care extend beyond the child’s relationship with subsequent caregivers, most notably to problems in peer relationships (Rutter 1981; Hodges & Tizard 1989). It may therefore be useful to consider expanding diagnostic criteria to symptoms linked with early severe deprivation rather than strictly in terms of the current relationship. The final criterion, that there be a history of pathogenic care, is discussed below.

Alternative definitions of the phenotypes

Attachment disorders may be best viewed on a continuum of disturbance rather than as a pure categorical distinction, because evidence from studies of other forms of psychopathology supports a dimensional approach. The difficulty has been in deciding on what continuum to place attachment disorders. In particular, the section on theoretical links with attachment theory highlighted the ambiguous connection between the current definitions of attachment disorder and attachment theory, and the problems in relating the two. Lieberman & Zeanah (1995) and Boris & Zeanah (1999) sought to place attachment disorders on a continuum or spectrum with attachment classifications found in typically developing and high-risk children. This required a complete reformulation of the definition of attachment disorder. The strength of their approach is that it is anchored within attachment theory, and seeks to bridge the research on disorganized and severe forms of insecurity with attachment disorder. A key feature of their alternative definition of attachment disorder is the creation of a category of ‘disorders of non-attachment’ (Howe 1995). This group of children would include those who would meet the current DSM-IV and ICD-10 criteria. On the other hand, a potential liability of this approach is that it does not elucidate how, or if, the attachment theory framework described by Bowlby and others applies to children who experienced severe pathogenic care and exhibit disorders of non-attachment. It remains to be seen if this alternative definition provides conceptual, clinical or empirical advantages over the established psychiatric classifications.

A further possibility for refining current definitions of attachment disorder is to pay greater attention to the ‘disorganized’ insecure classification that has been subjected to rigorous study in the developmental and clinical literature. As noted above, the origins, links with psychopathology and longitudinal course of children classified as ‘disorganized’ in conventional assessments have been well documented (Solomon & George 1999). This is not to say that the ‘disorganized’ classification is tantamount to disorder or that it has any particular similarities to the existing forms of attachment disorder; neither seems to be the case. Instead, the case for focusing on ‘disorganized’ attachment is that it is known to be a risk for psychopathology (Greenberg 1999) and that it is often superimposed on the standard secure and other insecure categories, suggesting at least indirectly that the qualities described as disorganized may be separable from secure or insecure attachment *per se*. Furthermore, a number of authors have suggested that the links between attachment and psychopathology are greatest in the context of children classified as having a disorganized relationship (Boris & Zeanah 1999; Greenberg 1999). There are a number of limitations in attempting to extend further the connection between ‘disorganized’ attachment and a disorder of attachment. Not least of these is that the base rate of ‘disorganized’ attachment is higher than would be expected for a particular disorder of childhood and that, at least to date, a ‘disorganized’ classification is possible only with the use of the Strange Situation assessment

(Solomon & George 1999). Nevertheless, compared with the very limited information available on the inhibited form of attachment disorder, the clinical prospects for further research on ‘disorganized’ attachment are promising.

Numerous alternative approaches have been proposed to define attachment disorder, and some even include checklists and cut-off scores. Unfortunately, these other alternative definitions suffer from several severe problems, such as the absence of a clear conceptual foundation and the inclusion of separate—albeit co-occurring—symptoms, including symptoms as far afield from attachment as learning difficulties. This latter set of alternative definitions, which are much more akin to the more general and vague notion of institutional syndrome, will only lead to further confusion about the attachment disorder phenotypes.

One limitation of all proposed definitions of attachment disorder is that they focus exclusively on behaviour and on young children. Assuming that attachment disorder can persist past early childhood, what do the phenotypes look like in middle childhood or beyond? Few hints are available. In their longitudinal study, Tizard & Rees (1975) and Tizard & Hodges (1978) noted excessive talking and, from teacher reports, persistent conversation as possible markers of disturbance so there is a suggestion that there may be verbal as well as behavioural signs of disinhibition. Our own clinical observations also suggest that intrusive or personal questions and persistent questioning (without apparent genuine regard for the answer) may be important components in older children. In addition, unawareness of social boundaries and marked deficits in social understanding and interpretation of social cues may be sociocognitive features that are associated with, or part of, attachment disorders in older children. Even less is known about the more specific attachment concept of ‘internal working models’ of relationships in children with attachment disorder. Describing the sociocognitive underpinnings and correlates of attachment disorder is a next important stage for research, and could lead to avenues for intervention.

Finally, phenomenological accounts are all but non-existent and must await developmentally informed clinical research. Regardless of the outcome of further investigation, clinical observations attest to the significant parental concerns raised about the child’s safety and about the child’s difficulties in establishing relationships with others. Parents also frequently report considerable distress about the difficulty of forming a psychological connection with the child. These latter features also require research interest and clinical attention.

The remaining sections on comorbidity, prevalence, aetiology and course are concerned with the disinhibited form of attachment disorder. There is virtually no parallel or supporting evidence for inhibited attachment disorder; the implications of this for current and future diagnostic formulations are considered in the section.

Comorbidity, disorder spectrum and associated features

Attachment disorders must be distinct from other behavioural and cognitive problems if they are to be viewed as a viable clinical entity (Cantwell & Rutter 1994). The limited available evidence for disinhibited attachment disorders suggests that they are distinct from other disorders.

It is not surprising that cognitive delay figures prominently in many of the case reports of attachment disorders because the circumstances necessary for the development of attachment disorder might also lead to moderate to severe developmental delay. Fortunately, there is unambiguous evidence that disinhibited attachment behaviours are distinguishable from developmental delay. The strongest support for this position comes from the research of Tizard & Rees (1975) on ex-institutionalized children. The key feature of that research is that some children exhibited indiscriminate friendliness despite being cared for in all respects—except for the absence of a consistent caregiver—and had an IQ within the normal range. Moreover, even in a sample of deprived children, some of whom exhibited severe cognitive delay, attachment disorder behaviour was distinguishable from cognitive delay (O’Connor *et al.* 2000).

There is also modest but consistent evidence that disinhibited attachment disorder behaviour overlaps with, but is not identical to, other behavioural problems in children. In the first instance, available case study material (reviewed above) indicates that although co-occurring problems are sometimes evident in children presenting with disinhibited attachment disturbances, the form of the coincident psychopathology varies. Empirical evidence is much more limited, but also indicates that the overlap between disinhibited attachment disorder behaviour and other forms of psychopathology varies from minimal to moderate. In the sample of children adopted into the UK following deprivation in Romania, a modest correlation was obtained between parent- and teacher-reported emotional and behavioural problems and disinhibited attachment disorder symptoms. An overlap with attentional/hyperactivity problems was suggested as potentially especially noteworthy (O’Connor *et al.* 2000). Analyses also reveal that attachment disturbances can be distinguished from co-occurring ‘institutional’ syndromes (Wolkind 1974; Rutter *et al.*, 2001).

The relevance of aggressiveness as a comorbid symptom is perhaps especially controversial. In some case reports (Howe & Fearnley 1999), the authors have placed much weight on aggressiveness as a core feature of the disturbance, rather than as a co-occurring problem (see also ICD-10). Most of these reports are of children with a history of severe maltreatment. By contrast, studies of institutionalized children have not, by and large, emphasized aggressiveness as a common outcome, either on its own or in combination with attachment disorder behaviour (Tizard & Hodges 1978; O’Connor *et al.* 2000; Rutter *et al.*, 2001). Indeed, passivity rather than aggressiveness has long been associated with institutional rearing (Goldfarb 1945). Consequently, at present it may be best to view aggressiveness

not as part of the attachment disorder phenotype, but rather as a distinct co-occurring problem, with its roots probably in the history of severe maltreatment that preceded the disruption. Many other kinds of clinical problems are noted in reported cases, including eating problems, self-injurious behaviour and post-traumatic stress disorder, but few symptoms are consistently and systematically reported to co-occur with attachment disorder symptoms.

At present, it is best to maintain more narrowly defined definitions of attachment disorder rather than suppose that other distinct disturbances (such as conduct disorder) are part of the phenotype. However, if there is a move to extend the diagnostic boundaries of disinhibited attachment disorder, then the most likely extension would be toward including symptoms known to be associated with early severe caregiving deprivation. One commonly reported feature of children with (a history of) attachment disorder is an impairment in peer relationships (Freud & Burlingham 1973; Hodges & Tizard 1989; O'Connor *et al.* 1999). It is not yet clear from existing research if peer problems are an expression of a more general disturbance in social and attachment behaviour with adults, or if disturbances in peer relationships index a separate — albeit related — difficulty linked with early deprivation. Two sets of findings are noteworthy in this regard. First, there is evidence from the UK study of Romanian adoptees that problems in peer relationships could not be entirely explained by disinhibited attachment disorder behaviour (O'Connor *et al.* 1999). Specifically, in only a relative minority of cases did attachment disturbance extend to the peer domain. Secondly, primate research also suggests partly separate developmental lines for child–parent attachment behaviour and peer relationship behaviour (Freud & Dann 1951; Suomi 1999). Thus, although disturbance in peer relationships is a frequent characteristic of disinhibited attachment disordered children, these clinical phenomena may have somewhat different aetiologies and developmental courses. Further investigation of the sociocognitive correlates of attachment and peer problems may help to resolve this issue.

Prevalence

The rate of attachment disorder is thought to be very low, but the actual prevalence has remained a mystery since its inclusion in the psychiatric nomenclature. The diagnostic precondition that children exhibit attachment disorder in response to pathogenic care probably contributes to the uncertainty about the disorder prevalence because there is no consensus about what constitutes pathogenic care. As a result, it is not clear what population of children would need to be sampled in order to derive a prevalence estimate. If, for example, documented child maltreatment constituted 'pathogenic care', then a very sizeable number of children could be 'at risk' for the disorder. In the USA, this may involve more than 1.5 million children each year (National Research Council 1993; Sedlack & Broadhurst 1996).

Alternatively, given that most reports of disinhibited attach-

ment disorder derive from the residential, foster care and high-risk adoption settings, these may be the populations that will be informative for estimating the prevalence of attachment disorder. Even if the latter groups (or a particular subset) were thought more appropriate for a study of disinhibited attachment disorder, the scope of the problem could still be very dramatic. That is because the number of children who experienced protracted periods of foster or residential care and/or multiple care placements (usually following documented maltreatment) is large, at least in the USA and UK (Shealy 1995; Minty 1999).

The UK study of Romanian adoptees provides partial insight into the likelihood of severe disturbance following grossly pathogenic care. In a sample of 154 children (which excluded children who met criteria for pervasive developmental disorder), severe disturbance was found in 29 (19%) children at age 6 years (O'Connor *et al.* 2000). However, the finding that duration of exposure to deprivation was strongly associated with the rate of severe disinhibited behaviour (e.g. 7% in children adopted into the UK by age 6 months but 31% in children adopted between 24 and 42 months) further underscores the need for a clearer definition of pathogenic care. Should the definition of pathogenic care consider both severity of care and developmental timing (age)? Does severe deprivation limited to the first 2 months of life satisfy the pathogenic care criterion?

It remains for further research to reconcile the large numbers of children who may be at risk for disinhibited attachment disorder with the apparently rare occurrence. Because of the way the diagnosis is defined, research on the prevalence of this disorder cannot be separated from research on aetiology.

Aetiology

The criterion that 'pathogenic parental care' be included in the diagnosis of disinhibited attachment disorder is controversial on conceptual grounds (Zeanah 1996). One of the immediate difficulties is the failure to recognize that while poor parental care and insecure attachments are known to contribute to the development of a range of childhood disorders, from emotional problems to conduct disturbances, symptom lists for these latter disorders make no mention of parental care or causality. However, despite the problems of including pathogenic care as a symptom, few would doubt that pathogenic care has an essential aetiological role. We can draw some further aetiological conclusions from available data, although the uncertainty about what qualifies as pathogenic care pre-empts an adequate understanding of aetiology, as noted above.

First, individual differences within the normal and at-risk range of caregiving are most probably irrelevant to the origins of disinhibited attachment disorder, although perhaps not to its longitudinal course. The primary reason for suspecting that this is the case is the observation that the disinhibited attachment disorder phenotype appears qualitatively different from the attachment relationships described in normal and at-risk samples. Moreover, studies of normal and at-risk populations have not

identified behaviour patterns that resemble those found in disinhibited attachment disordered children.

Second, despite the very limited evidence on the origins of inhibited attachment disturbance, some authors have suggested that the aetiologies of the disinhibited and inhibited forms of attachment disorder may be distinct. In particular, the disinhibited form of attachment disorder appears to result *only* where there has been very severely disrupted care; namely, a virtual absence of care in the early months or years of life. On the other hand, the inhibited form of the disorder may be more closely allied with severe maltreatment (e.g. ‘persistent disregard’ of the child’s basic needs; Gaensbauer & Harmon 1982; Zeanah & Emde 1994). It seems likely that the distinction between having no caregiver and having a maltreating caregiver may be an important one in terms of the ontogeny of attachment behaviour and, in turn, the expression of attachment disordered behaviour. However, the effects of these two forms of pathogenic care may be exceptionally difficult to distinguish in clinical and social care contexts because it is increasingly common for children to experience both severe maltreatment and multiple unsuccessful placements with carers (Shealy 1995; Minty 1999).

We also need to consider whether or not maltreatment *per se* is sufficiently ‘pathogenic’ to meet diagnostic requirements. Careful and systematic studies of maltreated children typically do not find behavioural/emotional disturbances that resemble attachment disorder symptoms (Cicchetti *et al.* 2000). More specifically, the nature of attachment relationships of maltreated children seems adequately described by attachment theory and adequately assessed by traditional approaches (Cicchetti & Barnett 1991). These findings suggest – albeit indirectly – that most instances of maltreatment would not be expected to lead to an attachment disorder, although there is obviously a need for more direct research on this topic.

Third, the absence of a consistent caregiver appears to be sufficient for the emergence of marked disinhibition. So the tendency for clinical reports to focus on children in severe and multiple-risk settings may not be illuminating as regards aetiology. As Tizard & Rees (1975) demonstrated, attachment disorder behaviour may develop in the *absence* of economic deprivation and *despite* adequate opportunities for social interaction with adults and peers. Although necessary, pathogenic care is not sufficient to bring about severe attachment disorder behaviour. Thus, 18% of the Romanian adoptees brought into the UK after 2 years of age showed no signs of attachment disturbance when assessed at age 6 years (O’Connor *et al.* 2000).

Fourth, cognitive delay does not play a (necessary) aetiological or contributing role to the development of disinhibited attachment disorder behaviour (Tizard & Rees 1975; O’Connor *et al.* 2000). Nonetheless, very cognitively delayed children may exhibit some of the features of attachment disorder behaviour, and there may be a frequent co-occurrence of cognitive delay in children exhibiting attachment disorder behaviour (Richters & Volkmar 1994; Hinshaw-Fuselier *et al.* 1999).

Another area in need of further inquiry is whether, and to

what extent, there are individual differences in children’s vulnerability to developing disinhibited attachment disorder behaviours following exposure to pathogenic care. All of the studies of Romanian adoptees referred to above indicate that a sizeable minority of children do not exhibit severe disturbance despite grossly pathogenic care; the same can be said of other studies of institutionalized children. Similarly, there is, by implication, indirect evidence that many children who experienced maltreatment followed by multiple placements do not exhibit disinhibited attachment disorder.

Longitudinal course

Knowing the longitudinal course of disinhibited attachment problems would have very substantial theoretical implications (e.g. is there a sensitive period after which normal attachment patterns do not form, and will the offset of disinhibited attachment disorder behaviour coincide with the formation of a new attachment?) and clinical and practical applications (e.g. what is ‘typical’ progress for a child in forming attachment relationships with a foster/adoptive parents?). However, neither attachment theory nor alternative theoretical positions provide clear predictions on the longitudinal course of attachment disorder behaviour. The prevailing assumption in applied child care and clinic settings is that disinhibited attachment disorders are persistent, but this issue has not yet received systematic attention (Rushton *et al.* 1995).

Only three studies have presented systematic data on the stability or change in disinhibited attachment disorder behaviour. Two studies of children adopted from Romanian institutions (Chisholm 1998; O’Connor *et al.* 2000) found no significant change in the mean level of disinhibited behaviour over a comparatively short period, e.g. from age 4 to 6 in O’Connor *et al.* (2000). The latter study also reported stable individual differences over this time period ($r = .59$). The only study to report a sizeable change in the level of disturbance is by Tizard & Rees (1975) and Tizard & Hodges (1978) who assessed children at ages 4.5 and 8 years. However, although improvements were noted, in some children the level of ‘overfriendly’ behaviour had not returned to normal levels by age 8 years and some level of social problems persisted into adulthood (Jewitt 1998), so there were differences compared with a non-institutionalized group of children. Whether the greater reduction in problems in Tizard’s study compared with the Romanian studies is explained by the longer time interval or less pervasive and severe deprivation is unknown.

One further longitudinal finding of interest is that the formation of a new attachment relationship and the expression of affectionate behaviour toward the adoptive parent are not coincident with an offset of excessively and inappropriately sociable behaviour toward strangers. As noted above, all three studies of Romanian adoptees found that some children whose behaviour toward the adoptive parent in the separation–reunion paradigm was coded as ‘secure’, nevertheless exhibited signs of disinhibited attachment disorder behaviour (Goldberg 1997;

Chisholm 1998; O'Connor *et al.* 2001). Tizard & Hodges' (1978) findings are also consistent with this impression. Conceptually, these findings impugn the validity of the 'secure' classification in many children, and raise doubts about the utility of conventional assessments of attachment quality. Clinically, these findings suggest that interventions need to address multiple components of the child's behaviour with others, rather than focus exclusively on the quality of the child–parent relationship.

Assessment and reliability

There is no established protocol or assessment strategy for measuring attachment disorders in a clinical or research context. This may explain why even experienced clinicians disagree when asked to apply current diagnostic guidelines to case material (Boris *et al.* 1998). Despite this parlous state of affairs, some leads for assessment can be suggested.

There are two somewhat separate issues concerning assessment: what information is essential for a diagnosis and how such information may be best obtained. As Boris *et al.*'s (1998) study showed, criteria set forth in current nosologies will not likely be sufficient for shaping clinical judgement. Thus, documenting inappropriate or 'indiscriminate sociability' toward strangers is not likely to satisfactorily distinguish children with a disinhibited attachment disorder. That is partly because accurately assessing, in this case, a disinhibited disturbance necessitates a consideration of the context of the behaviour. At present, neither diagnostic system provides leads in any direction. A further reason for expanding the assessment strategy beyond the specific symptoms is that focusing on the diagnostic criteria alone will do little to advance our understanding of the phenomena in clinical or theoretical terms.

Determining what additional clinical material should be collected may depend, in part, on the methods of collection that are available and practical. In the first instance, observations should have a central role because they have been critical in the history and development of the construct and because observations provide information that may not be readily obtained through other methods. At the very least observational assessments will be useful in identifying the core behavioural feature of disinhibited behaviour, 'excessive familiarity with relative strangers'. Structuring the observational assessment correctly may accomplish three goals.

- 1 Observations may be used to differentiate the level of sociable, and perhaps even comfort-seeking, behaviour directed toward a caregiver(s) compared with a stranger(s) (e.g. a clinician).
- 2 Detecting 'indiscriminate friendliness' toward strangers could be detected in the course of a clinical assessment; the opportunity to examine behaviour toward two separate strangers (e.g. different members of the assessment team) might well provide a reliable index of the level of disinhibition.
- 3 Direct interaction with the child in the course of the assessment may reveal the ways in which the child's 'indiscriminate sociability' may be manifest, e.g. physical contact-seeking,

intrusive personal questions or other violation of personal boundaries in order to further define the disturbance in social behaviour and cognitions.

Thus, observational assessments can yield important confirmation of the level and severity of disinhibited behaviour.

Establishing a lack of attachment behaviour toward the caregiver is necessary to diagnose either attachment disorder. However, observing attachment behaviour or, more importantly, the lack of attachment behaviour where it would be expected, could present a substantial challenge for the clinic setting. The lesson from developmental research is that a moderately stressful situation is needed to elicit attachment behaviour from the young child (Ainsworth *et al.* 1978; Cassidy *et al.* 1992). Standard observations of child–parent interactions in the waiting room or consulting room may not therefore be very helpful for assessing attachment behaviour. The role of a parent–child separation procedure to elicit attachment behaviour may be useful but, as noted above, there may be serious limitations of using conventional assessments for deprived populations. There is the further concern that, at least with older (school-aged) children, observational assessments have not been shown to elicit attachment behaviour. It may be that observational methods may prove to be more useful for documenting disinhibition than for detecting a failure to exhibit attachment behaviour toward the caregiver, which may be more reliably obtained from the parent.

A clinical interview is a second means of collecting information on attachment disorder behaviours, and may be used with caregivers and others in a caring role (e.g. primary teachers). The interview format may be particularly useful for gathering information on the child's attachment behaviour toward the caregivers in order to determine if any of his or her relationships serves an attachment function. Particularly noteworthy would be instances in which the child sought out a caregiver when distressed or, alternatively, failed to seek out a caregiver when distressed, or was equally likely to seek comfort from a nearby stranger. Given the presence of attachment disorder behaviours, the failure of the child to seek out and derive comfort from a caregiver, in the form of physical contact or confiding, may signal a much greater disturbance and a much poorer prognosis.

The interview format may also be particularly useful for gathering information on key symptoms and further data not necessarily required for diagnosis but important nonetheless: notably the history of disturbance, the regularity of occurrence, and the circumstances in which disordered behaviours occur. In terms of history, it will be especially important to ascertain the nature of any changes in the child's responsiveness to the caregivers and in the child's disinhibited/inhibited behaviours (e.g. since placement). Furthermore, in the case of disinhibited behaviour, it will be important to document if the disturbance occurs in the absence of the caregiver or only in his or her presence. Also, if the child wanders away from caregivers without checking back, it will be important to assess the degree of dangerousness or threat to the child, if the child is equally likely to wander off in all unfamiliar settings, and what steps have been taken to modify the child's behaviour.

In the absence of an established assessment protocol, certain safeguards seem essential. The most important is the need to collect information from a variety of sources. However, having collected data from alternative sources, there is no certainty that the information collected will provide a consistent or coherent clinical picture. For example, although the case for an observational assessment seems strong, we do not know if observational assessments can reliably elicit attachment disorder-relevant behaviour. Similarly, because of the complexity of the attachment disorder phenotypes, it may be difficult to elicit reliable information in an interview format. Difficulty communicating the nature of the disturbance with parents and carers may lead to a high false-positive response. In one study, approximately 50% of adoptive parents of early placed and presumably non-deprived children reported mild symptoms of disinhibited attachment disorder behaviour (O'Connor *et al.* 2000). A presumed false-positive rate of 'overfriendly' behaviour (disinhibited behaviour in a non-deprived family-reared sample) was also found by Tizard & Hodges (1978), although the rate was much lower at 10%.

Summary

Two decades after entering the diagnostic lexicon, attachment disorders remain poorly understood. The few data available on the phenotype, aetiology, associated features and longitudinal course are derived from studies of a broadly and inconsistently defined disinhibited behavioural pattern using a diverse set of measurements. However, despite the methodological problems in previous studies, a reasonably compelling case can be made that disinhibited attachment disorder behaviour represents a distinct clinical phenotype. Importantly, a similar conclusion cannot be made for the inhibited form of attachment disorder, which remains difficult to define and evaluate. Although the inhibited form of attachment disorder may not withstand close scrutiny, a case may be made for greater clinical attention to the disorganized form of insecure attachment. There is certainly no suggestion that it can be used diagnostically, but it appears to be a far more promising lead for further research on attachment and psychopathology than, for instance, inhibited attachment disorder or many of the alternative definitions of disorder that have been proposed.

Intervention and clinical management

The last decade has witnessed a considerable integration of attachment theory with clinical treatment approaches, in terms of both the theoretical links and practical approaches to intervention (Lieberman 1991; van den Boom 1995; Fonagy 1999). Several groups have documented significant and clinically meaningful improvements in child behaviour and parent-child relationship quality following attachment-based interventions (van den Boom 1995; for a review see Lieberman & Zeanah

1999). Van Ijzendoorn *et al.*'s (1995) review of available studies provided encouraging evidence that attachment-based interventions are helpful in modifying parental sensitivity, with the effect on attachment security somewhat weaker or perhaps slower to respond to intervention.

Commonalities of established and empirically supported attachment-based interventions are discussed by Lieberman & Zeanah (1999) and van den Boom (1995). For example, there is a focus on real-life interactions between parent and child, especially concerning the parent's sensitivity; parental representations may also be assessed and integrated into the treatment. More work is needed to understand better the mechanisms underlying these interventions and whether the beneficial effects of attachment-based interventions are comparable to or greater than those found with alternative approaches. Nevertheless, there is a strong and growing empirical base supporting attachment-based interventions.

Very little is known about the form and effectiveness of interventions for children with attachment disturbances severe enough to warrant the attachment disorder label. It is natural to suppose that interventions developed for attachment disorder would build on the existing knowledge about effective attachment-based interventions, but this has not been the case. On the contrary, given the severity of disturbances found in very severely deprived children, some authors suggest, in the absence of any supporting evidence, that these children may be best served by specialist interventions that do not have much in common with the attachment-based approaches mentioned above. A consequence of this situation is a disjunction in the treatment given by clinicians in the adoption/foster care field (Levy 2000) and those in a clinical academic setting (Lieberman & Zeanah 1999). Virtually all of the attention to interventions for attachment disorder derives from the former rather than the latter.

There are some similarities among the 'alternative' approaches for treating children with attachment disorders. Although not adequately evaluated, these approaches deserve mention in this review because they are attracting increasing attention in adoption and foster care settings. Rather than attempt to review these alternative therapies, key features and limitations are provided.

Of the 'specialized' treatments for attachment disorder, so-called 'holding' therapies have attracted attention (Hughes 1999). Although described in an attachment theory context, the actual interventions prescribed bear little resemblance to attachment theory and, in many ways, the approach is antithetical to the principles underlying the formation of a secure attachment relationship. Specifically, the use of intrusive holding interventions, sometimes involving a therapist rather than a parent, contradicts the emphasis on promoting sensitive and responsive caregiving. The rationale often provided for this form of intrusive and counterintuitive treatment is that attachment disorders do not respond to traditional interventions; however, evidence for this position is lacking. It is possible that just as attachment disorder is different in kind to the types of attachment insecurity,

qualitatively different treatments would be required. To date, this position has not been substantiated with systematic research. This is an important and unfortunate oversight because intensive costly inpatient treatment is not to be recommended before less intensive and less invasive approaches prove ineffective.

The very few evaluations of alternative or holding therapies (Myeroff *et al.* 1999) suffer from substantial conceptual and methodological flaws, such as small and selective samples, uncertain validity of the attachment disorder diagnosis, the absence of relevant attachment outcome data, and no comparison with other less costly and invasive treatments. There is, therefore, no evidence to support this form of intervention. Much more needs to be learned about the form and effectiveness of interventions for children with attachment disorder behaviours.

One further clinical question with notable clinical and policy implications concerns the contribution of the adoptive or foster carer to the offset of attachment disorder behaviour. In particular, are individual differences in caregiver sensitivity associated with clinical progress? Is adequate parenting ‘good enough’ for a clinically meaningful improvement, or is progress in attachment disordered children dependent on extraordinarily sensitive parenting? In other words, what is the caregiver’s contribution to the child’s progress? Available anecdotal, clinical and research reports tell us little about how the caregiver influences the child, but make clear the adverse effect of the child’s attachment disturbance on the adoptive/foster caregiver. Indeed, one positive aspect of the large and growing grass roots effort to popularize attachment disorder has been to alert professionals to the particular and very distressing problems faced by a significant minority of adoptive and foster parents. What is not known is what kinds of support are helpful in reducing parents’ distress. Answers to the above questions may optimize support to families and aid in determining what kinds of placements may be especially well suited to children with severe attachment disturbances.

Of course, interventions may take other forms, including therapeutic foster home and therapeutic milieu in a residential setting. It is therefore necessary that further clinical research considers a range of intervention settings (Shealy 1995) rather than assume a permanent family setting and focus exclusively on child–parent relationships.

Summary

Despite the substantial evidence supporting the use of attachment-based interventions for the treatment of even severe relationship disturbances, little is known about the effectiveness of intervention with children who exhibit attachment disorder behaviour. The lack of systematic evaluation of proposed alternative approaches, coupled with a questionable conceptual and clinical foundation of these treatments, suggest that substantial scepticism is required. One way to progress beyond the underdeveloped state of interventions for children with attachment

disorder behaviour is to foster greater co-ordination between clinicians from diverse settings, and a wider appreciation of the particular clinical issues that confront professionals working in foster care and adoption settings.

Conclusions

This chapter has sought to review the historical and theoretical basis of the attachment disorders in infancy and early childhood, and the available evidence supporting its reliability, validity and response to intervention. Based on this review, several summary statements are offered. First, the basic disturbance referred to as disinhibited attachment disturbance has a solid foundation in clinical reports dating back over half a century and an increasing number of empirical studies; the second form of attachment disorder, referred to as inhibited, lacks substantial and compelling clinical or research support. Nevertheless, there is, in general, minimal evidence of the reliability and validity of the attachment disorders as currently formulated and validating the diagnostic phenotypes will require much further research. Given the number of alternative definitions, however, there is a real danger of further diagnostic confusion and slow progress in clinical understanding and treatment. Secondly, the lack of a consistent caregiver appears to be a necessary but by no means sufficient condition for the disturbance to result. At present we know little about why some children exposed to apparently ‘sufficient’ pathogenic care do not develop the disorder. Thirdly, attachment theory may provide a useful framework for understanding the attachment disorder behaviour, but the concept of attachment disorder remains only loosely associated with attachment theory, and there remain some important conceptual inconsistencies. Finally, the patterns of behaviour defined as attachment disorders are relatively resistant to change, even an intervention as radical as adoption. It is not yet clear what kinds of intervention and support may promote clinical outcomes of disturbed children.

It is obvious that there are many unresolved issues surrounding the attachment disorders. Progress in resolving many of these outstanding questions will require cross-disciplinary clinical research that brings together basic scientific questions with those derived from child care policy and practice.

Wetting and Soiling in Childhood

*Graham Clayden, Eric Taylor, Peter Loader,
Malgorzata Borzyskowski and Melinda Edwards*

Introduction

Problems of continence in childhood are common and generate a great deal of distress. Most children come, quite early in their development, to follow their caregivers' expectations for cleanliness and dryness. Both maturation and learning are likely to be involved.

The course over time—with successively fewer children affected at higher ages—is suggestive of a developmental delay. Many animals control deposition of excreta so that it is done outside the places they live, so some aspects of continence can be seen as developing biological functions.

Social learning is also likely to play some part. The requirement to use lavatories is a product of civilization and organized sewage systems. Different cultures impose different expectations. For instance, the high expectations of the East African Digo produce a very different toilet training approach from the maturational readiness method that is now prevalent in the Western world (de Vries & de Vries 1977). The Digo believe that infants can learn soon after birth and begin motor and toilet training in the first weeks of life. Dryness, both by night and day, is usually accomplished by the end of the first year; it involves only walking a few steps away from living areas. In Westernized societies, by contrast, the constraints of the nappy and the lavatory make for later acquisition.

Control of excreta requires integrity of the autonomic innervation and smooth muscle of bladder and gut, together with adequate function of the spinal motor and sensory nerves. Competent defecation and micturition require more than the mechanics of control: children need to have reached the necessary cognitive level to appreciate what is required and the value of continence to their caregivers, and the motivational state to follow the expectations. In both, there is a complex interplay between these functions and the reactions of caregivers, and impairment can result from dysfunction at any of the levels. Wetting and soiling differ in detailed mechanisms and are considered separately.

Faecal incontinence

Normal development of defecation

Defecation is episodic from birth. The rectum contains faeces until there is a stimulus to release them. In infancy, the mecha-

nism of elimination is a contraction of the rectum as a reflex response to being distended. The contracting rectum activates an inhibitory nerve impulse to relax the involuntary muscle at the anus (the internal sphincter), and the contents of the rectum are then expelled. The frequency of elimination depends on the amount of faeces, and therefore on diet and absorption. The normal range is wide—usually between three times a day and once in 3 days—and it may be as infrequent as once a week in otherwise normal people. Increasing control is acquired during development. One aspect of this control is the ability to delay defecation so that the child has time to reach the lavatory. There is a learned response to the sensation of rectal contraction and anal inhibition: to contract the voluntary part of the muscle around the anus (the external anal sphincter) and puborectalis, and thereby to defer the act of elimination. This sensation, and the relaxation of the involuntary sphincter, become more intense with increasing rectal filling. The voluntary sphincter is subject to fatigue after about 30 s in children and 60 s in adults. Other postural muscles are then used to defend faecal continence. The child needs to have developed the necessary physiological functions of the autonomic nervous system, the gut smooth muscle, and the spinal motor and sensory nerves. Children also need to have reached the necessary developmental age to appreciate what is required, and to have acquired the motivation to do so—essentially to please and be rewarded by their caregivers or avoid their displeasure, and often to take pride in achievement.

Another aspect of self-regulation is that the child learns to respond to the sensation of rectal contraction by visiting the toilet, relaxing the external sphincter and allowing the rectum to expel its contents. This is plainly complex: it must depend upon the caregiver to convey and reward the expectation. It is often accompanied by communication from the child to the parent, such as a shout, to signal their need for help. A third aspect of increasing control is learning to recognize early signals of rectal fullness and assist the process of defecation with the voluntary musculature of the abdomen, so that the toilet can be used at convenient times and before the impulse is urgent. This learning of control is also done in collaboration with parent or other caregiver—that person notices the child's physiological cues and often anticipates them; prompts and encourages the use of the pot or the lavatory; and approves of proper use and discourages elimination elsewhere. The relationship between them is the context of toilet training and is influenced by it.

Another set of challenges comes later in development, when

competence at home has to be transferred to the outside world, especially school. A new and more complex set of rules appears: longer delay between rectal fullness and elimination is usually expected, and the demand on self-control is correspondingly greater. Furthermore, the personal demands are greater: children may have to learn to assert themselves by asking to leave the classroom, and they may have to endure or outface the ridicule of other children.

What is abnormal?

Children within a culture vary considerably in the age by which continence is acquired. Large-scale studies have been conducted using parental questionnaires with a mixture of recall and current information (Bellman 1966). They indicate a steadily decreasing prevalence of incontinence with increasing age. The absence of any discontinuity is quite compatible with a sudden change in individuals; but it argues against an absolute standard of normality. Most children in Westernized societies have unreliable faecal continence in their first 2 years.

Some 10% of 3 year olds are still soiling at least once a month; by the age of 3.5–4 years the rate has dropped to less than 5%; at the age of 7 years the figure is around 1.5%. These findings, and those of other surveys such as that of preschool children in the UK by Stein & Susser (1967), led to the general adoption of a diagnostic cut-off at the fourth birthday (Quay & Werry 1972). After that time, soiling more frequently than once a month is regarded as an elimination disorder if it is not attributable to a general medical condition. In people with developmental delays, a mental age of 4 years rather than a chronological one is taken as the diagnostic threshold.

At the age of 10–12 years, soiling at a frequency of once a month or more affected 1.3% of boys and 0.3% of girls in a community survey (Rutter *et al.* 1970). Constipation and soiling problems are about the tenth most common reason for consulting a general paediatrician in the UK and contribute to 25% of the workload of a paediatric gastroenterologist. Only a small minority are referred to child mental health professionals, and these will tend to have more marked psychological problems than other children. By the age of 16, soiling is rare and no adult series have been reported. A good long-term outcome can therefore be anticipated for most.

Social expectations may be more demanding than medical ones. The 10% of 3 year olds who are soiling regularly may well find that this bars them from entrance to preschool playgroups or nurseries. A young person with intellectual impairment may well be socially handicapped by soiling. Treatment may be very useful even if a mental age of 4 has not yet been attained and a diagnosis of encopresis has therefore been withheld.

Types of faecal incontinence

Faecal incontinence is a general term embracing any sort of inappropriate deposition of faeces. There are several patterns of incontinence, and several types of possible dysfunction. The

clinical pattern can give clues to the dysfunction that is involved, but does not automatically imply it.

One pattern is that of fluid faeces leaking frequently. The investigation of this pattern should be by referral to a paediatrician. When there is a medical cause of abnormal stools, then it should not be seen as an elimination disorder and it is not discussed further here. Psychological factors may sometimes be involved in the development of frequent fluid stools (Wender *et al.* 1976).

A second pattern is that of the passage of liquid or semisolid faeces into the underclothes. This is the most common pattern presented for treatment, and it points to the retentive type of dysfunction, which is considered in more detail below. The rectum is distended, and children often do not realize that soiling has taken place. The retention is a result of constipation. The term ‘constipation’ refers to difficulty in defecation. No precise definition is agreed and many use it to indicate an abnormal interval between episodes of defecation. A stool is often described as ‘constipated’ implying hardness or dryness. Most children and their families use the term if defecation is associated with pain during the passage of the stool, irrespective of the frequency.

Normally formed stools may also be passed into the underclothes in the absence of retention. This is the normal pattern of soiling in very young children, and when older children show it in the absence of retention then they may never have learned to use the toilet consistently.

Another pattern of incontinence is the deposition of normal stools in inappropriate places. Clothes are not soiled, but faeces may be found in the child’s room or in other rooms; they may be obvious or concealed; they may even be wrapped and placed in the oven or the freezer. This pattern is more common in psychiatric than in paediatric practice. It is sometimes referred to as ‘encopresis’ but the terminology is inconsistent; in North American practice and in this chapter encopresis means faecal incontinence as defined above. The pattern of controlled but inappropriate deposition often implies that the physical functions are intact, and the reasons for the problem need to be sought in motivation and intrafamilial relationships.

It is also useful to keep in mind the distinction between primary and secondary encopresis—defined by whether or not there has ever been a period of continence. The secondary group includes that described by Anthony (1957) as ‘discontinuous’—in whom good early control was followed by a pattern of inappropriate deposition, which contrasted markedly with the generally orderly, clean and obedient style that they brought to other aspects of their life.

These different patterns of incontinence have been identified by clinical descriptions (Anthony 1957; Levine 1975; Hersov 1994; Hyman & Fleisher 1994). They are not mutually exclusive, and often shade into one another. For example, a child with retention and overflow may come to deposit faeces in inappropriate places as a consequence of the shame and anger that their initial problems entailed. As another example, a child may successfully clear retained faeces, yet be left with a diminished sen-

sitivity to rectal sensation that causes the inappropriate passage of normal stools. The same child may therefore show different patterns at different stages of development. Nevertheless, recognition of the different patterns is useful in directing the clinician's attention to the dysfunctions that are likely to be involved.

Causal pathways

Pathophysiology of retentive soiling

The majority of children referred to encopresis clinics—as many as 95%—show the pattern of functional constipation and retention with overflow (Loening-Baucke 1996). Several studies have been carried out on the alterations of function, recording changes in the pressure inside the rectum and the electrical activity of the various muscles involved (Meunier *et al.* 1979; Loening-Baucke & Cruikshank 1986; Loening-Baucke *et al.* 1987; Wald *et al.* 1986; Hatch 1988). Lack of sensitivity to rectal distension and weakness of the external anal sphincter and pelvic floor are the main findings. Some children also show an abnormal contraction of the voluntary muscles of the pelvic floor during defecation.

The reason that faecal soiling occurs when the rectum is overloaded with retained faeces is an inhibition of normal sensation. Normally, as described above, the contracting rectum both sends a sensory signal and activates an inhibitory nerve impulse to relax the internal sphincter. (This reflex is absent in Hirschsprung disease because the gut nerve network fails to reach the anus during embryonic development.) By contrast, in the child with persistent faecal loading of the rectum, the sensation of rectal filling is diminished or absent. The child is therefore not aware that the involuntary sphincter is being inhibited by the contracting rectum. Accordingly, there is no cue to contract the external sphincter and other voluntary muscles, and faecal soiling occurs. Children may fail to empty their rectums for several weeks and so soiling becomes continuous, with brief remissions occurring when the filling of the rectum is so gross that a massive stool is passed. This is often associated with pain and fear because of the size, hardness and uncontrollable nature of this massive stool. Once the retained stool is passed there may be some days of continence but the cycle of retention and then overflow soiling recurs. Children also learn that defecation is painful and so aggravate the problem by actively obstructing defecation even when they reach the point of rectal loading that produces the urge to defecate.

As the child grows older and if the problem persists, there are physical and psychological consequences. Any obstructed hollow organ of the body will tend to enlarge to accommodate the contents without risking complete obstruction to the function. (Examples can be found at all ages, from the baby of a few weeks with a hugely enlarged stomach as a result of overactivity of the stomach sphincter, to the elderly man whose bladder is chronically distended as a result of prostatic obstruction to micturition.) The rectum will likewise enlarge and the problems of faecal retention increase so that the stool may be permanently

resident in the rectum with the continuous passage of looser stool around it. Even following effective clearance of the stool the sensation of the urge to defecate is often diminished for many months or even years. It is quite common for the overflow soiling to be gradually replaced by another pattern of encopresis because of this diminished sensation, especially if the child prefers to think about anything else rather than issues related to visiting the lavatory or taking medication.

The initiating causes of retention are various including painful conditions such as anal fissure, and fearful ones such as aversion to the toilet (and see below). Once retention has developed, its relief is usually a necessary condition for clinical improvement.

Genetic contributions

There are two main reasons for thinking that there may be genetic contributions to faecal soiling: it runs in families, and it is associated with other problems (such as enuresis) that are known to have genetic components in their aetiology. Bellman's (1966) data on familial incidence are notable because they are based on screening a total population of 9425 7-year-olds entering schools in Stockholm, with an excellent compliance rate (94%), and drew on detailed evaluations of the boys who soiled and comparisons with controls. Among the encopretic boys, 15% had a biological father who admitted to having soiled after the age of 7 years, and this high figure was significantly different from the zero rate in the parents of controls. There was also a 9% rate in the brothers who were old enough to show the symptom; and a zero rate in the brothers of controls. Statistically, many more of the fathers and brothers must have been prone to soiling than were prepared to admit it, so a reporting bias could have confounded the comparison, and that of other studies so far.

The transmission could be genetic or environmental. About half of the previously encopretic fathers in Bellman's series had memories of harsh punishment, and tended to pass this on to their children; half did not. The study designs that will clarify the mode of transmission—twin, adoptive and molecular genetic—are still awaited

Toilet training

There have been major changes during this century in the expectations of training. In American culture a change was captured and timed by Klatskin's (1952) survey of child care practices in New Haven around 1949, by comparison with those in Chicago around 1940 (Davis & Havighurst 1946). Sixty eight per cent of parents in the earlier study, and only 6% in the later one, had started bowel training before the age of 6 months. A directive model had been replaced by a more relaxed approach of awaiting a child's maturational readiness.

Several developmental tasks are involved in toilet training. The first is the child's learning to delay the call to stool. Like other forms of learning, this is likely to be facilitated by the setting of clear goals and the provision of consistent reinforcement.

Factors that detract from this could include a lack of parental sensitivity to the child's communication of the need (or impairment of communication in the child); disorganization within the family, witnessed by problems in acquiring other types of attainment; indulgent attitudes that do not particularly set early continence as a goal; or reluctance to foster independence in the child. Another developmental task is learning to use the toilet. This will require not only the acquisition of the skills needed, but also a willingness to employ them. If the toilet becomes aversive, then reluctance to use it may underlie both retention and the use of other places. Harsh or premature training practices might lead to the toilet becoming a place of fear and shame, and therefore being avoided.

However, empirical investigations have not yet given unequivocal support to any of these putative psychological influences. When a controlled comparison between families with and without a soiling child was carried out, there were no significant differences between the groups in the toilet practices and training provided by the parents (Borowitz *et al.* 1999). Bellman (1966) also found that the mothers of an epidemiologically ascertained series of encopretic boys were no more or less likely than control mothers to have started training their sons early. On the other hand, she did find that the mothers of encopretic boys expected their children to be fully trained at an earlier age than did control mothers, so there was a bigger gap between achievement and expectation—and perhaps a greater sense of failure and tension—for the encopretic. Coercive techniques and laxness of training were both more common in the parents of boys who soiled themselves. Perhaps the lack of replicated findings from group comparisons implies, not that training techniques do not influence continence, but that no *single* technique is associated with delay.

How can one summarize the confusing evidence on toilet training? Research is still needed. So far, the findings on cross-cultural variations (Oppel *et al.* 1968) suggest that the time of beginning training may have some influence on the average age at which continence is acquired but that the details of training do not. This is in keeping with evidence about enuresis from children reared in kibbutzim: when the caregiver started toilet training earlier, the child was dry earlier (Kaffman & Elizur 1977). The effect was not large, but the evidence is particularly useful because it separates the training function from the relationship with parents. Parental attitudes and emotions are more likely to be associated with soiling beyond the age that is normative for the culture—especially when continence has been acquired and then breaks down—but it is not yet known which is cause and which is effect.

Other psychological influences

Family factors other than the techniques of toilet training could also be involved through the developmental mechanisms previously outlined. Anthony's descriptions of discontinuous encopresis emphasized the very clean and obedient attitude of children in other parts of their life; the idea being that encopresis

might be a means of expression of resentment or rebellion when other expression is denied. Other intrafamilial factors are equally unproven, but often seem salient to clinicians. Investigators have commented on high frequencies of family disharmony and marital problems and hostile dependent relationships between child and parent (Bemporad *et al.* 1971). The frequency of associated problems may be high in clinical series because they have contributed to the referral rather than to the soiling. Levine's (1975) description of 102 new referrals to a paediatric clinic is worthy of note because it took some account of the issue of heterogeneity and compared 'primary encopresis' (in which incontinence had been continuous from early childhood) and 'secondary encopresis' (in which continence had been acquired and then lost). The group with secondary encopresis was more likely to come from families on welfare, and in that group the time of onset of soiling could be associated (retrospectively) with a disruptive family event—notably, the loss of a parent, a traumatic entry into school, or the birth of a sibling.

It has been hard to develop adequate control for the clinical likelihood that several different patterns may be present rather than a single cause. Clinical descriptions are a first step. Silver (1996), for example, described several family patterns based on an audit of 104 sets of clinic notes.

- 1 Unhappy children in families with clear difficulties (including child abuse, death of a parent, rejection, parental argument, very tense mothers), where soiling was seen as an expression of stress and unhappiness.
- 2 Recent family stress or traumatic events precipitating the soiling, such as the birth of a sibling, starting school or death of a grandparent.
- 3 Family factors that perpetuated soiling, including parents who are reluctant to control their children and who tolerate immature behaviour too well.
- 4 About half of the sample of families had no unusual problems and appeared warm and supportive.

As another (unvalidated) example, Anthony (1957) described prototypes of children:

- 1 who had never acquired continence, came from neglectful families, and who might be aggressive but seldom felt any disgust;
- 2 who had attained continence successfully but were overcontrolled, ashamed and compulsive, with compulsive mothers; or
- 3 who were 'retentive' with stubborn, battling and provocative interactions.

Chronic constipation and/or soiling may be an indicator of child sexual abuse (Oliver & Buchanan 1979). The development of encopresis may represent a defence against further anal assault, or the child may refuse to open his bowels because of an injured and painful anus (Clayden 1987).

Stressors outside the family are suggested by experience and consideration of the developmental functions involved. There may, for instance, be pressing reasons not to use the toilets at school if they become havens for bullies. Shy children, or those in repressive classroom atmospheres, may find it very difficult to convey their need to use the toilet.

Developmental delays

There are associations between encopresis and other developmental delays—enuresis (see below), sensorimotor incoordination and slow language development (Bellman 1966; Bemporad *et al.* 1971) and low IQ (Olatawura 1973). These associations are based only on parental report in referred cases, but seem consistent across studies. Several reasons are possible; the finding is compatible with the idea that some cases can be seen as showing an immaturity of development.

Associations with psychological disturbance

Most surveys of psychological problems in clinically referred children who soil are flawed by lack of representativeness in the sample, small sample sizes and lack of good control groups. The result is a contradictory set of conclusions in the literature: that behavioural problems are no more common than in a normative sample (Friman *et al.* 1988), or that emotional and behavioural problems are substantially more common (Young *et al.* 1995).

More controlled epidemiological data are needed. In the Isle of Wight surveys, it was possible to go beyond parent ratings, which are likely to include marked halo effects, and consider how far soiling reported by parents predicted psychological disorder as identified from several sources, including teacher reports (Rutter *et al.* 1970). Soiling was significantly associated with a diagnosis of psychiatric disorder, being more than three times as common in boys who soiled than in boys who did not; and more than eight times more common in girls who soiled than those who did not.

There are several good reasons why psychological disturbance might be associated with encopresis. There might be a genetic link. The family factors mentioned above might give rise both to soiling and to disturbance. We do not yet know how far it would be the case that the association between psychological disorder and encopresis would still hold for children without other types of adversity. In principle, psychological disorder might give rise to soiling. If this is the case, then it would have to apply early in development; and the many longitudinal studies of the course of children with psychiatric disorder have not identified soiling as a specific outcome in any of them. Psychological problems might also develop as a result of chronic soiling, whatever the initial cause. Faecal soiling can be very aversive to caregivers. Anthony (1957) commented that ‘there is a special type of hatred reserved for the encopretic child’. The child’s incontinence can be perceived—or misperceived—as intentional and rejecting; and parents may then react with anger or disgust. Physical abuse can focus around the chastisement of the supposed wickedness or dirtiness of the soiling child. Children in turn react with fear or anger; with excessive compliance or overt rebellion in other areas of life.

Other psychological consequences are also seen in clinical practice. The chronicity of the problem and its embarrassing and shaming nature lead to denial and dissociation. This intensi-

fies the problem with soiling, as children may appear to be unaware of, or uninterested in, their continence and develop an apparent indifference to personal hygiene. This denial can also lead to refusal to become involved in any routines, treatments or precautions which might reduce the social impact of the problem. As the child appears to take no interest in the soiling, it often results in parents having to become involved in coping with the incontinence. This involvement in these personal and intimate functions is very natural for parents of young children but becomes increasingly inappropriate as the child enters adolescence. This may significantly interfere with the adolescent’s development of independence and ability to take on responsibilities. It puts the whole family at risk of relationships becoming frozen at too immature a level. There is even a risk that this stasis of teenage development is subtly perceived as being a benefit. There may be a gain from having a permanent 7 year old rather than confront the tensions and anxieties of being or having a teenager. Faecal incontinence provides both the reasons for children to be much more dependent on their parents and a means to continue this, especially if it leads to more time being spent at home than at school.

Management

The usual pattern of management of chronic retention and soiling is an initial paediatric assessment based on the clinical history and initial examination. In general terms, the later the child’s problem presents to paediatricians, the less likely there is to be a major organic abnormality of the anatomy of the anus or rectum. Similarly, the more that soiling is described as the main problem, the less likely there is to be an obstructive anal cause, such as Hirschsprung disease. Significant faecal retention is usually detected by palpation of the child’s abdomen. The anus is usually inspected to ensure its normal position and to assess whether the sphincter muscle appears to be contracting appropriately. When stools can be palpated in this way, further imaging of the gut with X-rays is unnecessary.

The first line of treatment is to evacuate residual stool if it is present. The standard method has been to use an enema, but over the last decade orally administered medications have reduced the need for this. Once the obstructing stool has been cleared maintenance laxatives need to be used for many months to prevent stools from re-accumulating. The response to medication will depend on the capacity of the rectum. In those children who can only defecate on a regular basis in response to high dosage of stimulant laxatives, such as senna, there is likely to be a degree of megarectum. In the majority of children the rectum shrinks back to its normal size slowly over time and stimulant laxatives are slowly reduced usually because their effects become unnecessarily forceful. The paediatrician judges the progress of the physical resolution by the dosage of medication needed to control the constipation.

The value of laxative medication is reasonably clear: randomized controlled trials have shown it to be preferable to no treatment (Nolan *et al.* 1991). Furthermore, the treatment is specific

in that it appears not to be helpful for children who have a non-retentive pattern of soiling (van Ginkel *et al.* 2000).

Psychological treatments

Psychological aspects are always part of the management; many paediatricians have demonstrated a good understanding of psychological and family factors, and include attention to them in their approach to treatment (Garrard & Richmond 1952; Coekin & Gairdner 1960; Clayden & Agnarsson 1991). The soiling is often both the cause and the effect of a behaviour or emotional difficulty. A vicious cycle is often present, especially if parents or teachers have focused on the soiling in a negative fashion rather than having urged the child to defecate regularly to avoid accidents.

The starting point for management of the individual case should be a comprehensive assessment of the type of soiling and the mechanisms responsible for its occurrence. Different treatment approaches are required for the young child who has never been toilet trained, the child with impacted faeces and overflow soiling, the child who is frightened to defecate or to use the toilet, and the child who is intentionally defecating in inappropriate places.

Behavioural and cognitive-behavioural therapies

The most common behavioural approach is basic toilet training based on the principle of operant conditioning, with rewards for sitting on the toilet at set times and for passing stool on the toilet. Toileting after meals is good timing, because it benefits from the gastrocolic reflex. Positive reinforcement is provided by means of star charts, and appropriate rewards may be negotiated with the child and parents. This approach on its own is perhaps most suitable for children who have never established a toileting routine. Toilet training programmes are best carried out at home (Blechman 1979), but an inpatient setting can help in more complicated cases, or when the child is severely constipated and requires washout or even manual evacuation of faeces.

This simple positive reinforcement approach has mostly been evaluated in combination with medical management including laxatives. A systematic review of controlled trials by McGrath *et al.* (2000) finds it ‘probably efficacious’, being superior to biofeedback, to laxatives in children who are constipated, and to medical management in the non-constipated (one trial each).

More extensive behaviour therapy includes, in addition, training relaxation of the external sphincter in defecation and rewarding increases in dietary fibre intake. The McGrath *et al.* (2000) review rated this too as ‘probably efficacious’, but without evidence on whether it was superior to simple behavioural approaches.

Biofeedback techniques have been used to condition patients to be more sensitive to a stimulus distending the rectum and to heighten voluntary external sphincter response, with the patient watching or listening to a signal of the level of external sphincter contraction (Kamm 1998). Van der Plas *et al.* (1996) found

biofeedback to add nothing to laxative treatment in a randomized controlled trial and a long-term outcome study by Loening-Baucke (1995) came to the same conclusion.

Most therapies, whether or not this is explicitly stated, include a fundamental aspect of cognitive therapy by helping children to understand the nature of the problem and view themselves more positively. Buchanan (1992) emphasized the notion of ‘demystification’ of the symptoms and the importance of empowering the child with knowledge and ownership of their body. Comprehensive treatment programmes often include an educational component to help children understand the process of defecation and how they can help themselves (Levine & Bakow 1976; Clayden & Agnarsson 1991; Stark *et al.* 1997). There are very similar components in the family approach of White (1984), and art therapy may help children to express their feelings when they cannot do so verbally.

Many clinicians (Sheinbein 1975) argue that the family should always be involved in the treatment of the soiling child. In one sense, this is nearly always the case. Parents are usually involved in the development and implementation of a behavioural programme, and parallel work may be carried out with the parents (usually the mother) of a child seen in individual psychotherapy. However, the focus of therapy in these cases remains the child—whether this be with regard to the child’s behaviour or his or her internal world.

Family systems therapy (see Jacobs & Pearse, Chapter 57) has a broader goal—to change patterns of family interaction that are seen as causing, or at least maintaining, the child’s soiling. For example, episodes of soiling could occur when there is tension between the parents, serving to distract from marital conflict that would threaten the integrity of the family. Soiling is often treated by family therapy in the UK but accounts of this, let alone treatment trials, are poorly represented in the literature. The most influential account of family work with soiling has been provided by White (1984) who aimed to externalize the problem and join with the child in a battle against the ‘sneaky poo’. Using both drama and humour, White emphasized the need to engage the child in dealing with his or her problem, with the parents having a supportive role. The work lacks outcome data but may be particularly relevant for children whose defecation is controlled but inappropriate. One retrospective audit of outcome for 108 children (aged 3–6 years) stated that White’s approach gave better results than family behavioural techniques, and was rated as more helpful by parents (Silver *et al.* 1998).

Combinations of treatments

Given that childhood soiling is a multifactorial condition, involving a complex interaction at the biological, psychological, family and social levels of human functioning, it is not surprising that many workers have developed multidisciplinary and multimodal treatment programmes (Levine & Bakow 1976; Chaney 1995; Wright & Walker 1977). These include a variety of educational, psychological and medical interventions and are used in

both inpatient and outpatient settings. The aims of such programmes should be to reduce the anxiety and guilt caused by the problem, restore children's self-confidence, instil hope for the future, empty the bowel of retained faeces (when relevant) and inculcate a regular toileting regime. A combined behavioural and medical treatment programme has been shown to be superior to behaviour therapy alone, and to medical treatment with laxatives alone (Cox *et al.* 1998).

Stark *et al.* (1997) described a standard protocol for children with retentive soiling and who had failed to respond to routine medical management. Treatment consisted of separate group sessions (six in all) for children and parents, with components of the programme including psychoeducation about soiling, medical management, behavioural contracts with the child, and sticker charts/rewards for compliance. Outcome data were provided on 59 children, of whom 86% had stopped soiling by the end of treatment.

The danger of such treatment packages is that they can come to be routinely applied to all cases, and this may result in less attention being given to a comprehensive assessment. Berg & Jones (1964) pointed out that a joint approach still needs to be tailored to the individual case, with the right combination of physical and psychological interventions being employed according to need. Until the evidence is clearer, we recommend a liaison model, involving paediatricians and child mental health workers, for children who fail to respond to routine medical management (Clayden 1992).

Treatment in adolescence

Treatment in the later part of childhood and adolescence becomes more difficult because relationships within families and with friends are often profoundly affected by the bowel problem. It is unfortunately just the stage in young people's lives that they may resist engaging with agencies attempting to help them, especially if the therapist has to focus them on the areas from which they have dissociated. It is not unusual for the young people to have mixed feelings about their therapists. One of the key areas is for them to be given more and more personal responsibility for their problem. This is possible only if they are also given more autonomy in deciding which treatments to take or whether to continue therapy. It is advisable that choice and responsibility are increased, especially in teenagers, who, as a group, are very likely to opt out of their role in management if their treatment appears to be easily subsumed by another. The dilemma for those attempting to help them is that making demands on them is likely to distance them from the help which they are more likely to seek if given that autonomy and choice. It is for this reason that therapy for young people is on the basis of consensus. Some will shy away from unpleasant physical treatments, such as enemas—which they may still fear even years afterwards. Fortunately, the development over the last few years of initial treatments for constipation which are more easily tolerated should reduce the prevalence of young people who are afraid of restarting treatment.

Prognosis

Encopresis usually resolves spontaneously before adolescence (Bellman 1966), and most cases improve in the course of routine medical management. However, long-term follow-up studies are more pessimistic than the outcome results reported from major centres would suggest. They suggest that some 30–40% of cases continue to have symptoms for several years (Sutphen *et al.* 1995; Loening-Baucke 1996; Rockney *et al.* 1996), and the problem may occasionally persist into adult life (Fraser & Taylor 1986). A chronic course has serious psychosocial implications for the child and his or her family, and places a heavy burden on health care resources. Several workers have identified particular factors that suggest a poor prognosis and which point to the need for specialist treatment.

Characteristics of the child that have been found to be associated with a poor outcome include learning difficulties, hyperactivity, reading problems, particular childhood characteristics (excessive moodiness, disobedience, fearlessness), and non-compliance with treatment (Levine & Bakow 1976). The presence of behavioural problems has also been found to militate against successful treatment (Young *et al.* 1995; Stark *et al.* 1997). Rappaport *et al.* (1986) identified a high-risk group where the child demonstrated not only poor compliance but also an external locus of control. Some authors have described characteristics of the family and of parenting style that are associated with a poor outcome. These include social disadvantage (Taitz *et al.* 1986), and disorganized or chaotic families (Stark *et al.* 1990, 1997).

Urinary incontinence

Normal development of urination

Urinary continence is the function of storing urine in the bladder until it is socially appropriate to void. The volume of urine is determined by water intake, renal function and its hormonal control—which includes the secretion of vasopressin from the posterior pituitary under neural control.

The bladder performs only two functions: storage and emptying. In the normal situation the bladder fills, with very little rise in pressure, until capacity is reached. Efficient storage depends on the ability to hold a large volume of urine at low pressure. During filling the urine is held in the bladder by the bladder neck mechanism, which is composed of smooth muscle, and the distal (external) sphincter, which is composed of striated muscle and is under voluntary control. At capacity voiding is initiated. The bladder muscle (detrusor) contracts with simultaneous opening of the distal sphincter. The bladder neck is pulled open and voiding continues until the bladder is empty and the sphincters then return to their occlusive role. Children learn to use the voluntary musculature of the pelvic floor to raise the neck of the bladder and thus to defer voiding until the time and the place are appropriate; they also learn to initiate micturition voluntarily by low-

ering the neck of the bladder. Effective urinary storage and voiding requires intact connections between the pons, the sacral plexus via the cauda equina, the pudendal nerves (S2–4) and the hypogastric plexus (T11–L2) to innervate the bladder and sphincter. The smooth muscle of the bladder (detrusor) is innervated by parasympathetic postganglionic fibres whose ganglion cells are located in the bladder, with the preganglionic motor neurones reaching the bladder via the pudendal nerve.

Effective voiding also involves the learning and the motivation of the child. As with faecal continence, learning is involved in several stages: inhibiting micturition, making use of the consequent delay to go to the toilet, signalling to parents that they need to go there, voluntary micturition in the toilet, and visiting and using the toilet before the urge to pass urine is so strong that it can be delayed no longer.

Bladder voiding is more frequent than faecal elimination, and dryness through the night is correspondingly harder to reach than cleanness. How far nocturnal dryness is acquired by learning or by maturation has been controversial. On the one hand, some have found it hard to see how something can be learned during sleep. On the other hand, the evidence from the Israeli kibbutzim suggests that when caregivers expect dry beds earlier, the children follow suit (Kaffman & Elizur 1977).

What is abnormal?

In normal development, the age at which children acquire bladder control is variable. Most children of normal intelligence and health can successfully reach the lavatory in the daytime and use it appropriately without wetting themselves by the age of 4 years. By the fifth birthday, only about 1% of children have troublesome daytime wetting. Children generally achieve urinary control by day before night, and bedwetting is common even in later childhood. The values for the prevalence of nocturnal enuresis, in the surveys described by Butler (1998), were 15–22% for males and 7–15% for females at the age of 7 years. Even by the age of 18 years, about 1% of males (and a lower proportion of females) still have enuresis at night.

The figures from different surveys are hard to bring together because of differences in methods, populations studied and definitions of enuresis. There is no one level of frequency of wetting that is obviously abnormal, and study definitions have varied from one to 21 times a month. Further, there is no one age at which children cease to wet, but a gradual decrease in numbers with age. The diagnostic categories of nocturnal and diurnal enuresis therefore have no absolute distinction from normality, and illustrate the difficulty of imposing categories upon a dimensional distribution.

How should one decide what is abnormal? DSM-IV and ICD-10 give explicit rules. The essential feature of enuresis is the repeated voiding of urine into the bed or the clothes that is not caused by a general medical condition such as diabetes. Whether or not the voiding is involuntary is irrelevant to the diagnosis. It usually is involuntary, but it is often hard to know the exact mix

of motives and awareness. The main distinctions are according to the situation in which it occurs (nocturnal only, diurnal only or both) and whether there has been continuous wetting since early childhood (primary enuresis) or wetting has reappeared after a dry period (secondary). Whether or not the diagnosis should be given depends upon severity and impact: either the enuresis should happen at least twice a week for a period of at least 3 months, or else there should be impairment as a result of the problem, such as restriction of activities, poor self-esteem or stigmatization by others.

One way of deciding on the cut-off would be by examining the frequency of bedwetting at different ages and determining whether there is a critical period during which continence is normally acquired. Verhulst *et al.* (1985) criticized the diagnostic definition of nocturnal enuresis with data from an epidemiological survey of 2600 Dutch children sampled from municipal registers.

The percentages of boys and girls who wet the bed at least twice a month at different ages are shown in Fig. 47.1. The suggestion is that for girls there is a rapid decline in prevalence between the fourth and sixth years and the fifth birthday is a rational cut-off, but for boys the decline in prevalence comes later, and the eighth birthday would be a better mark for them. This kind of argument from a discontinuity in development is useful; but, as discussed by Rutter & Taylor (Chapter 2), it does require rather large numbers to make the case. A difference between 6 and 2% for one gender at one age in a study of this size corresponds only to about three children and therefore may not be robust.

Another way of validating classification could be by examining the variations in course at different ages. In the second and third year of life, about 40% of children become dry in the succeeding year (Oppel *et al.* 1968). Thereafter, the rate of acquisition of dryness slows down. Of children who wet their beds, 15–16% experience spontaneous remission each year (Forsythe & Redmond 1974; Clark *et al.* 1994), and the figure is similar at all ages from 5 to 12 years. This approach has not given indication of an age beyond 4 years after which wetting is abnormal.

Another aspect of the definition of enuresis is that the child should have a developmental level corresponding to a chronological age of at least 5 years. This developmental level requirement is rather restrictive. Enuresis is more common in young people with a moderate or severe learning disability, but it is by no means universal; incontinence can make a considerable difference to the range of activities and environments that are available and to the burden on caregivers. Treatments such as the alarm can be successful in people with chronological ages higher than 5 years but mental ages well below. There is no need to wait for the arbitrary developmental milestone to be reached before offering treatment.

The implication of the uncertainties over definition is that clinicians should not base their practice slavishly upon the diagnostic manuals. The presentation of enuresis for treatment is based as much upon parental attitudes and tolerance as upon the

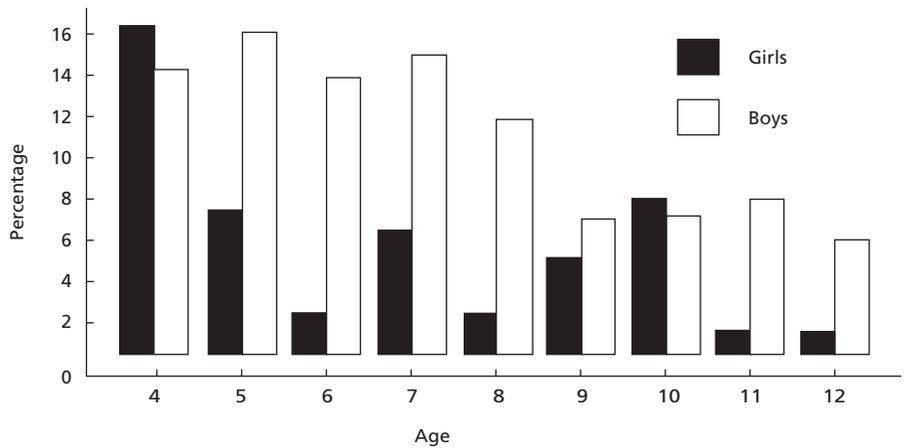

Fig. 47.1 Prevalence of bedwetting. The figure shows the percentages of boys and girls who wet the bed at least twice a month at different ages.

child's wetting; most enuretic children are never treated (see below). The decision to treat should be based on the impact of the problem rather than solely on its exact form.

Day wetting (diurnal enuresis) is far less prevalent than nocturnal enuresis and is experienced by more girls than boys (Berg 1979; Fielding & Doleys 1988). Hellstrom *et al.* (1990) reported that 3.1% of 7-year-old girls and 2.1% of boys of that age regularly wet during the day. As with nocturnal enuresis, the natural history is one of gradual resolution: each year 14% of 5–9 year olds become dry; and the corresponding rate is 10% for 10–18 year olds (Forsythe & Redmond 1974).

Types of urinary incontinence

There are several patterns of urinary incontinence which need to be established from the history (Shaffer *et al.* 1994). One—the most common—is of bedwetting (nocturnal enuresis) with no daytime problem. A second is that of diurnal enuresis, with or without bedwetting. To these three main types, other distinctions need to be added. The history may be of primary enuresis which has continued directly from the normal incontinence of early childhood. Alternatively, wetting may have started only after a period in which the child has successfully been dry (secondary enuresis).

Incontinence of urine is not usually associated with any other abnormality of micturition but, when it is, the pattern needs noting because it may well call for physical investigation of urinary function. The complaint about some children will be that they are depositing urine in inappropriate places, such as living rooms or bedrooms. As for encopresis, the pattern will direct enquiry towards motives for doing so rather than towards reasons for impairment of bladder function.

There are other sources of heterogeneity: boys compared with girls; those with psychiatric disorder compared to those without; those with developmental delays compared to those without; and those who do or do not show one of the types of pathophysiology described below. Many of the less common

types are still in need of investigation. Only one type—nocturnal enuresis without daytime wetting—has received a good deal of research.

Causal pathways

Nocturnal enuresis

The aetiology of bedwetting has attracted a good deal of research. It has been known for a long time that there is a strong tendency for it to run in families. Of children with nocturnal enuresis, 70% have a parent or sibling who was late in becoming dry (Bakwin 1971). The rate of affected parents is much higher than in a control group (Jarvelin *et al.* 1991). Bakwin (1971) found that identical twins were almost twice as likely to suffer from nocturnal enuresis as non-identical twins, suggesting strongly that there is a genetic contribution to the transmission. Molecular genetic evidence has not yet indicated a single gene. Analysis of polymorphisms of microsatellite markers has suggested possible linkage sites on chromosomes 22, 8, 12 and 13 (von Gontard *et al.* 1999a). The locus on chromosome 22, for example, was linked to enuresis in about 40% of families studied. Replication is needed before any of these loci can confidently be accepted; the most likely conclusion in present knowledge is that there is genetic heterogeneity.

Environmental factors in the aetiology have been suggested chiefly by associations found in case-control comparisons. A wide range of such associations has been found, including later initiation of toilet training, a higher rate of stressful life events (for secondary enuresis only), urinary tract infection, and constipation (reviewed by Shaffer 1994). In addition, large-scale epidemiological studies have found further associations. Children of lower socioeconomic groups and from large families living in overcrowded conditions were more at risk of enuresis (Butler 1994). Rona *et al.* (1997) described results from a national sample of nearly 15 000 children in the UK. Nocturnal enuresis was again associated with low social class (albeit in girls

only), and also with African-Caribbean origin, mothers who smoked, mothers who gave birth while still teenagers, and being the second- or third-born in the family in comparison with the first-born.

In most instances the causal mechanisms that underlie these associations are not known. Fergusson *et al.* (1986) described a multivariate analysis of potential risk factors on the age of acquisition of continence in a longitudinal study of a birth cohort. The most important predictor was a family history of enuresis, and contributions also came from the child's developmental level at 1 and 3 years of age, and the child's early sleeping patterns. A wide range of psychosocial factors were measured, but they were not predictors of primary enuresis once the other influences had been taken into account. Secondary enuresis in this cohort of children was best predicted by two factors: being late to attain nocturnal bladder control, and being exposed to a high rate of adverse life events (Fergusson *et al.* 1990).

Pathophysiological mechanisms have been suggested by other associations found in case-control studies. The review by Shaffer (1994) concluded that there was evidence for lower functional bladder volume in those with enuresis, anatomical changes in the neck of the bladder, shorter stature, later puberty, worse motor co-ordination, and shorter hours of sleep as a toddler. The association with sleeping difficulties was emphasized by a questionnaire study on a national sample in Finland. Enuretic boys had more frequent nightly arousal and early morning waking than controls, while enuretic girls had more nightmares than non-enuretic girls (Moilanen *et al.* 1998). The national UK sample by Rona *et al.* (1997) also found an association between nocturnal enuresis and disturbed sleep. However, laboratory studies have found an apparent absence of association with abnormal sleep architecture (Shaffer 1994). Wetting can occur at any stage of sleep (Mikkelsen *et al.* 1980), so lack of waking to bladder cues is unlikely to be caused by altered stages of sleep, at least for most children. It may well be that people with enuresis have a normal pattern of shifting from deep to light sleep (Stage I) when the bladder gets full, but then fail to wake from light sleep (Watanabe 1995).

The neuroendocrine influences on urinary secretion have received considerable research attention. Most people show a considerable reduction of urine output at night, but some children with nocturnal enuresis produce more urine at night than controls (Norgaard 1991). Sodium excretion at night is also greater than in normal controls (Natochin & Kuznetsova 2000). This nocturia is not necessarily caused by altered secretion of the antidiuretic hormone vasopressin, for plasma levels in those with enuresis appear to be normal (Robertson *et al.* 1999); rather, there appears to be a nocturnal reduction in renal sensitivity to the antidiuretic effect of vasopressin. This research has led to the successful introduction of a synthetic analogue of vasopressin as a treatment (see below). It is not yet clear whether the response to vasopressin is predicted by vasopressin levels, but the response does seem to be greater in those who do not have a reduced functional volume of the bladder (Eller *et al.* 1998; Neveus *et al.* 1999). This, if confirmed, suggests that a different mechanism

may be at work in those with diminished bladder capacity, which may be a different pathogenetic pathway.

Reviewers have often suggested that the symptom of wetting at night can be the result of several distinct disorders (Butler & Holland 2000). The evidence briefly summarized above suggests that one mechanism is either a lack of vasopressin release during sleep or a nocturnal insensitivity of renal tubules to vasopressin; that inco-ordination of voiding mechanisms, reflected in reduced functional bladder volume, is a second; and that reduced waking from light sleep in response to the sensation of a full bladder may be a third. Research is expected to clarify how far these different patterns map on to the underlying genetic and environmental influences.

Daytime wetting

Diurnal enuresis differs in several respects in its associations: the sex ratio is different; it is more likely to be associated with structural and functional disorders of the urinary tract; and less likely to predict that other family members will have shown enuresis (Hallgren 1957).

Diurnal enuresis is more likely than nocturnal enuresis to be associated with a structural abnormality. There is much less systematic research, and clinical experience guides practice. The causes include transient wetting following acute emotional stress, careless wetting as a result of poor technique and tight clothing, detrusor instability, weakness of the bladder neck, giggle incontinence, urinary tract infections, infrequent voiding, incomplete bladder emptying and anatomical abnormalities such as ectopic ureter or neuropathic bladder. The neuropathic bladder may be diagnosed late; causes include open and closed spina bifida, sacral agenesis, transverse myelitis, autonomic neuropathy, spinal cord tumour, and spinal cord trauma, as well as the more difficult to recognize occult neuropathic bladder and non-neurogenic neurogenic bladder. Sexual abuse has a recognized association with secondary wetting. Psychological factors probably play an important part in children who fail to empty their bladders effectively or frequently enough. The secondary pathophysiological changes in bladder smooth muscle and bladder function that then occur are similar to those of the megarectum that develops in children refusing to defecate. This bladder dysfunction is referred to as Hinman syndrome (Hinman & Bauman 1973) and is another good example of an incontinence problem that is best managed by a combined medical and psychological approach.

Psychological problems in children with enuresis

Psychiatric disorder is present in a significant minority of children referred because of enuresis. For instance, a recent survey of clinic attenders by von Gontard *et al.* (1999b) found that 40% of children had at least one ICD-10 diagnosis other than enuresis, with disruptive behaviour disorders outnumbering all others. Referral practices will vary from place to place but, in general, services for children with enuresis need to ensure that

they have resources or collaborations to cope with comorbid problems.

The association with psychological deviance is also present when community surveys include questions about wetting and questionnaire ratings of psychological symptoms. A national health survey in the USA, involving more than 10 000 children, found a higher rate of deviance in the enuretic than the non-enuretic with an odds ratio of about 1.8 (Byrd *et al.* 1996). Similar degrees of association have been reported from Finland (Moilanen *et al.* 1998), Ireland (Devlin 1991), New Zealand (McGee *et al.* 1984) and the UK (Kolvin *et al.* 1972; Rutter *et al.* 1973). In the large survey by Byrd *et al.* (1996) the risk was similar among children with infrequent and frequent bedwetting, but greater in older than younger children, in girls than in boys, in children who wet both by day and by night, and in those with secondary enuresis by comparison with those who had never been dry. Many of these associations are replicated in other countries: enuretic girls were more disturbed than boys in Rutter *et al.*'s (1973) study, especially on teacher ratings; and those with secondary enuresis were more at risk than those with primary enuresis in the Kolvin *et al.* (1972) survey.

Of the possible reasons for the association, referral bias to clinics plainly cannot explain it all because of the robustness of the finding in unselected samples. There is a possibility of psychiatric disorder being a direct cause of enuresis; for example, by altering the motivation of affected children. Rutter *et al.* (1973) found that children who became secondarily enuretic were more likely to show psychological deviance before the enuresis started. This suggests that they were under more stress or that the deviance caused the enuresis. However, the latter does not seem like a complete explanation, because of the failure of treatments such as psychotherapy, anxiolytics and stimulant drugs to help enuresis.

Enuresis may sometimes cause psychiatric disorder. Feehan *et al.* (1990) and Fergusson & Horwood (1994) reported longitudinal studies in which there was a predictive effect of nocturnal enuresis on later adolescent disturbance; it was only a small association once potentially confounding factors had been allowed for, but it was still present. The best evidence is that specific treatments for enuresis, such as the alarm, do reduce other psychological symptoms in randomized controlled trials (Moffatt *et al.* 1987; Longstaffe *et al.* 2000); although clinically it must be said that treatment of the enuresis seldom results in a complete recovery from comorbid disorders. Clinically, too, children often present a picture in which stigmatization by others and emotional upset are direct consequences of wetting. Enuresis can be a considerable source of embarrassment often invoking ridicule or punishment. Children may suffer various adverse emotional and behavioural consequences: they may develop poor self-esteem, feeling they are dirty, lazy or smelly and isolated with their shameful secret. Restrictions to social activities, such as staying with friends/families or school trips, are not uncommon (Butler 1998) and children may be loath to develop close personal relationships for fear of being 'found out'. Ollendick *et al.* (1989) found that children regarded wetting in

class as the third most stressful event possible (only behind 'losing a parent' or 'going blind'). Enuretic children have a lower than average sense of self-esteem (Wagner *et al.* 1988). An outward indifference is not uncommon (Schaefer 1979). Enuresis can also place a burden upon family relationships and resources, and is a significant financial burden (pants, washing facilities, extra sheets, etc.). It seems plausible that this kind of secondary effect could explain the disproportionate increase of risk in those where wetting would have greatest impact (teenagers rather than younger children and boys rather than girls), rather than those whose wetting is most severe.

Both enuresis and psychological disturbance may also be common consequences of a single cause, or be the consequences of causes that tend to occur together. Enuresis, as described above, is associated with other developmental delays and with social adversity and stress: it is not self-evident that these are aetiological factors, but they are known to be associated with psychiatric disorder as well. The greater risk of those with secondary enuresis is also in keeping with this view, because of the association of secondary enuresis with stressful life events that may also give rise to psychological symptoms (see Sandberg & Rutter, Chapter 17). What is not yet clear is whether the association between stress and secondary enuresis would still hold if children with overt psychological disturbance were excluded.

Clinical management of wetting

Many parents never consider that wetting is a problem and—particularly for monosymptomatic nocturnal enuresis—never seek advice. Sometimes this may reflect good coping, but sometimes the stigmatizing effects of bedwetting mean that there is avoidable impairment. One survey in France indicated that one-third of children with moderate to severe nocturnal enuresis are never presented to doctors (Lottman 1999). In the UK, only 50% of the parents consulted a doctor for enuresis in their child (Rona *et al.* 1997). In a survey in Ireland, enuresis was distressing for most families yet most children never saw a doctor about the problem (Devlin 1991).

Most wetting is rightly dealt with at the primary health care level, often by nurses attached to general practices or to schools. In the UK, there are a number of specialist enuresis clinics led by health visitors. Children referred to paediatricians and child mental health services have often not responded to symptomatic measures, or show signs of emotional disturbance in addition to (or as a consequence of) their wetting.

It is noteworthy that surveys of clinical practice in many countries have suggested that management commonly falls far short of that recommended by guidelines or supported by evidence. In France, 20% of doctors did not prescribe treatment, and the majority offered advice on lifestyle and diet in the first instance (Lottman 1999). When treatments were proposed, they consisted of drugs rather than the enuresis alarm. In Ireland, less than two-thirds of those assessed had a urine test and 40% of parents remained dissatisfied with the outcome of the visit to the doctor (Devlin 1991). Children were more likely to be prescribed med-

icine than other treatments, and the enuresis alarm was recommended for only one in 10 children. It is puzzling that medication is so often preferred to the alarm when the latter is more effective, safer and less expensive. It does not seem to be driven by parental preferences. One study from the USA reported treatment practices when families were given the option of different therapies (Schulman *et al.* 2000). Families mostly chose an alarm (31%), followed by desmopressin acetate (22%) and oxybutynin (9%). Some preferred no treatment (23%). One year after the first visit, children whose parents chose the nocturnal enuresis alarm were the most likely to be completely dry. The barrier to the use of the alarm seems likely to be in professional custom, and perhaps lack of familiarity with the technique. Whatever the reasons, the unstandard and often unsatisfactory nature of routine management suggests that specialist time may be well invested in educating and working with primary care practitioners to enhance practice.

Assessing physical factors

A careful history is the key to effective management and should include a family history of the symptoms. It is also essential to record the daytime symptoms, such as the frequency of wetting, urgency, details of bladder habits (lavatory visits) and frequency of voiding. A great deal of valuable information may be obtained from frequency-voiding and voided-volume charts. Knowledge of the bowel habits and the child's development is essential and this should include questions on gait and acquisition of walking and speech as a guide to other functions that may be affected by spinal nerve abnormalities or developmental delay.

Clinical examination should include examination of the abdomen to assess whether the bladder is palpable or percussible (which would suggest incomplete bladder emptying), the kidneys are palpable, or the child is constipated. Inspection of the spine, sacrum, perineum and legs for wasting including the reflexes for asymmetry and an absent perianal reflex and an abnormal gait may provide evidence of a neuropathic cause for the wetting. Children with spina bifida rated incontinence as one of the most distressing and challenging aspects of their condition (Lie *et al.* 1991), above problems with mobility. The perineum inspection may demonstrate an anatomical abnormality or show continuous leakage of urine. Where there is a combination of incontinence of urine and faeces it is particularly important to exclude neurological abnormality.

Urine should be sent for culture and evidence of other specific medical conditions should be sought as indicated, such as polyuria in diabetes or failure to grow at the expected velocity in chronic renal failure. Upper airways obstruction has been associated with nocturnal enuresis in children (Weider *et al.* 1991; Maizels *et al.* 1993), and nocturnal epilepsy may occasionally present with enuresis. On the whole, however, investigation is rarely indicated in children with nocturnal enuresis alone. If a child reaches 15 or 16 years and there has been little response to

treatment then a videourodynamic study to assess bladder and urethral function may be indicated, even in the absence of signs or history suggestive of any other abnormality.

Children in whom abnormalities are detected in the history or examination, or who have had a urinary tract infection, should be referred to a general paediatrician who will investigate further and may decide to refer on to a specialist centre.

Assessing psychological factors

Enquiry should be made about the presence of psychiatric disorders. If they are present, the enuresis should not automatically be attributed to them. In some cases assumptions have been made about children's inability to attain continence because of their other physical problems or mental conditions (e.g. autism or learning disability) whereas with considerable perseverance and support and extended training periods continence may be achieved (Hyams 1992).

The family's social circumstances, attitudes and expectations should be asked about. Stressful events should be enquired for, such as separation from a parent, birth of a sibling, marital separation, starting school or moving house. Sexual abuse may be an underlying cause for secondary onset enuresis, but there are likely to be other indicators associated with abuse and these should be borne in mind (see Glaser, Chapter 21). The home environment (e.g. bedtime routines and access to the toilet at night) can influence nocturnal as well as daytime enuresis and should be asked about. Rigid or harsh toilet training or (conversely) complacent neglect of training may be suspected from expressed attitudes as well as from self-reports of training practices. Problems in school that might relate to stress and the effect that the wetting has on the child in the classroom are also essential information.

Treatment of urinary incontinence at night

Education and reassurance about prevalence, normal development and the low risk of a disease being the cause are essential first steps in management. Many people think that enuresis is a result of the child being lazy and this should be challenged. Reward systems and incentives are often used from an early stage of treatment. These should be based on achievable goals, records of positive gains and be valued and meaningful to the child. The child will need to see that success is possible and becoming dry has positive consequences. Possible rewards include stars, stickers and treats. It is important to motivate children by increasing their participation and responsibility for helping to minimize the consequences of wetting. This may involve devising programmes and rewards directly with them, and encouraging children to place wet items in the washing basket or change wet sheets without disturbing parents.

The treatment of nocturnal enuresis is usually successful. If common-sense methods, such as rewards for dryness or waking the child and encouraging micturition during the night, have not

already been tried by parents, then they may be advised but usually there should be little delay before recommending the use of enuresis alarms. They are the most successful form of intervention. Systematic review of many random-allocation controlled trials leaves no doubt that it is a well-established therapy (Mellon & McGrath 2000). Around 60–80% of children using an alarm have achieved continence within 2–4 months of treatment (Gustafson 1993; Clark *et al.* 1994; Butler 1998). The older alarms, involving electrode sheets on the bed, have been superseded by miniaturized body alarms. A sensor is attached to underpants to detect urine as soon as it is voided; the alarm itself is attached to pyjamas, or a wristband or pocket, or can be positioned with an extension lead so as to wake the parents. The key aim is to wake the child, and he or she should then void urine appropriately.

The exact psychological mechanisms by which the alarm exerts its effects are not wholly clear, and may vary between children. A learning model is supported by the fact that the treatment is less effective if there is a delay between voiding and the alarm sounding (Collins 1973) and by the clinical observation that the course of treatment is often gradual, with the first signs of success being the shrinking of the size of the wet patch on the sheets. The original rationale was one of classical conditioning: the alarm is the unconditioned stimulus (UCS), waking and voiding appropriately is the conditioned response (CR), and the process of learning is the association of the indifferent stimuli (full bladder and the other signals for micturition) with the UCS so that they can produce the CR. However, this has not been rigorously tested. It is also possible that the alarm works through altering motivation (which is presumably responsible in those cases where the child becomes instantly dry as soon as the alarm is worn), through operant conditioning (in which the sound of the alarm is an aversive consequence), or through a beneficial focusing of parental concern.

The alarm is a safe treatment. The low risk of developing skin ulceration has been removed by the modern body alarms which work on very low voltages. There are limits to its value, some of which can be removed by good technique.

- 1 The treatment is troublesome: it demands time and energy from the child and caregivers, and failure of treatment is more likely in the context of a disturbed family. The alarm should always be demonstrated and explained, and doubts need to be discussed sensitively.
- 2 Premature termination of the therapy is quite common. It can be reduced by careful instructions about what to do and arranging follow-up; the family should be cautioned that in starting the treatment they are taking on a commitment to a 3-month course that may be only gradually successful.
- 3 The child may fail to wake to the alarm. This can often be answered by a louder buzzer or by arranging for the parents to wake the child.
- 4 There is a significant relapse rate: perhaps one-third of children who succeed initially will start to wet again. This can often be answered by a repeated course, preferably with overlearning:

after continence is acquired, the use of the alarm is continued and a fluid load is given on going to bed (Young & Morgan 1972).

Time spent in going over these details of therapy with families is rewarded by a higher success rate. Butler (1994) cautioned against the use of alarms when parents were likely to use coercive or punitive responses to them.

Other behavioural techniques have been advocated, but tend to be less effective and considerably more troublesome. Dry bed training (Azrin *et al.* 1974) involves an intensive programme of rewarding appropriate micturition at intervals through the night and practice in delaying micturition in the hope of increasing the functional capacity of the bladder ('bladder training'). Neither this nor its components have a sound evidence base.

Medication can reduce the frequency of night wetting. Desmopressin is an analogue of the naturally occurring anti-diuretic hormone, with a longer duration of action and no tendency to produce vasoconstriction. It has been compared with placebo treatment in random-allocation trials, and produces significantly more dry nights (Skoog *et al.* 1997). This has been of considerable theoretical interest (see above) but its efficacy is probably not as great as the alarm, e.g. only 77 out of 399 children achieved complete dryness in an open trial by Tullus *et al.* (1999). Furthermore, relapse when desmopressin is stopped is the rule. Nevertheless, it can be a useful way of helping children who need to be dry for a short period, for instance to allow them to make a visit or a school trip, and it sometimes helps when the alarm has failed. The dose is 20–40 µg at bedtime if given as a nasal spray, 200–400 µg at bedtime if given as tablets. Its use is in general safe (provided it is not given to people with cardiac or renal disease), and a surveillance programme for more than 200 children taking it over a period of 1 year did not detect any seriously adverse effects (Tullus *et al.* 1999); in particular, hyponatraemia was not encountered. Nevertheless, there is a small risk of harm and a case of hyponatraemic convulsion has been reported after unsupervised self-administration (Apakama & Bleetman 1999), so it is important to give clear advice about avoiding overhigh doses, especially to strongly motivated young people.

Oxybutynin (dosage 2.5–5 mg three times daily with the last dose at bedtime) is an anticholinergic drug which increases bladder capacity by an action on the detrusors. Adverse effects can be troublesome, and it is not of proven value for enuresis that is nocturnal only, but some clinicians prescribe it (or other anticholinergics) for those cases in whom there is a reduced functional bladder volume secondary to detrusor instability that causes daytime wetting.

Tricyclic and tetracyclic antidepressants have a greater effect than placebo in reducing the frequency of wetting. Twenty-two trials were summarized in a systematic review (Glazener & Evans 2000). Although the quality of trials was often poor, the conclusion was clear: the drugs are more effective than placebo, comparable with desmopressin, and are associated with, on average, a reduction of wetting by about one wet night per week.

On the other hand, complete cure is not common, and even the limited gains are often lost when the treatment stops. Further, overdoses are very dangerous, although uncommon. We think these drugs should seldom be used nowadays—but they often are.

Treatment of daytime wetting

The treatment of diurnal enuresis is less well supported by an evidence base of controlled trials. Detection and treatment of associated urinary tract infection is important. The body alarm (see above) can be adapted for daytime use, but it may be equally effective to use a simple wristwatch alarm to remind the child to go to the toilet at intervals through the day (Halliday *et al.* 1987) or for a sympathetic teacher to remind and encourage the child to use the toilet at times chosen to anticipate the enuretic episodes. Management is based on clinical understanding of the reasons for the problem in the individual case. Anxiety management or problem-focused work can be used to overcome fears about using the lavatory (which include fears of the flush, the dark, general safety or dealing with aspects of privacy or bullying in using lavatories at school). Bladder training can be used when there is clinical suggestion of reduced functional volume (such as urinary frequency). It includes a regular toileting programme, for example hourly intervals of being taken to the toilet and then increasing the time intervals between voiding when successful. Retention control, sphincter control and biofeedback techniques have been used, but sound evidence for their value is lacking (McKenna *et al.* 1999). Anticholinergic drugs, such as oxybutynin (see above), may also be useful in these circumstances. Psychotherapeutic approaches may be considered when the evidence suggests an underlying emotional conflict with enuresis as the presenting symptom or when emotional/behavioural problems coexist or are a consequence of wetting.

The isolation that many families suffer as a result of faecal or urinary incontinence can be alleviated by showing them that others are involved and interested in the conditions. Support groups are very helpful in providing information and contact points. Children and parents should be given information on the services and aids available and on support groups, such as the Enuresis Resource and Information Centre (ERIC), which has leaflets designed for children, teenagers and families, and the Continence Foundation Helpline.

Conclusions

The most common disorder of toilet function is monosymptomatic nocturnal enuresis. Considerable progress has been made in elucidating its pathophysiology. Much remains to be done, and the suggestions that different mechanisms apply to different children deserve further exploration. Nevertheless, an effective approach to therapy exists and most children can expect to be helped if it is applied. It is therefore disappointing that routine treatment in many parts of the world falls well short of best prac-

tice. The wider application of treatments known to be effective is therefore a priority for the field.

By contrast, the management of diurnal enuresis has only a slender evidence base, and the priority should be the establishment of a better understanding. The use of genetically informative designs and reliable measures of psychological and physiological change seem likely to be useful.

Most children who soil do so as part of a pattern of retention of faeces and rectal overload. The combination of paediatric management with behavioural advice is an effective model and deserves to be widely adopted. The uncommon problem of children with normal defecation who nevertheless deposit faeces in inappropriate places remains neglected by scientific investigation. There is scope and need for basic clinical research to establish a better understanding of the attitudes, motivation and abilities of affected children.

For all these disorders, it remains true that they cause a good deal of distress. The need for several perspectives makes it essential that there is good liaison between all the services available: the GP, community paediatric clinic team, the incontinence services with specialist nurses and incontinence advisors, the general paediatrician, tertiary specialist paediatric and surgical specialists, the child psychologist and the child psychiatrist. Each professional should be fully aware of the indications for further referral and joint management dependent on the severity of the symptoms and their impact upon children's lives.

Introduction

Severe paediatric illnesses have been shown to affect negatively the course of early emotional development in some children (Pless & Roghmann 1971; Cadman *et al.* 1987; Gortmaker *et al.* 1990; US Department of Health & Human Services 1999). The risk for diagnosable psychiatric illnesses in children with severe paediatric illnesses is approximately twice the rate of disturbance found in healthy children. Approximately 30–40% of children with severe paediatric illnesses have comorbid psychiatric illness. Clearly, the majority of children with severe medical illnesses are extremely resilient; however, in those paediatric patients with a comorbid psychiatric illness, appropriate recognition and prompt intervention are critical.

The events associated with the diagnosis and treatment of a severe paediatric illness often constitute a series of negative life events. Even sensitive paediatric care involves a spectrum of illness-related challenges that are appropriately classified as a category of risk factors for early developmental psychopathology. The impact of these illness-related risk factors varies, based on a set of illness characteristics that will be discussed later in this chapter. The presence of additional biological, interpersonal or societal risk factors in physically ill children further increases the likelihood of negative psychosocial outcomes. Consequently, severely ill children should be considered a high-risk group for the development of psychopathology; they are likely to benefit from preventive interventions that can be provided in collaboration with primary care physicians.

Neurological illnesses represent a special subset of paediatric illnesses (see Goodman, Chapter 14). Epilepsy, brain tumours and other neurological disorders have an even higher degree of comorbidity with psychiatric problems when compared to paediatric illnesses that do not involve overt brain dysfunction. This is presumed to be a consequence of the direct pathophysiological effects of neurological lesions on neurotransmitter systems that ultimately result in the occurrence of both neurological signs and behavioural symptoms.

A systematic clinical approach to helping children with severe paediatric illnesses requires an understanding of the interactions among the broad set of risk factors that have been demonstrated to be associated with the onset of psychopathology. The adaptation of children to environmental stressors can be conceptualized as the product of the cumulative interactions of both risk and protective factors. The pathways involved in the expression of emotional symptomatology have not been well defined.

However, a key aspect of the mechanism almost certainly involves the expression or suppression of underlying susceptibility genes. An emotionally spontaneous child with a supportive family who has experienced a series of early successes can be expected to cope well with the early onset of a severe paediatric illness. This is not to suggest that the physical symptoms and emotional disruptions associated with the disease do not provide a challenge for both the child and the family, but rather that the child will eventually succeed in meeting these challenges. In contrast, an infant with a ‘difficult’ temperament is more vulnerable. Early in the life of the child who is hard to soothe, there is a high probability that parental responsiveness will not be linked as strongly to an experience of comforting. Furthermore, parental positive stimulation is likely to be less frequent as well as less contingent on infant cues (Mrazek *et al.* 1985). As a consequence of these more problematic early experiences, children with difficult temperaments are more likely to develop less secure attachment relationships. For a child with few early successes and some biological limitations, the onset of a severe physical illness may prove to have serious behavioural and emotional consequences. When the onset of severe physical illness occurs simultaneously with other disruptions in the emotional homeostasis of the child, the risk for a negative outcome is further increased. The evidence that such negative reciprocal interactions are central to problems in emotional development is primarily clinical, although additive models highlighting the impact of multiple hospitalizations, particularly when associated with other risk factors, have empirical support (Quinton & Rutter 1976; Sameroff 1998).

Psychiatric considerations relevant to specific physical illnesses

It has been well recognized that similar chronic diseases have common physical limitations and emotional consequences. However, unique characteristics of a specific paediatric illness have been shown to result in variation in the relative risk for comorbid psychiatric illness. Seven severe paediatric illnesses are reviewed with the objective of highlighting aspects that result in differential risk for associated developmental psychopathology. The rationale for selection of these specific diseases is to contrast their illness-related risk factors. However, each of these paediatric illnesses represents a unique set of risk factors that help to

focus the clinical approach to the patient (see also Rauch & Jellinek, Chapter 62).

Asthma

Asthma is a reversible reactive airway disease triggered by a variety of immunological, infectious, physiological and emotional triggers. There is increasing evidence that asthma is heritable, and that its expression involves multiple susceptibility genes.

Asthma is the most prevalent chronic illness of childhood. In the USA and UK, estimates of prevalence vary from approximately 3%, using questionnaires that focus on a previous diagnosis of asthma, to 12%, based on reports of episodes of wheezing in the past year. By 1994, approximately 4 million children in the USA reported having had asthma in the preceding 12 months, representing prevalence rates of 5.8% in children less than 5 years of age and 7.4% of children aged between 5 and 14 years (Mannino *et al.* 1998). The highest rates are reported in isolated populations, particularly among Pacific Islanders, where the prevalence varies between 20 and 30%. The lowest prevalence rates have been reported in Scandinavia, Switzerland, Israel and Japan, where less than 2% of children have been identified (Cookson 1987).

Three primary factors have been put forward to explain these differences. The first is that differences in genetic vulnerabilities exist in different racial and ethnic populations. This has been particularly suggested as an explanation for why small populations with a high frequency of consanguineous matings have high prevalence rates. A second factor is the variability in the methodology of ascertainment of 'caseness'. Clearly, studies that accept a history of episodic wheezing as the equivalent of the diagnosis will have elevated rates. A more recent suggestion has been that variability in the physical environment may explain increased prevalence. However, this explanation does not address the finding that some of the lowest rates were found in highly developed industrial countries with considerable air pollution.

There is strong evidence that immunoglobulin E (IgE) has a central role in the mechanism of symptom expression in allergic asthma and that the regulation of IgE antibody level is under genetic control. However, asthma, like most paediatric illnesses, is best conceptualized as a syndrome with multiple genes involved in a range of possible aetiological interactions. In this regard, it illustrates interactions that occur between physiological and psychological processes. Some children appear to have a simple form of asthma that is limited to attacks that are triggered by exposure to allergens. Conversely, some asthmatic children appear to have no allergic symptoms, but their illness is triggered by a wide variety of physical and psychological factors. The majority of children present a more complex clinical picture that involves an interaction of triggers that ultimately result in bronchial constriction. Both elevated serum IgE and early proximal emotional stressors, as measured by documented difficulties in parenting, have been shown to be predictive of the onset of

asthma in children at increased genetic risk for developing the disease (Mrazek *et al.* 1999).

There is little evidence to suggest that mild asthma, defined as wheezing episodes easily controlled by inhaled bronchodilators, is associated with increased early psychopathology. However, quite severely asthmatic children, who have persistent functional disability and require multiple medications including corticosteroids to control their symptoms, have been shown to be at increased risk for emotional disturbance. Epidemiological studies have focused on the issue of severity of illness as a predictor of psychopathology (McNichol *et al.* 1973). Subsequent studies have highlighted the importance of understanding the development of emotional symptoms within the context of other risk factors for psychopathology (Steinhausen *et al.* 1983). Even preschool samples composed of very serious asthmatic children have had rates of psychopathology that have exceeded 50% (Mrazek *et al.* 1984, 1998). These high levels of disturbance can be contrasted with the relatively positive adaptation of very young asthmatic children who have less severe forms of the disease (Gauthier *et al.* 1977, 1978). In severely asthmatic older children, affective disorder is common and has serious implications for survival (Miller 1987). Both the presence of affective symptoms and disturbance in family functioning were independently associated with a higher probability of fatal episodes in very severely asthmatic children. Hypoxic seizures, a previous respiratory arrest, and rapid decrement in steroid dose were also associated with a fatal outcome (Strunk *et al.* 1985).

Families often develop idiosyncratic beliefs about the illness. Given that asthma is heritable, the diagnosis can be particularly upsetting to the parent who is asthmatic. Parents who have mild asthma virtually never consider their illness a cause for concern regarding the decision to have children. In contrast, adults with severe asthma often seriously weigh the potential risk for their offspring. The decision of a severely asthmatic woman to have a child is often complicated by her realization that her own disease may become more difficult to control while she is pregnant. Approximately one-third of asthmatic women experience some increase in their asthmatic symptoms during a pregnancy.

Given that the early physical and emotional environment of a child at genetic risk for asthma may affect the risk of illness expression, the non-affected parent is now in a position of shared responsibility regarding the child's outcome. Conversely, the successful rearing of a child at increased genetic risk for the illness is increasingly viewed as a consequence of good caregiving rather than simply 'good luck'.

The establishment of the diagnosis of asthma can be quite difficult. Controversy exists over what symptoms are sufficient to establish the diagnosis. Recurring wheezing episodes during infancy that are associated with respiratory infections resemble an asthmatic attack and have been labelled as asthma by many primary care physicians. However, the prognostic implications of infectious wheezing or wheezing bronchitis are very different from the diagnosis of asthmatic episodes in the absence of infection. The perception and response of the family will be quite

different if the first wheezing attack is perceived as simply an isolated symptom associated with one of the inevitable respiratory illnesses of early childhood rather than the beginning of a chronic illness. Increasingly, there is evidence that early asthmatic attacks should be treated intensively and that such treatment will minimize the likelihood of the development of chronic asthma. A reasonable position is to consider the first attack of wheezing in a vulnerable child as possible evidence of the existence of underlying genetic vulnerability to asthma. Such a position should be accompanied by considering strategies to minimize additional symptoms through management of the child's exposure to allergens, infections and intense emotional distress.

In children with very mild asthma, there is virtually no disability. The illness can be controlled quite effectively through the use of inhaled bronchodilators. In more progressive forms of the illness chronic corticosteroids are required, and limitations on physical activity occur as a consequence of respiratory symptoms, as well as a variety of corticosteroid side-effects that can affect vision, learning and physical development. Those with mild asthma have a completely normal physical appearance. In contrast, severe debilitating disease that requires corticosteroid treatment often results in cushingoid stigmata, growth retardation and scoliosis. Children with these signs of advanced disease are at the highest risk for having problems adapting to the developmental challenges of adolescence.

Asthma tends to be an episodic illness. Consequently, most asthmatic children experience intervals without symptoms during which they can function normally. These remissions provide reasonable hope that the illness will eventually be controlled. However, for very severely asthmatic children, their prognosis is more guarded. Fatal asthmatic attacks in children have been increasing over the past two decades although there has been some suggestion that the rate has begun to stabilize (Sly & O'Donnell 1997). The risk of a fatal episode is elevated if the asthmatic child has an emotional disturbance or there is family dysfunction (Strunk *et al.* 1985). While these risks are most acute for severely asthmatic children who require corticosteroids to control their symptoms, rare cases of children with milder disease who have died from asthma have been reported.

In summary, asthma presents a prototype of a complex illness with multiple genetic and environmental factors interacting in a manner that ultimately results in the development of a chronic illness. Those children with severe illness are at highest risk for developing emotional and behavioural difficulties and this is particularly true if their families are having difficulties in adapting to their illness and providing appropriate support and structure.

Atopic dermatitis or eczema

Atopic dermatitis or, as it is more commonly called, eczema is an allergic skin condition that almost always begins during the first years of life. It is mediated by IgE sensitization and usually involves quite localized areas of the skin. In a minority of children with atopic dermatitis, severe lesions develop that are very

distressing. The diagnosis is based on the presence of an intense pruritic rash that often begins on the face and extensor aspects of the extremities. Serum IgE levels are frequently elevated. Eczema usually resolves during childhood, but the condition can persist throughout life. Occasionally, atopic dermatitis develops in adulthood.

The incidence of atopic dermatitis in childhood is probably less than 5% (Halpern *et al.* 1973). Only a small number of these children suffer from the more pervasive or debilitating forms of the illness. Evidence of a genetic aetiology is supported by family studies (Ferguson *et al.* 1983), and the underlying heritable hypersensitive IgE response.

Studies of adults with atopic dermatitis have suggested an increased comorbidity of depression (Preston 1969). Small clinical studies have reported that exacerbations of skin lesions were associated with life stressors (Ullman *et al.* 1977). The paediatric clinical literature includes reports of individual children who have responded well to psychological interventions (Mirvish 1978), although systematic analyses of interventions have not been available. There is some suggestion that early avoidance of antigenic foods and prolonged breastfeeding may decrease the likelihood of the illness in at-risk samples (Matthew *et al.* 1977; Zeiger *et al.* 1989).

The care of young children with atopic dermatitis is challenging as it is necessary to support children in acute distress before they have the cognitive ability to cope with their discomfort. Parents must find a way to prevent their infants from aggravating the illness by scratching the lesions. Given that these infants are often upset and uncomfortable for prolonged periods, it is surprising that there have been no systematic studies examining the association between the early onset of severe eczema and later emotional difficulties. Furthermore, the illness often resolves in the first 2 years of life so that many children are completely amnesic for the experience. This unusual set of disease characteristics would allow an examination of the hypothesis that early disruption of the caregiving relationship, because of frustrations involved in controlling the child in order to prevent excoriation of pruritic lesions, may be associated with later interpersonal difficulties.

Atopic dermatitis is a familial illness, but one with relatively few long-term implications. Therefore, parents are generally not concerned about their children inheriting the disease. However, the primary treatment of the illness involves medicating the lesions, preventing scratching and identifying potential allergens in order to eliminate these substances from the environment of the child. Parents must therefore be alert to the behaviour of their child and be prepared to make difficult life changes. A common conflict is making the decision to give up a family pet after it is recognized that contact with the animal appears to be a primary precipitant for the skin lesions.

Differential diagnosis is not usually a problem. Seborrhoeic dermatitis may be confused with eczema, but the psychological consequences of a delay in arriving at the accurate diagnosis are minimal, as seborrhoeic dermatitis is a self-limited rash that is usually confined to the scalp and flexural areas of the extrem-

ities. One implication of making the diagnosis of atopic dermatitis is the recognition that the child is at risk for other allergic problems, such as hay fever and IgE-mediated asthma. If the child has a family history of asthmatic illness, the diagnosis of eczema can be conceptualized as an indicator of elevated risk for the later onset of allergically mediated asthma (Mrazek *et al.* 1999).

In older children with persistent and severe eczema, issues of disability and physical appearance become relevant. While it is rare that any permanent disability is created, wrapping the arm of the child to control acute episodes makes it difficult for the child to participate in sports and engage in other physical activities. When eczema spreads to the arms and face, it can be quite unattractive. The skin can become encrusted and 'weepy' if the child is allowed to scratch the skin and the excoriated lesions become secondarily infected. Supportive families are usually able to tolerate the changes in the appearance of their child with minimal difficulty. Parents who place a high value on physical appearance may experience an unattractive child as a threat to their own status and self-worth. The sudden development of overtly unattractive lesions in a previously highly valued and beautiful infant has been reported to be associated with emotional rejection of the child. Early sensitization of the parents to the negative implications of this rejection is often a sufficient intervention. Although eczema has the appearance of an infectious disease, it is not contagious. The irrational fear of contracting the disease from the child should be directly addressed while emphasizing the need to provide continued emotional support that includes physical contact.

When the lesions of the skin persist, they often have a more serious impact on the child's sense of self-esteem. In these cases, more aggressive psychiatric treatment is indicated to help the child cope with these negative self-perceptions. Throughout the process, the ultimate favourable prognosis should be stressed. This strategy is particularly effective if severe rashes have been typical for the family. Involving previously affected family members whose skin has healed is a good strategy to use with younger children who have a problem with abstract projections regarding the course of their illness into the future.

Cystic fibrosis

Cystic fibrosis is the most prevalent autosomal recessive genetic illness of childhood. In Caucasian populations, approximately 5% of adults are heterozygous for polymorphisms of the cystic fibrosis transmembrane conductance regulator gene (*CFTR*) (Riordan *et al.* 1989). These carriers have one normal allele that is able to code for a sufficient amount of the *CFTR* protein to prevent the onset of the symptoms that characterize what was once a fatal illness. Approximately 1 in 2000 children are homozygous for defective *CFTR* alleles and develop cystic fibrosis. Although this pattern of inheritance has been recognized for years, recent discoveries demonstrate that a wide range of defective polymorphisms result in the illness. The *CFTR* gene is located on the short arm of chromosome 7. The protein that is

coded for by *CFTR* plays a part in the maintenance of the chloride permeability of chloride channels. Variations in the alleles associated with the illness are associated with variations in the production of the protein and subsequently variation in the clinical presentation of the illness. Currently, 600 polymorphisms have been reported (Davidson & Porteous 1998) which have been divided into five general classes (Zielenski & Tsui 1995). For example, one mutation may primarily affect chloride channel function in the sweat glands and pancreatic ducts while another may affect airway epithelia. Although the range of physical symptoms is broad, classic features include chronic bronchial airway obstruction that often leads to respiratory infections, and maldigestion that results from defects in the production of pancreatic enzymes. Other organs that may be affected include the liver, intestines and genitals, usually through a mechanism that involves an increase in the viscosity of secretions.

There has been a significant increase in the life span of children with cystic fibrosis. Currently, the mean age of survival has risen to approximately 40 years of age, with 90% of children with the illness reaching adulthood (Elborn *et al.* 1991). Pulmonary function assessment demonstrating a decrease in forced expiratory volume was shown to be a strong predictor of mortality in advanced patients (Kerem *et al.* 1992).

Many complications exist, including a delay in sexual development. Ninety-eight per cent of males with cystic fibrosis are sterile (Tauszig *et al.* 1976). Furthermore, pregnancy in females with cystic fibrosis is a high-risk medical condition because of the likelihood of deterioration of the respiratory function later in the pregnancy. Problems in adjustment because of the limitations of the illness have been specifically reported during adolescence (Bywater 1981).

Cystic fibrosis is almost always diagnosed during infancy or in early childhood. The diagnosis should always be suspected in families in which there is a pedigree with identified affected relatives. Even in the less frequent circumstance of the marriage of two carriers with no known first- or second-degree affected relatives, a preliminary diagnosis is usually established once multiple symptoms emerge.

It is now technically possible to identify affected individuals through prenatal screening and this practice has been increasingly well accepted, with enhanced survival now being demonstrated in those children who receive intensive treatment from the first day of life (Dankert-Roelse & Meerman 1995). Traditionally, genetic counsellors have cautioned two carriers of an autosomal recessive gene about choosing to have children given that their chance of having an affected child is one in four. However, some parents are quite willing to take this level of risk. For some, the knowledge that prenatal diagnosis and the possibility that abortion are available provides them a clear strategy for eventually having unaffected children. Other families are prepared to raise a child with cystic fibrosis even when they are made aware of the very substantial emotional and fiscal burden associated with the diagnosis. However, for these decisions to be adequately informed, it is critical that potential parents receive

comprehensive information regarding the pulmonary care and physical therapy that affected children require, as well as frank information regarding expected medical complications and life expectancy.

Severity of cystic fibrosis has been identified as the primary predictor of psychiatric disturbance in children with the disease (Steinhausen *et al.* 1983). Approximately one-third of the children with severe cystic fibrosis developed serious emotional disturbance and another 22% had less severe problems. However, even in children with quite advanced disease, enhanced quality of life reports were associated with positive coping strategies in both patients and their parents (Staab *et al.* 1998). Whereas a full range of psychiatric problems has been noted in children with cystic fibrosis, eating disorders have been specifically cited as developing at an increased frequency (Pumariega *et al.* 1986). The most frequent concerns in these children related to anxiety concerning the actual treatment of the disease (Steinhausen & Schindler 1981). Despite ascertaining that the probability of a shortened life span was the most difficult disease-related emotional issue for children with cystic fibrosis, these children's fears were rarely verbalized until late in the course of the illness (Petzel *et al.* 1984). This illness presents clinical problems associated with impending mortality. As the disease progresses, families and providers need support to manage their feelings of anticipated loss and the frustrations associated with the limitation of therapeutic interventions.

Previous therapeutic approaches for children with cystic fibrosis have focused on medical and emotional supportive strategies (Mrzek 1985). However, positive family and peer support appears to be an important protective factor for the emotional development of children with cystic fibrosis (Venters 1981; Graetz *et al.* 2000). Achieving medical compliance is also a key management issue (Czajkowski & Koocher 1986). Initial optimism concerning the use of gene therapy has been tempered by the relatively unsuccessful efforts to transfer intact polymorphisms able to produce normal membrane transductance in affected children (Alton & Geddes 1995; Rosenecker *et al.* 1998).

Juvenile onset insulin-dependent diabetes mellitus

Juvenile onset insulin-dependent diabetes mellitus (IDDM) is an uncommon paediatric illness in young children. It affects very few preschool-age children, and only about 1 in 500 school-age children and adolescents. IDDM is a disease of the islet cells of the pancreas, which results in a deficiency in the production of insulin. There is clear increased familial risk for the development of diabetes (Riley *et al.* 1990) and diabetic complications (Sequist *et al.* 1989). Maternal-type diabetes, particularly in older mothers, has been demonstrated to be a risk factor for diabetes in children, together with neonatal infections, pre-eclampsia and caesarean section delivery (McKinney *et al.* 1999). Another recent study examining risk factors for the development of nephropathy in children with Type I diabetes found that children who had parents with Type II diabetes and nephropathy were at increased risk (Fagerudd *et al.* 1999). Al-

though the specific pattern of inheritance has not been established, progress in the identification of children at increased risk is being made through molecular genetic techniques. New evidence supporting a complex mode of inheritance has included documentation of susceptibility loci on chromosome 6 at 6p21.3 (Froguel 1997), on chromosome 11 at 11q13 and 11p15 (Hashimoto *et al.* 1994; Nakagawa *et al.* 1998; Vafiadis *et al.* 1998) and on chromosome 14 at 14q24.3 (Field *et al.* 1996).

Insulin-dependent diabetes rarely affects very early parent-child relationships because of its usual later onset. Given the probability of a normal early maternal experience, risk for relationship-related disorders should not be elevated. Given that there is minimal central nervous system involvement, neuronal dysfunction should not be considered a major risk factor for psychopathology.

Although it has been hypothesized that emotional stressors could have a role in the initial onset of the illness, Kovacs *et al.* (1985) did not find such an association in their cohort. However, a relationship between 'stressor scores' and both low serum glucose levels and triglyceride concentrations has been reported in diabetic adolescents (Chase & Jackson 1981). An association between disturbances in family interaction and overall diabetic control of adolescents as measured by elevated glycosylated haemoglobin (HbA_{1c}) has also been demonstrated at the 5-year follow-up assessment after initial diagnosis (Gustafsson *et al.* 1987). Characteristics of mothers' interactions with even preschool-aged children have been shown to distinguish children who had difficulty in maintaining adequate glycaemic control from those who were easily controlled (Garrison *et al.* 1990). Diabetic patients have been reported to be at some increased risk for emotional disturbance, but modest rates have been reported (Wilkinson 1987). In Wilkinson's study of adult diabetics, 18% were diagnosed with a psychiatric disorder and these were predominantly some form of depressive or anxiety disturbances. More severe chronic diabetic samples have been shown to be at greater risk, with 51% having been identified as having a psychiatric diagnosis in a sample evaluated for pancreatic transplantation (Popkin *et al.* 1988). Much higher risk has been documented for children who have required repeat hospitalizations for ketoacidosis when compared to children with diabetes who could be controlled as outpatients. In this study, 88% of the hospitalized diabetic children met the criteria for at least one psychiatric illness as compared to 28% in the outpatient group. Additionally, the hospitalized group was reported to have lower self-esteem and social competence (Liss *et al.* 1998). A special risk in depressed diabetics is attempted suicide by the method of insulin overdose (Kaminer & Robbins 1988). Problems in adjustment to the diagnosis of diabetes in children have also been reported (Ahnsjo *et al.* 1981).

Fortunately, few physical deformities are associated with IDDM. However, Moran (1984) has reported relatively high levels of anxiety in children related to their fears of hypoglycaemic and hyperglycaemic coma as well as later vascular complications. During adolescence, it is common for teenagers to have difficulty adhering to the relatively strict dietary protocols

and restrictions in their activity. The link between environmental stressors and diabetic control in children has also been studied (White *et al.* 1984). In these studies, ketoacidosis was linked to either dietary indiscretion or insulin mismanagement in only a minority of the cases (5–10%). However, in a majority of the cases family difficulties were felt to be associated with less adequate control. During adolescence, the patient must begin to assume greater responsibility for the treatment of the illness and begin to appreciate that there is a direct relationship between careful compliance and disease sequelae.

A major concern for many children with IDDM is the uncertainty that is associated with the future course of their illness. This includes both fear of severe ketoacidotic episodes and diabetic sequelae. More cognitive difficulties have been demonstrated in diabetic children with more persistent illness (Gath *et al.* 1980). Poor diabetic control was correlated with:

- 1 the presence of psychiatric disorder;
- 2 difficulties in reading; and
- 3 adverse psychosocial risk factors.

Cognitive difficulties in the abstract/visual reasoning subscale of the Stanford Binet Intelligence Scale have even been noted in children with relatively mild hyperglycaemia if the onset of their illness occurred before 5 years of age (Golden *et al.* 1989). Similarly, problems in cognitive processing speed, acquisition of new knowledge and conceptual reasoning ability have been documented 2 years after diagnosis. These problems may be the result of persistent hyperglycaemia (Northam *et al.* 1998).

Kovacs *et al.* (1985) described variability in the coping of diabetic children. Approximately 64% of the children in this cohort reported some social withdrawal and sadness but did not merit a diagnosis; however, 36% could be diagnosed with a psychiatric disturbance. Affective disorders were the most frequent diagnoses, but 93% of the children with these disturbances recovered over the course of the first year of their diabetic illness.

The interaction of psychiatric disturbance and the control of diabetic symptoms continues to be an area of investigation. Severe psychiatric disturbance in either the child or parent has been shown to account for approximately 44% of the variance in blood glucose level. It has also been shown to predict low glycosylated haemoglobin concentration in the children (Fonagy *et al.* 1987). In Fonagy *et al.*'s study, nearly one-third of the children had an emotional or behavioural difficulty and these children were determined to be less responsible in caring for their illness.

Juvenile rheumatoid arthritis

Juvenile rheumatoid arthritis (JRA) is characterized by chronic joint inflammation and is the most common rheumatoid disorder of children. The disease has been divided into three major categories: systemic, pauciarticular and polyarticular. While all three categories are best classified as complex diseases with an oligogenetic inheritance pattern, there is some suggestion that they each have unique genetic characteristics. Specifically, a polymorphism of the tumour necrosis factor alpha has been

reported to be associated with systemic JRA but not with the other categories (Date *et al.* 1999).

The incidence of JRA has been difficult to establish definitively. Approximately 10–20 children in 100 000 have been reported in countries with reasonable ascertainment. Prevalence estimates have been as high as 400 in 100 000 in an Australian study, but are generally in the range of 100–200 in 100 000 children (Andersson 1999).

Systemic arthritis usually presents in children during the first five years of life. Immunoglobulin A (IgA) and platelet levels are usually very elevated. Liver and cardiac involvement are common. Growth retardation can be severe and complicated by the necessity of using corticosteroids (Ansell 1999). Amyloidosis is a relatively rare, but potentially fatal complication. Polyarticular disease with a positive rheumatoid factor may advance rapidly and has a relatively poor prognosis. In contrast, children with pauciarticular disease have a better outcome. Knees and ankles are more commonly involved than elbows, wrists or neck. A chronic insidious uveitis can occur with any form of the illness.

The diagnosis of JRA has proven to be challenging. Whereas fever is a non-specific feature that co-occurs with the presentation of joint pain in most patients, the pattern of the fever is variable and may occur in a prolonged spiking pattern in about 40% of children (Miller 1998). An elevated fibrin D-dimer has been reported to be present in JRA patients and associated with fever and abnormal leucocyte counts, which is predictive of the ultimate severity of the illness (Bloom *et al.* 1998). The traditional treatment of JRA continues to be pharmacological. Aspirin and corticosteroids remain the standard approach, with some children requiring gold, methotrexate or penicillamine (Ansell 1999). The importance of physical conditioning has been emphasized in children with polyarticular disease, and has been shown to decrease the severity of the joint lesions as well as enhance the functional endurance of the joints (Klepper 1991).

Not surprisingly, disease severity has been associated with the occurrence of behavioural problems as ascertained by parental questionnaire (Daltroy *et al.* 1992). A similar finding was noted in a study of young adults in which 21% of a clinical sample were assessed to be clinically depressed. The occurrence of depression was associated with the degree of disability (David *et al.* 1994). However, a recent study comparing children with JRA and chronic fatigue syndrome found that patients with chronic fatigue syndrome and their parents both reported more psychological symptoms. Of note, only two of the JRA patients had systemic disease and little detail of the severity of the illness was reported (Carter *et al.* 1999).

Children with JRA have been assessed to determine the accuracy with which they understood the nature of their illness (Berry *et al.* 1993). While the expected improvement in understanding was demonstrated with age, a surprising lack of understanding of the illness was found at all ages, suggesting a need for greater attempts to help children understand the nature of their illness.

Leukaemia

The most common paediatric malignancy is leukaemia. Nevertheless, leukaemia is a relatively rare disorder with a prevalence of less than 0.05% during childhood. The introduction of chemotherapy and irradiation therapy has continued to alter dramatically the clinical course of the illness over the past 30 years. Currently, the 10-year life expectancy of girls with acute lymphoblastic leukaemia has reached 73% and for boys it has reached 64% (Pui *et al.* 1999). Although these constitute a huge improvement over the recent past, many children still succumb to the disease. The term 'Damocles syndrome' has been appropriately coined to describe the chronic state of uncertainty that characterizes the lives of these children (Koocher & O'Malley 1981).

The genetic basis of leukaemia is gradually becoming more clearly defined. There are certain subtypes of the disease that appear to be familial but the majority of children with leukaemia do not have a positive pedigree for the disease. Evidence for susceptibility genes have supported the position that leukaemia has a complex genetic pattern of inheritance with gene sites on chromosome 9 at 9p21 (Faderl *et al.* 1999; Heerema *et al.* 1999), chromosome 13 at 13q14 (Coignet *et al.* 1999) and chromosome 17 at 17p11.2 (Stacey *et al.* 1999).

Leukaemia represents a disease where there is little evidence that life stressors effect the onset, although a recent report has shown that women over 35 years of age may be at increased risk of having a child with leukaemia (Hemminki *et al.* 1999). Furthermore, there is little to suggest that any defined parental disturbance or behaviour is associated with the onset of the disease. The emotional reactions of the family to the initial diagnosis are usually disbelief, anger and grief. A recent report has suggested that both mothers and fathers have an increase in psychiatric symptomatology immediately following diagnosis and that mothers tend to seek social support while fathers use more active coping strategies (Hoekstra-Weebers *et al.* 1998). For teenagers recovering from leukaemia, a somewhat paradoxical link between less family cohesion and the successful completion of treatment has been reported, which may be associated with the developmental needs of adolescents to separate successfully from their families (Rait *et al.* 1992).

Complications can arise in the establishment of the diagnosis of leukaemia. A primary problem is that many of the early signs of the illness, such as increased infections, lethargy and weakness, are non-specific. Once the illness is suspected, the diagnosis can be made definitively through laboratory examination. However, as it is now universally agreed that prompt and aggressive treatment is highly beneficial for the long-term survival of these patients, unnecessary delays in establishment of the diagnosis can lead to both guilt and the attribution of blame.

During the early phases of the illness, there is little physical deformity. Later, weight loss and prominent bruising can be a problem. However, the severe prognosis that is associated with the later stages of the illness usually overshadows the changes that occur in physical appearance.

There have been relatively few studies documenting elevated levels of emotional disturbance in children with leukaemia (Kupst *et al.* 1984; Greenberg *et al.* 1989). However, Sawyer *et al.* (1986) demonstrated elevated levels of behavioural and emotional disturbance when children with leukaemia were compared to their siblings. More leukaemia survivors were also placed in special education programmes than were their siblings, and this was particularly likely if they received cranial radiotherapy. Although these children gradually seemed to adjust to their illness over the 4-year follow-up period, they were still found to have more difficulties in school as documented by both parent and teacher reports (Sawyer *et al.* 1989). Longitudinal studies into early adulthood have reported no increased psychiatric morbidity in survivors of acute lymphoblastic leukaemia, but persistent problems in interpersonal relationships have been well documented (Mackie *et al.* 2000). Long-term survivors who had received cranial radiotherapy were less likely to enter college than their siblings (Haupt *et al.* 1994).

The care and treatment of leukaemia is inevitably a burden for both the child and parent. The necessity for repeated painful bone marrow biopsies as well as other invasive procedures can make these hospitalizations frightening experiences for these children (Dahlquist *et al.* 1995). The use of high-dose corticosteroids has been reported to be linked with decreased cognitive performance as well as lower achievement scores (Waber *et al.* 2000). Furthermore, the use of cranial irradiation has been shown to have a variety of negative neuropsychological sequelae, particularly if the treatment is administered before the child is 8 years of age (Moehle & Berg 1985; Anderson *et al.* 2000). If both cranial radiation and intrathecal methotrexate treatment are employed, a larger number of psychological sequelae are noted, as well as associated abnormal computerized tomography (CT) scans (Pavlovsky *et al.* 1983). Brouwers *et al.* (1984) also demonstrated abnormalities on CT scans as well as more frequent neuropsychological deficits and attentional disturbances in patients with documented evidence of atrophy. Eiser (1998) suggested that these attentional difficulties could play a part in decreased performance on a range of cognitive measures. Very few patients showed calcifications, but those children with calcifications demonstrated the greatest neuropsychological dysfunction. These findings are similar to results from studies that examine cognitive function in children with primary brain tumours receiving whole-brain radiotherapy (Packer *et al.* 1989).

Systemic lupus erythematosus

Systemic lupus erythematosus (SLE) is a chronic autoimmune disease characterized most frequently by involvement of the kidneys, skin, joints and central nervous system, but regularly affecting the heart and lungs. The key laboratory finding is an elevated serum level of immunoglobulin G (IgG) antibodies that are specifically reactive to nuclear constituents such as double-stranded DNA and chromatin (Tsao *et al.* 1997). The most common presentation in childhood is the occurrence of skin rash and

arthritis associated with a fever, but there is considerable variability in the initial symptoms, earning the illness the colloquial name 'the great imitator'. As few as 40% of children present with the macular red facial rash that was the original basis for the name of the illness. The absence of this sign makes the disease more difficult to diagnose during childhood. The mean delay from onset of first symptoms to diagnosis is 1.2 years (Silverman 1996). Although this time can be as long as 2 years, it is reported to be much shorter in tertiary paediatric referral centres (Lacks & White 1990). In paediatric practices, the mean age of onset is approximately 12 years. The illness has been reported in infants, but rarely presents before the age of 6. Approximately 80% of paediatric patients are girls as compared to 90% of adult onset SLE. The incidence of the illness has been reported to be as high as 20 in 100 000 children, while the prevalence of this chronic illness is estimated to be 10-fold greater or 20 per 10 000. The illness occurs in all races but may be slightly more likely to occur in African-Americans and Hispanics than Caucasians.

A family history has been reported in 12.5% of children diagnosed with the illness. This pattern is typical of a complex heritable illness with an oligogenetic basis. Twin studies support this conclusion with an approximately 10-fold greater likelihood of concordance in monozygotic vs. dizygotic twins. Furthermore, the risk of a sibling developing the disease is approximately 20 times higher than the risk in the general population (Tsao & Wallace 1997). The number of candidate susceptibility genes is growing, with a prominent candidate located at 1q41–q42 (Tsao *et al.* 1997).

Although the prognosis of the illness has been gradually improving, relatively recent reports suggest that the 5-year survival rate is still only approximately 85% (Lacks & White 1990). Most children suffer considerable morbidity both the involvement of target organs or as the consequence of the treatment required. Arthritis occurs in almost all children with the illness. Proliferative glomerulonephritis is reported to occur in approximately 20–84% of affected children. Estimates of the comorbidity for severe neuropsychiatric complications have been reported to be between 17 and 69% and include major depression, psychosis and cognitive dysfunction (Lacks & White 1990).

The traditional treatment of the illness involves the use of salicylates or non-steroidal anti-inflammatory drugs. The focus of treatment always includes the arthritic complications and frequently includes the use of corticosteroids which have well-known neuropsychiatric sequelae. More aggressive treatment includes the use of hydroxychloroquine, methotrexate, azathioprine, cyclophosphamide and cyclosporin, which all have major side-effects (Silverman 1996).

Cognitive impairment in adult patients with non-central nervous system SLE has been reported in as many as 29% of patients, with much higher levels found in patients with documented central nervous system involvement (Kosora *et al.* 1996). The severity of cognitive impairment has been shown to vary over time in a manner parallel with the exacerbations and remissions of physical symptoms. This variability supports an

approach of longitudinal evaluation as opposed to assessments at a single point in time (Bleiberg & Bunning 1998). A recent study of patients with SLE who had not been recognized as having psychiatric symptomatology revealed surprisingly similar rates of neuropsychological impairment, suggesting an underrecognition of psychiatric comorbidity (Sabbadini *et al.* 1999). The use of magnetic transfer imaging rather than the less sensitive magnetic resonance imaging identifies central nervous system involvement in patients without psychiatric symptomatology, and demonstrates that SLE patients with neuropsychiatric symptoms have more extensive brain involvement (Bosma *et al.* 2000). With ever-increasing capacity to demonstrate early central nervous system involvement, targeted intervention can be linked to attempts to maintain cognitive function through the initiation of earlier aggressive systemic therapeutic intervention. Whereas the occurrence of psychiatric morbidity is clearly common in young patients with SLE, there has been surprisingly little systematic assessment of emotional symptomatology in children. Adult patients without overt central nervous system involvement were reported to have elevated scores on the clinical scales of the Minnesota Multiphasic Personality Inventory (MMPI) when compared to normal controls (Kosora *et al.* 1996). Similarly, in an independent study, about 50% of adults with SLE were reported to meet criteria for a psychiatric disorder (Waterloo *et al.* 1998). Emotional distress has repeatedly been shown to be reported by patients without overt central nervous system involvement as demonstrated by traditional clinical findings (Denburg *et al.* 1997).

Physical symptoms without evidence of somatic aetiology

Physical symptoms commonly present in the absence of known organic disease. In the past, these problems have often been classified broadly as hysterical symptoms. More recently they have been referred to as somatization disorders, dissociation disorders or conversion disorders (Kihlstrom 1994). The diagnostic challenge related to defining this group of disorders has been the dramatic heterogeneity of symptoms. This variability has made the reliable definition of phenotypes problematic. Despite this limitation, somatization disorder has been shown to be somewhat heritable, more common in girls, and linked to alcoholism and sociopathy in male relatives (Guze 1993). Concordance of conversion symptoms in identical and fraternal twins has not been established, resulting in some uncertainty regarding the degree of heritability of this condition (Jaworowski *et al.* 1998).

Many of these conditions involve neurological symptoms: paralyse or incoordination (dissociative movement disorders); convulsions (pseudoseizures; see Goodman, Chapter 14); or loss of visual acuity or blindness in portions of the visual field (dissociative sensory loss). Somatoform autonomic dysfunction (characterized by diarrhoea, palpitations, hyperventilation, flushing and sweating) must be distinguished diagnostically

from a wide range of medical disorders. Neurasthenia (chronic fatigue), hypochondriasis (preoccupation with the possibility of an underlying disease), and somatization disorder (multiple persistent somatic symptoms) are characterized by common symptoms that mimic the presentation of organic syndromes.

The concept of a disorder being defined chiefly by the absence of a physical explanation has always been problematic. The primary reason for this common concern is the anxiety associated with the possibility that an affected child may have an underlying physical disease that remains undiagnosed. Such concerns are justified as some children with organic brain disease have been previously diagnosed as having conversion disorders (Rivinus *et al.* 1975). Furthermore, organic symptoms regularly occur in children who also have functional symptoms. This is well illustrated by children with epilepsy who also exhibit exaggerated pseudoseizures or by the perpetuation of episodic abdominal pain that initially began as a result of a parasitic infestation. In the pursuit of possible physical causes, intensive investigations may be carried out which unfortunately carry their own iatrogenic risks.

The question facing the clinician is how aggressively to verify a negative finding when faced with an ill child and a concerned family. Sometimes the form of the symptom is in itself enough to argue strongly against a physical cause, as illustrated by diplopia appearing when one eye is covered even though in rare circumstances a dislocation of the lens can produce monocular diplopia. Similarly, if a symptom is clearly related in time to an external stressor, such as abdominal pain that is consistently linked to leaving for school, a history and examination may well be sufficient grounds on which to base a diagnosis. On the other hand, physical illness can arise even in children with psychologically determined disorders, and necessary investigations may be overlooked because of a psychiatric label. Good communication between paediatrician and psychiatrist is crucial (see Rauch & Jellinek, Chapter 62) and physical reappraisal of disorders believed to be psychogenic should be undertaken if they do not improve when a stressor believed to be responsible has been ameliorated.

Yet another issue in the interpretation of negative findings is the appreciation of the limitations of scientific knowledge and organic causes. In the past, some illnesses have been regarded as purely psychogenic that are now known to have organic contributions. Common examples are Crohn disease or narcolepsy. There is little doubt that unsuspected organic dysfunction continues to result in physical symptoms that are better described as cryptogenic than psychogenic. Such problems of definition make it difficult to obtain consistent estimates of prevalence. The most common somatic symptom attributed to psychological causes is diffuse pain that is often in the abdomen or head. Abdominal pain affected 32% of young Swedish adolescents with a frequency of at least once a month, whereas headache affected 67% of those studied (Larsson 1991). However, in this as in other surveys, there is no means of determining which cases could be confidently attributed to psychological disturbance. There is an association between somatic symptoms and

self-reports of high levels of emotional distress in psychiatrically referred children (Ryan *et al.* 1987), children with chronic illness (Wallander *et al.* 1988) and epidemiological surveys (Kashani *et al.* 1989). However, the aetiological role of specific stressors in the initiation of these symptoms has not been demonstrated.

Particular care needs to be taken in the assessment of somatic symptoms when the patient and the professional come from different cultures. Cultures vary in the types of words that are used to describe illness and in their members' readiness to seek help; e.g. Thai parents rate their children's problems as less serious and more likely to improve than do American parents (Weisz *et al.* 1991). Although a skilled translator can help to reduce linguistic barriers to understanding the nature of complaints, there may be more profound differences. Kleinman (1986) examined the Chinese concept of neurasthenia, which is defined solely in terms of somatic symptoms. He found many similarities between those affected and those Chinese who would be classified as depressed using Western criteria. The vast majority of these Chinese patients who were labelled as neurasthenic responded to antidepressant medication. The somatic terminology used by Chinese patients followed their political and social insistence that the roots of personal malaise should be sought in physical illness. This did not mean that the somatic complaints were unreal, or that the Chinese patients really had depression rather than neurasthenia. The implication is that the meaning of a somatic complaint needs to be interpreted in the light of knowledge about the culture's understanding of illness.

In the treatment of somatic symptoms, most authorities advocate an attempt to help the child and family understand why abnormal illness behaviour has developed in order to achieve a more adaptive solution to their problems (Goodyer & Taylor 1985). Suggestion and encouragement towards a gradual resumption of normal function can be useful (Dubowitz & Hersov 1976). However, systematic trials of such supportive treatment have not been conducted. While recurrent abdominal pain is regarded as having a good prognosis by many paediatricians (Graham 1986), follow-up studies of children seen for abdominal pain indicate that nearly half continue to suffer the same symptoms in adult life (Apley & Hale 1973; Christensen & Mortensen 1975). This more guarded outcome is based on studies of children who have been referred for an inpatient evaluation and is probably not generalizable to the majority of cases that are managed by primary care clinicians in outpatient settings.

Illness-related risk factors

A quantitative and analytical approach to the examination of the relationship of paediatric illness to early emotional development can be facilitated by conceptualizing the occurrence of a physical illness as a complex set of emotional stressors that have specific component characteristics. Such a frame of reference increases the precision with which variability in psychological

outcomes can be examined. This strategy also provides a bridge between clinical investigators interested in studying the effects of generic chronic illness and those who have been interested in linking a specific paediatric illness with distinct behavioural outcomes. If two diseases share similar illness-related risk factors, it is logical to expect that their impact on emotional development should be similar. In contrast, if two illnesses share only a single characteristic, such as a chronic unremitting course, but have different onsets and aetiologies, it would not be reasonable to expect that such contrasting conditions would have a similar impact on the emotional adjustment of a child. The following eight illness-related risk factors represent common problems that may require clinical intervention.

Age of child at time of illness onset

To appreciate the impact of age of onset of a physical illness, it is necessary to place the onset of the illness into a developmental context (see also Rauch & Jellinek, Chapter 62). Some stressors that are particularly disruptive for toddlers will have minimal negative consequences for adolescents. Furthermore, the concept of illness for children evolves in parallel with their cognitive development (Millstein *et al.* 1981; Perrin & Gerrity 1981; Burbach & Peterson 1986).

Early studies of hospitalization suggest that separation phenomena are particularly difficult for children in their second to fourth year of life (Prugh *et al.* 1953). In examining the very early experiences of severely asthmatic children with multiple hospitalizations in the first 3 years of life, a sensitive period between 6 months and 2 years also seemed to be associated with later behavioural difficulties (Mrazek 1992). Disruptions in the formation of primary attachment relationships during the first 2 years of life have been shown to have persistent effects on later relationships. Consequently, illnesses that result in unplanned and prolonged early separations from primary attachment figures during these critical years would be predicted to have a more disruptive effect on subsequent emotional development than illnesses that have a later onset.

During the school years, illnesses that interfere with the participation of children in normal family and school events are believed to be particularly potent stressors. During this period, gender differences also begin to play a part. Boys appear to be more sensitive to illnesses that interfere with their ability to participate in athletics, while girls may be more sensitive to problems that result in their inability to take full advantage of the support provided by their school-age peer group. For example, school-age girls with chronic illnesses have been reported to have modestly higher levels of social anxiety than similarly ill school-age boys (Meijer *et al.* 2000).

In adolescence, diseases that interfere with the process of establishing greater independence are particularly problematic (Orr *et al.* 1984). Becoming a member of a peer group and developing an intimate sexual relationship become critical developmental challenges. Medical problems with sexual stigma such as venereal disease, and physical disfigurement such as facial

burns, can have more dramatic emotional sequelae than more debilitating illnesses that are essentially invisible (Love *et al.* 1987).

Parental responsibility for the treatment of paediatric illness

A powerful factor related to the adaptation of a child to serious paediatric illness is the response of the family. Whereas problematic parenting should be considered a major risk factor, exceptionally sensitive and effective parenting is appropriately conceptualized as a potent protective factor. Reciprocally, the chronic illness of a child is conceptualized as a stressor that can have a negative effect on the marriage of the parents (Sabbeth & Leventhal 1984; Klinnert *et al.* 1992). Siblings of children with chronic illness have also been reported to have more behavioural problems (Tritt & Esses 1988). The link that these sibling studies suggest is that a decrease in mutual parental support can be associated with a decrease in the quality of parenting provided to both the ill and the healthy children within the family. Sibling vulnerability increases further if the care of the ill child requires a large amount of parental involvement, leaving little time for parenting a healthy brother or sister.

Given that developmental capacities shape how children perceive their illnesses, it is surprising how little empirical research has been directed towards examining the interaction of age of onset of illness and familial response on the emotional development of children with specific paediatric diagnoses. Factors that have complicated such investigations include limitations in current methods of quantitatively assessing familial protective factors. Every paediatrician knows that strong families are associated with positive clinical outcomes for their patients. A classic developmental example of family-specific variability is the range of appropriate parental support for a chronically ill teenager. These adolescents need to develop as independent individuals. A family style that supports intense commitment on the part of parents to provide physical therapy for a young child may lead to very good medical and emotional outcomes for the preschool child, but this same highly attentive and controlling behaviour may be problematic for a teenager. There must be a developmentally appropriate transition in family style to ensure that as an adolescent, the ill teenager assumes appropriate treatment responsibilities for his or her illness. More attention to the developmental implications of both the course of paediatric illness and the appropriate family responses is needed in order to clarify the significance of these developmental factors in the ultimate expression of psychological disturbance. Progress in quantification of these dimensions should lead to better studies of the specific impact of problematic parenting (Mrazek *et al.* 1995).

Unfortunately, in some circumstances, parents actually play a part in the onset of a paediatric illness through poor judgement, negligence or frank abuse. The most extreme example is Münchausen by proxy syndrome, in which a parent intentionally creates an illness in a child (see Emery & Laumann Billings,

Chapter 20). The possibility must be included in the differential diagnosis of children with a wide range of chronic paediatric conditions (Meadow 1982, 1985). The parent responsible is virtually always the mother. What is often the clue to the discovery of this form of abuse is that the mother who is inflicting the illness upon her child does not appear distressed by the persistence of the illness. From a psychological perspective, this absence of maternal concern may be more problematic for the adjustment of the child than the actual physical discomforts or disruptions associated with the medical symptoms.

Another circumstance that can influence the ability of the family to support the prescribed medical plan effectively is when a non-intentional injury occurs as a result of an action by the parent. An illustration would be the case of a father who is responsible for a vehicle collision in which he is uninjured, but his daughter sustains multiple fractures. The ability of this father to make the recovery of his daughter a primary personal goal has two positive consequences. First, the direct support of his daughter will serve as a protective factor for her emotional development. Secondly, her recovery will help him to begin to deal with his predictable feelings of guilt. Should he withdraw from participating in the provision of her care because of his sense of responsibility for her injury, this should be conceptualized as a risk factor for both father and daughter.

In other circumstances, it can be difficult to attribute responsibility. An example is a child who develops pneumonia and subsequently asthma during a period of intense family stress when his or her parents have been unavailable. In this circumstance, the parents may raise the question of whether their child being left in a large child care centre for many hours a day and exposed to many sick children could be related to the onset of the pneumonia and the subsequent onset of persistent asthma. The clinician is often tempted to provide reassurance to the parents by minimizing the links between their actions and the course of the physical illness. This clinical strategy is often supported by the belief that the parents' guilt may ultimately have a negative impact on the child and that accepting some responsibility for the occurrence of the illness is irrelevant to the subsequent management of the disease. This perspective must be counterbalanced with the knowledge that the child's risk for recurrent exposure to other illness-related risk factors may be high in this family without the benefit of an intervention designed to support appropriate parental behaviour.

Degree of heritability of the illness

A special circumstance exists related to genetic inheritance. Once parents decide to have a child, the transmission of a particular genetic trait becomes an estimated probability. Currently, parents have little control over the probability that their child will inherit a susceptibility gene for a particular illness or trait. Although this situation is likely to change (see McGuffin & Rutter, Chapter 12; Skuse & Kuntsi, Chapter 13), at present it is important that both the mother and father be made aware of any increased risk for physical illnesses that their children may have

as a consequence of their genetic make-up. When the genetic risk for an illness in their future child is remote, the decision to have a child is universally supported by family physicians and the community at large. In these cases, the occurrence of an unlikely outcome tends to have a relatively limited negative impact on the subsequent adaptation of the family. However, when the genetic risk is known to be high, as in the case of parents who previously have had a child with cystic fibrosis, there is potential for much more conflict. The decision to have another child is taken with full knowledge that there is a 25% likelihood that the next child will have the illness as well as a 50% chance that he or she will be a carrier of this well-understood autosomal recessive condition. In this case, the 'blame' is shared equally by both parents, as they are necessarily heterozygotes or carriers for cystic fibrosis.

The definition of responsible behaviour regarding the decision to have a child in light of a well-defined risk for the development of a seriously debilitating paediatric illness is beginning to change. Whereas this topic is beyond the scope of this chapter, these ethical issues are central to the care of families carrying genes associated with severe illnesses. Furthermore, when the risk for a genetic illness is well defined by the genotype of a single parent who is carrying a dominant pathological allele, the situation is further complicated by the likelihood of one parent blaming the other for passing on the gene associated with the illness of the child.

It is usually easier for families to cope with the onset of a physical illness that is perceived as the result of bad luck or the 'will of God'. In such situations, the parents are victims together with their child. However, as more is understood about environmental risk factors and genetic vulnerability, fate will become a less common aetiological explanation.

Accuracy and timeliness of the establishment of the diagnosis

The process by which the diagnosis is established can play a significant part in the ability of the child and parent to adapt to the illness. A number of factors have a role:

- 1 the duration of time required to come to closure on the nature of the problem;
- 2 the certainty with which the diagnosis can be made; and
- 3 the sensitivity with which the diagnosis and its implications are transmitted to the child and the family.

The diagnostic skill of the physician is important because it contributes directly to the quality of the physician–patient relationship. A strong partnership in the care of the child can ultimately affect the prognosis for the child. A rapid and accurate diagnosis can facilitate this relationship while a misdiagnosis can lead to an acutely adversarial situation.

Prompt determination of the diagnosis is the standard of care and usual parental expectation. When the determination of the diagnosis is delayed through administrative postponements in scheduling of diagnostic testing, sensitive communication with the family regarding the components of the diagnostic

progress can mitigate the negative effects of a prolonged period of uncertainty.

Some illnesses are more easily recognized than others. A child who develops the classic sign of insatiable thirst coupled with an abnormal fasting serum glucose is not likely to be missed as being diabetic. In contrast, a number of illnesses can mimic asthma. These include vocal cord dysfunction, which cannot be established during the examination in the paediatrician's office as it requires direct visualization of the vocal cords that can only be observed during bronchoscopy (Christopher *et al.* 1983; Julia *et al.* 1999). Given that there is a strong association between vocal cord dysfunction and emotional disturbance, this differential diagnostic possibility should be considered carefully by a psychiatric consultant when asked to consider the role of emotional factors in children with treatment-resistant asthma.

Some illnesses, such as some of the leukaemias, can be definitively diagnosed upon inspection of the blood cells. However, prodromal symptoms can be quite vague and their significance may be minimized, delaying an appropriate work-up. Unfortunately, in cases where malignancies are discovered in relatively advanced stages, the question of why appropriate early investigations were not ordered is always difficult. Avoiding discussion of this issue may well have a negative effect on the doctor-patient relationship as well as on subsequent treatment.

A difficult responsibility is the communication to both the child and family of a confirmed grave or terminal paediatric diagnosis. Although good care involves open disclosure (British Medical Association 2001), the implications of sharing devastating information with a family in crisis is often difficult to ascertain. The entire situation can be further complicated if the physician is ambivalent about the need to share the prognosis with a relatively young child. The intensity of this conflict is illustrated by the care with which some physicians organize their practices to avoid these unhappy interactions. In these cases, a child psychiatrist can be particularly helpful by providing the paediatrician with some perspective on the emotional needs of his or her patient and the family of the child, to help ensure that they have the opportunity to explore the implications of the disease for the future of the family. Such a strategy is facilitated by the use of a multidisciplinary team approach to comprehensive care (Bingley *et al.* 1980).

One method that physicians use to cope with their paediatric patients who have terminal illnesses is to begin to focus on the treatment of the disease and avoid addressing issues related to how well the child is coping with the symptoms and prognosis. An important aspect of paediatric clinical care is to be able to help the family sustain hope for an optimal outcome while providing a realistic perspective on the medical risks that the child is facing.

Interference with function

Disability associated with chronic illness varies enormously. However, this variability in functional capacity is rarely con-

sidered as an independent variable in the analysis of risk factors associated with specific illnesses despite the clear link with long-term adaptation (Mattsson 1972; Cadman *et al.* 1987). Another factor that is rarely assessed is the substantive difference in the impact of the same disability according to the child's level of development. Although interference with intellectual processing has a negative role at all stages of development, cognitive deficits have a wider range of negative implications when the child must perform at a well-defined threshold in order to advance in school. Similarly, the inability to drive a car has no negative impact prior to the age when it is legally permitted, but can have very strong negative social connotations for older adolescents.

Disability is strongly related to the severity of the illness. An asthmatic child with easily controlled asthma may have virtually no functional disability whereas a severely asthmatic child may find it impossible to attend school consistently. Although both children may have some difficulty adapting to their illness, the probability of the occurrence of emotional difficulty is clearly higher with more severe illness (McNichol *et al.* 1973). A similar relationship between severity of renal disease and emotional adaptation has been noted (Garraida *et al.* 1988).

Impact on physical appearance

One of the most common concerns of chronically ill children is their anxiety about being physically different from their peers. This concern has often been seen to be a central aspect of a diminished sense of self-esteem (Burns & Zweig 1980). Given the importance of a positive physical appearance to the formation of a sense of self-worth, it is not surprising that disfiguring illnesses are associated with increased emotional vulnerability (Breslau & Marshall 1985).

Many illnesses result in no negative impact on physical appearance. Most asthmatic children appear to be physically normal until late in the course of their illness after long periods of respiratory compromise or as a result of physical changes secondary to treatment with chronic corticosteroids. Other illnesses, such as atopic dermatitis, can result in extensive unattractive skin lesions that are not associated with long-term physical handicap or any problems in athletic or cognitive achievement.

Again, there is a rarely appreciated association between age of illness and impact of problems in appearance. Specifically, very young children may have relatively little negative feedback regarding physical deformity from very accepting adults who care for them. However, as the peer group of a child assumes greater importance, emotional rejection based on negative response from other children can precipitate depressed mood. The classic period of peak sensitivity is adolescence, when children with severe problems of physical appearance most often show disturbances in emotional adaptation. Interestingly, little empirical evidence is available to demonstrate this frequent clinical observation.

Persistence of symptoms

Diseases vary in their pattern of symptom expression. Illnesses such as asthma and epilepsy frequently have long periods of remission in which children may have extended opportunities to interact with peers and attend school in the absence of physical reminders of their disease. Other illnesses are either unremitting or result in a gradual worsening of physical discomfort and disability.

Illnesses with more persistent or unremitting symptoms would be expected to have a more negative impact on emotional adaptation. However, there is little evidence to suggest chronicity as a primary factor. A possible alternative explanation is that some children with persistent disturbances learn to come to grips with their problems in an effective manner, while children who have intervals when they are free of symptoms continue to hope for a complete resolution of the physical difficulties. In any case, variability regarding this characteristic requires further investigation.

Hope for recovery

A brief encounter with a serious illness that results in a complete recovery is unlikely to have any negative impact on emotional development. However, children with a more uncertain prognosis have been described as having a ‘Damocles syndrome’ (see above). These children must come to live with considerable uncertainty about their long-term survival.

A primary concern in the treatment of children with a terminal prognosis is that they do not prematurely lose hope. Hopelessness is a cardinal symptom of clinical depression and associated with a poor prognosis. Some children are able to maintain a strong optimistic sense about their eventual recovery with little support and in the face of quite grave odds. A difficult goal that is a component of the work with children who have a terminal prognosis is to help them and their family to reach some level of acceptance of the inevitability of their impending death.

General therapeutic considerations

The role of the psychiatrist in the management of paediatric patients with serious illnesses is in transition. Traditionally, the primary therapeutic role has been to help children cope with their circumstances. Treatment has been expanded to include active interventions that involve parents and the family members as well as psychopharmacological management.

A recent development has been the increased awareness of the interactions of multiple risk factors that are frequently associated with the initial onset of many physical illnesses. Emotional stressors have been recently demonstrated to be linked to the onset of asthmatic symptoms (Mrazek *et al.* 1999), and it is hypothesized that a wide range of highly complex illnesses may involve similar mechanisms. As new knowledge about the genetic basis of specific physical illnesses is established, the challenge of

developing protective early interventions will become more clinically imperative. For these interventions to be appropriately employed, new techniques involving multiple specialists will need to be developed. New intervention trials must be designed in order to test appropriate early treatments and validate their efficacy.

In the past, chronically ill children who exhibited depressive symptoms were not recognized as having a comorbid psychiatric illness (Costello *et al.* 1988). In part this was because of an expectation that children with severe physical limitations would understandably begin to show social withdrawal and signs of discouragement. It is now the standard of practice to diagnose and treat depressive illness in children with chronic paediatric disorders.

Rehabilitation efforts for chronically ill children are also now more clearly known to have multiple benefits. Although it may not be possible to completely resolve either the underlying physical illness or the psychiatric and behavioural symptoms of some patients, the objective of achieving a better overall level of emotional adaptation is a critical treatment goal. For example, the respiratory status of severely asthmatic children has been shown to improve when they participate in active exercise training (Strunk *et al.* 1989a). Furthermore, overall decrease in the medical utilization of severely asthmatic children was demonstrated after their participation in a comprehensive rehabilitation programme with active psychiatric involvement (Strunk *et al.* 1989b). Similar results may be possible for a wide range of chronic problems and should be the focus of active investigations.

Primary prevention should be a component of a comprehensive approach to the care of children at genetic risk for the development of severe paediatric illnesses. An immediate scientific objective is to begin to define the physiological and environmental factors that affect initial expression of susceptibility genes. A first step in this process is to quantify the range of potential stressors for the target disease. This is currently being achieved by carefully monitoring the initial expression and subsequent exacerbations of illnesses in vulnerable children. An alternative methodological approach is to examine carefully the recent past experience of children who have had a recent onset of a significant disease.

Using either strategy, the key research objectives must include the identification of illness-related factors. This would have the attractive feature of providing more precise insight into the mechanism of initial gene expression. Although it is possible to speculate that a particular physiological mechanism may link the symptoms of a physical illness and a set of psychiatric symptoms, there are surprisingly few models. An exception is the clinically observed association that depression is common in children with severe asthma. Three competitive neurobiological hypotheses exist. The first is that an underlying disturbance in autonomic regulation, such as a shift in the sensitivity of cholinergic receptors to parasympathetic stimulation (Cockcroft *et al.* 1977), may place a child at greater risk for environmentally triggered bronchial constriction while at the same time influencing

the central nervous system in such a way as to result in increased dysphoric mood (Charney *et al.* 1981; Miller 1987; Mrazek & Klinnert 1991). A second potential mechanism could be that the contents of mast cells or basophils are released as a consequence of an immunologically mediated IgE reaction. These cells contain a wide range of substances that include both bronchial constrictors and neuropeptides (Leff 1988). Some of these neurohumoral proteins have been demonstrated to play a part in central neuroregulation of dysphoric states (Snyder 1980, 1982). A third potential mechanism could be primarily genetic, based on the possibility that a single gene is involved in the regulation of respiratory control and the regulation of central neurotransmitters. A fourth hypothesis represents a more traditional perspective that psychophysiological respiration changes are secondary to the negative subjective experiences of the asthmatic child. This explanation is based on the observation that severe episodes of respiratory insufficiency are often described as extremely frustrating and result in considerable social restrictions. The chronic experience of severe attacks subsequently becomes linked to repeated episodes of unhappiness, discouragement and depressed mood.

Only through systematic investigations will the most salient mechanism or combination of mechanisms responsible for this phenomenon become more clearly understood. Unfortunately, such investigations are difficult to conduct as a consequence of current methodological limitations. To continue the previous illustration, the study of depression in physically ill children is often confounded by the use of instruments designed to assess mood disturbance that equate physical symptoms with symptoms of affective disease (Heiligenstein & Jacobsen 1988). However, more definitive studies will become possible once reliable biological markers for affective disturbance have been clearly established.

It is ironic that partnership of paediatricians and child psychiatrists has not been more productive in designing empirically driven studies to investigate the aetiological basis of severe paediatric disease. Both specialties have a long tradition of recognizing and dealing with the emotional development of ill children. There is reason to be optimistic that renewed commitment to this shared mission will facilitate the application of new methodologies to the more comprehensive study of the complex biological processes underlying adaptation to these disorders.

Psychiatric Aspects of HIV/AIDS in Childhood and Adolescence

Jennifer Havens, Claude Ann Mellins and Joyce S. Hunter

Epidemiological overview of the HIV epidemic as it affects children and adolescents

Because of the steadily increasing rates of HIV infection in women of child-bearing age, HIV/AIDS has become a major worldwide threat to the health and psychosocial well-being of children and adolescents. By the end of 1999, 32.4 million people were living with HIV/AIDS: 14.8 million were women and 1.2 million were children under the age of 15 years (UNAIDS 2000). Despite improved medical treatment options and ongoing prevention efforts, the death rate from AIDS continues to grow and new infections continue to emerge, particularly in women and children. In 1999, 1.1 million women and 470 000 children died from AIDS (56% of the total deaths resulting from AIDS) and 2.3 million women and 570 000 children under the age of 15 years were newly infected with HIV. Nearly half of all people who acquire HIV become infected before they are 25 and die before they are 35 from AIDS-related conditions. These numbers reflect the significant threat of AIDS for children worldwide.

In the USA, the picture is less bleak, although HIV/AIDS continues to take its toll. While the advent of new medical treatments has significantly slowed the AIDS incidence in the USA, as of June 1999, 114 612 women, 3564 youths aged 13–19 years, and 8596 children aged less than 13 years were living with AIDS (Centers for Disease Control and Prevention 1999). Furthermore, between July 1998 and June 1999, among the states with confidential HIV reporting, there were over 6300 new cases of HIV infection in adult women, 786 new cases of HIV infection in youths aged 13–24 and approximately 260 new cases of HIV in children under the age of 13 years.

Over 90% of children with HIV/AIDS worldwide acquired the virus through mother–infant (vertical) transmission from their mothers either during birth or through their mother's breast milk (Centers for Disease Control 1999; UNAIDS 2000). In a recent randomized trial in sub-Saharan Africa, the frequency of breast milk transmission of HIV was 16.2% and the use of breast milk substitutes prevented 44% of infections (Nduati *et al.* 2000). However, the infants from both groups were at similar risk for dying by the age of 2 years, reflecting the limitations of bottle-feeding in many African countries.

In the USA and other developed countries, perinatal transmission of HIV infection has been substantially reduced by the use of zidovudine (AZT) by women during pregnancy and birth. In

the absence of zidovudine treatment, vertical transmission rates in the USA ranged from 15 to 30% (Centers for Disease Control 1995). Multisite studies by the Paediatric AIDS Clinical Trials Group found that rates of vertical transmission were reduced to 8% with the administration of AZT during pregnancy (Connor *et al.* 1994). In addition, several recent studies have found that elective caesarean section results in lower perinatal HIV transmission rates (Mandelbrot *et al.* 1998).

Unfortunately, standard medical treatments utilized in the developed world for the prevention of vertical transmission have not been implemented in much of the developing world, where the vast majority of new HIV infections occur. Of the 1.2 million children with HIV infection in the world, approximately 95% are in developing countries (UNAIDS 2000). In developing countries, economic conditions and health infrastructure inadequacies have limited women's access to AZT during pregnancy and thus rates of perinatal transmission continue unabated.

In addition to the direct effects of HIV infection, millions of children worldwide are affected by HIV infection and illness in their family members. By the end of 1999, 11.2 million infected and uninfected children under the age of 15 years were orphaned by their mother's death to AIDS. Many of these children also lost fathers (UNAIDS 2000). Particularly in sub-Saharan Africa, the huge numbers of children growing up without parents represents a major threat to the stability of the region.

In the USA, HIV also continues to cast a pall over a growing number of uninfected children and adolescents living with HIV infection in a parent and/or at risk of losing a parent to the disease. Recent projections are that 75 000–125 000 nationwide will have lost their mothers to AIDS by the year 2000 (Michaels & Levine 1992). While recent pharmacological advances in the treatment of HIV may reduce overall mortality, it is significant that women and ethnic minorities appear to be benefiting less from the life-prolonging impact of these new medications (Shapiro *et al.* 1999). Therefore, the children of these women are still at high risk for losing at least one parent and are clearly 'affected' by the HIV epidemic.

Also, given that at least half of HIV infections occur before the age of 25 years, adolescents remain one of the fastest growing risk groups. In the USA, among adolescent male cumulative AIDS cases, male-to-male transmission (34%) and transfusion of blood products in haemophiliac males prior to the initiation of blood screening (35%) are the most prevalent risk factors. Among adolescent female AIDS cases, heterosexual

contact (52%) and intravenous drug users (IDUs; 14%) are the most prevalent risk factors (Centers for Disease Control 1999).

In the USA, children infected and affected by HIV/AIDS are disproportionately from ethnic minorities and the offspring of IDUs. Among women over the age of 13 years with AIDS, 57% are black and 20% are Latina. Intravenous drug use is the primary risk factor for HIV infection in 42% of women with AIDS in the USA; heterosexual transmission from an IDU partner is the risk factor for another 16% (Centers for Disease Control 1999).

Corresponding with the association of HIV and substance abuse in women in the USA, 53% of children under 13 years with AIDS were born to women whose risk factor for HIV infection is their own or their partner's intravenous drug use (Centers for Disease Control 1999). Also corresponding with the demographics of AIDS in women, the majority of paediatric AIDS cases are black (58%) and Latino (23%). Among adolescents ages 13–19 years, 12% of males and 33% of females have injection drug use or sex with an IDU partner as their risk factor for infection. In addition to drug use, the majority of HIV-infected women, adolescents and children live in large urban environments, such as New York City, Miami, Florida, Newark, New Jersey, and San Juan, Puerto Rico, and are typically socioeconomically disadvantaged (Boyd-Franklin *et al.* 1995; Centers for Disease Control 1999).

Medical treatment issues

The rate of disease progression among children with HIV varies considerably, but is typically more rapid in children than in adults, regardless of the mode of infection (Mellins *et al.* 1998). In the first decade of the HIV epidemic, perinatally HIV-infected children had a considerably shortened life expectancy. In 1995 in the USA, 75–90% of perinatally infected children were expected to have symptoms by 1 year of age; 25–30% would have clinical AIDS. Two relatively distinct courses were described: a rapidly progressive course occurring in 20% of children, and a more common slowly progressive course. The death rate was greatest during the first year of life (>15%), and slowed after 2 years with many children remaining stable throughout their first 10 years of life (Mellins *et al.* 1998).

In the USA, advances in antiretroviral therapy, such as the introduction of protease inhibitors in 1996 and the development of combination regimens with greatly superior efficacy in viral suppression, have provided substantial clinical benefits to HIV-infected children both in terms of life span and quality of life. In general, the principles of HIV treatment are the same for HIV-infected children, adolescents and adults. However, there are some unique considerations for HIV-infected infants, children and adolescents, including possible prenatal exposure to HIV and maternal antiretroviral treatment, developmental and biomedical differences in children on clinical parameters used in assessing severity of paediatric HIV disease and treat-

ment needs, and issues of adherence to treatment by children and adolescents (HIV/AIDS Treatment Information Services 2000).

The use of combination therapy, including protease inhibitors, has led to substantial improvements in neurodevelopment, growth and immunological and/or virological status. Combination therapy is now recommended for all infants, children and adolescents who are being treated with antiretroviral agents (HIV/AIDS Treatment Information Services 2000). By 1999, the median life span for perinatally HIV-infected children was 8.6–13 years; between one-third and two-thirds were expected to survive at least to 13 years of age (American Academy of Pediatrics 1999).

While treatment advances have the potential to prolong life span and reduce the incidence of vertical transmission, these advances are only available on a widespread basis to children and parents living in the developed world. On an international basis, HIV infection in children continues unabated. In the developed world, rising rates of HIV infection in women are reflected in growing numbers of children living under the shadow of parental HIV illness. This chapter provides a review of the mental health issues associated with HIV infection in children and adolescents, as well as those issues associated with living with parental HIV illness.

HIV in children and adolescents infected through vertical transmission

Neurodevelopmental sequelae of HIV infection

From the beginning of the epidemic, there have been consistent findings of significant neurological, developmental, cognitive and language deficits in HIV-infected children (Epstein *et al.* 1988; Brouwers *et al.* 1990; Mellins *et al.* 1994; Belman *et al.* 1996; Englund *et al.* 1996; Coplan *et al.* 1998; Drotar *et al.* 1999). In general, the severity of neurological and neuropsychological compromise increases with the severity of HIV-related illness; the children with the most significant delays have higher viral loads and the most severe non-neurological health-related symptoms (Pulsifer & Aylward 2000).

Two relatively distinct neurodevelopmental patterns have been described: progressive encephalopathy and static encephalopathy (Epstein *et al.* 1988; Brouwers *et al.* 1991). Progressive encephalopathy, corresponding with the AIDS dementia complex in adults, is characterized by the loss of developmental milestones in young children and by declining IQ scores and increasing difficulties with language, attention, concentration and memory in older children. This neurodevelopmental pattern is a direct effect of HIV on the central nervous system and is associated with a poor prognosis. Static encephalopathy, characterized by non-progressive deficits in cognitive, motor and/or language function, is not directly attributable to HIV and is most likely associated with non-HIV risk factors. For many HIV-infected children, these factors may

include prenatal drug exposure, prematurity, low birth weight and heritable or environmentally mediated impairment (Epstein *et al.* 1988; Mellins *et al.* 1994).

Recent advances in antiretroviral treatment have the potential to ameliorate the development and progression of HIV-related central nervous system compromise. Zidovudine treatment alone has been shown to be associated with improvements in cognitive and neuropsychological functioning (Pizzo *et al.* 1988; Brouwers *et al.* 1990; McKinney *et al.* 1991; Brady *et al.* 1996). Current treatments, which combine several antiviral agents to achieve near total viral suppression, have the potential to reduce the prevalence and severity of central nervous system disease.

Diagnosis and treatment of AIDS encephalopathy in children

HIV-related encephalopathy is a common sequelae of HIV infection in children, reported in 21% of a cohort of 128 perinatally infected children followed in a national multisite study (Cooper *et al.* 1998). In addition to the loss of developmental milestones in young children and the declining IQ scores and increasing difficulties with language, attention, concentration and memory in older children, encephalopathic children manifest apathy, decreased social behaviour and symptoms of depression and irritability as compared to non-encephalopathic children (Moss *et al.* 1994, 1996).

Recognition of dementia-related behavioural sequelae and accurate differential diagnosis is clinically important for several reasons. First, parents and medical staff can misinterpret a child's increasing fatigue, decreased interest in and resistance to regular activities and regressive behaviour as oppositional behaviour or as depressive disorder. This can result in efforts to encourage the child to alter their behaviour when in actuality the behaviour represents sequelae of the disease process and is not within the child's control. Second, early in the presentation of AIDS dementia in children, stimulants such as methylphenidate can be very helpful to them in raising their energy level and improving their quality of life (Havens & McCaskill 1999). Third, progressive organic involvement in children is an important prognostic sign, generally accompanied by severe immunocompromise and signalling the endstage of the disease. This is an important time to shift gears in the work with children and their families to help them prepare for the final stages of the child's life.

Emotional and behavioural disorder in HIV-infected children

To date, the literature on emotional and behavioural disorders in HIV-infected children is extremely limited. In one of the few studies focusing on psychiatric disorder in HIV-infected children, Havens *et al.* (1994) found high rates of attention deficit hyperactivity disorder (ADHD): five out of 24 HIV-infected children (21%) met diagnostic criteria on a structured psychi-

atric interview. However, these rates were not different from those in a matched control group of children from similar backgrounds (children living in foster care who had been born to women who had used drugs during pregnancy).

While several other studies have also suggested a high prevalence of symptoms compatible with ADHD in HIV-infected children (Corsi *et al.* 1991; Hittleman *et al.* 1993), it is important to exclude other psychiatric disorders that may present with disruptive behaviours. Mood, anxiety and adjustment disorders in addition to bereavement reactions in children could easily mimic aspects of ADHD or may represent comorbid diagnoses. Early clinical reports suggested that HIV-infected children were at high risk for anxiety, depression, guilt and low self-esteem (Speigal & Mayers 1991; Wiener & Septimus 1991). Englund *et al.* (1996) reported that 13.3% of HIV-infected children between 3 months and 18 years of age manifested abnormalities of behaviour or affect, the most common being difficulties with social interaction. Tardieu *et al.* (1995) reported that 30% of HIV-infected children in their sample had moderate symptoms of anxiety, depression or behaviour problems. Havens *et al.* (1994) also found that HIV-infected school-aged children were found to have more symptoms of anxiety on self-report instruments than the uninfected children in their sample. Likely factors contributing to anxiety include higher levels of psychosocial stressors associated with HIV infection, such as frequent illness and hospitalization, concerns over health status, and family illnesses and instability.

It is important to note that none of the studies to date have found direct associations between HIV and emotional and behavioural problems. The complex backgrounds of HIV-infected children increase their risk for behavioural problems and also makes it difficult to establish causal relationships between HIV and behavioural outcomes, given the association of HIV with other high-risk factors (e.g. poverty, prenatal drug exposure, birth complications, family disruption). Features associated with prenatal drug exposure, such as prematurity, low birth weight and heritable parental psychopathology, may actually be more potent mediators of mental health problems in HIV-infected children than HIV itself (Havens *et al.* 1994; Mellins *et al.* 1994; Campbell 1997).

Moss *et al.* (1998) found that among a sample of 24 school-aged HIV-infected children, the majority had depression, anxiety and behavioural problem scores in the normal range. However, those who experienced more negative life events showed more psychological and behavioural problems. In the USA, the fact that the majority of HIV-infected children reside in inner-city environments suggests that they are at risk for significant life events including economic hardships, inadequate housing, inner-city violence and social discrimination (Levenson & Mellins 1992) and so related emotional and behavioural outcomes. Regardless of causality, there is clearly a constellation of factors associated with HIV infection in children that place them at risk for mental health problems and that need to be considered by mental health and education providers.

Psychotherapeutic issues in helping children cope with HIV illness

Communication about health

Children's age and/or developmental level dictate their capacity to understand the meaning of their HIV illness. Preschool-aged and young school-aged children generally cannot grasp the concept of chronic illness and understand episodes of HIV-related illness as discrete and unconnected events. Because of the stigma associated with HIV infection and young children's inability to contain information discretely, they are usually not informed by family members or health care providers about their HIV infection. As children age, communication about the nature of their health problems becomes more important, both to secure their participation in their health regimes and to facilitate the adjustment to living with HIV. Often, older school-aged children who are not directly informed of their diagnosis will deduce it from clues presenting in the medical care environment or elsewhere. A lack of open communication in these cases serves to isolate the child from adult help with issues related to HIV. These issues include coping with secrecy, stigma and potential rejection by peers, coping with chronic illness, and anxiety about the future (Boyd-Franklin *et al.* 1995).

Parents or other family caregivers often resist communication with the HIV-positive child about his or her health in an effort to protect the child from emotional distress (Mellins & Ehrhardt 1994). Often entangled with this motivation are one or more other factors: the adult's own fear of experiencing more intense pain about the child's diagnosis; parental fears about disclosing their own HIV infection through disclosure of the child's infection and/or parental guilt about having transmitted the virus to the child and their own HIV risk behaviours (e.g. sexual behaviour, drug use); and concerns that the child will disclose family secrets about HIV in undesirable ways.

While for adult family caregivers and health care providers the specific diagnosis of HIV is often a highly charged overwhelming element in their efforts to communicate to the child about health issues, it is in fact only a single component. The child may be more concerned about medications, medical appointments and procedures associated with a chronic health condition, or with impingement on functioning. Establishment of effective communication with the child on the broad range of health-related issues is of great importance. When the efforts of family caregivers and health professionals are not achieving this goal, a therapist may need to intervene. The starting point must be listening to the child to ascertain what the child knows and fears, and what information he or she actually wants. Often the child is seeking an admixture of medical data and affective material. One useful technique is to work with the child on making a list of questions. These questions provide a structure for adult responses, and help to assure that the child's needs frame the communication process.

Adherence to medical regimens

HIV-infected children, like those with many other chronic illnesses, may need to adhere to complicated medication regimens, attend numerous medical appointments and undergo frequent diagnostic procedures. While the use of antiretroviral therapies has resulted in improved life expectancy for HIV-infected children (Abrams & Nicholas 1998), these therapies require patients to follow arduous regimens that can interfere with everyday lifestyle (Katzenstein 1997). In a recent clinical trial of protease inhibitors, 30% of participating children discontinued the prescribed medications (Falkenberg 1999). Little is known about treatment adherence in HIV-infected children, although these results correspond with studies in other chronic diseases, including adult HIV. Typically, 40–50% of children do not use medications as prescribed (Becker *et al.* 1972). Even brief episodes of missed medication doses can permanently undermine HIV treatment (Macilwain 1997).

In studies of other childhood chronic diseases (e.g. asthma, cancer, diabetes) a combination of child, caregiver and provider psychosocial characteristics has been associated with adherence, including caregiver health, parenting style, child and caregiver knowledge of disease and treatment, family functioning and resources, satisfaction with medical care, provider–patient relationships, and child emotional and behavioural problems (Johnson 1980; Manne *et al.* 1993; Auslander *et al.* 1997; Bender *et al.* 1998).

Given the potential threats to each of these areas among HIV-infected children, they are at risk for non-adherence to treatment. Furthermore, the stigma and discrimination experienced by an HIV-infected child and their family may further complicate adherence to medications that must be taken throughout the day, often when the child is in school (Armistad *et al.* 1998). Many HIV-infected children are not told their diagnosis, which can further impede their co-operation with treatment. Moreover, HIV medications often have unpleasant tastes or side-effects. Engaging in a behaviour with noxious consequences for future health benefits is difficult for many adults; it is even harder for young children who are functioning at a concrete level of thinking, with limited future orientation.

Effective communication with the child about his or her health is the best foundation for securing the child's participation in these activities. Many families will need considerable support to administer the complexly scheduled medication for the child, and in managing the child's potential opposition to taking medication. Behaviour modification techniques, and especially positive reinforcement, may be very helpful to families in dealing with these issues. Offering the child as much control as possible ('Which pill do you want to take first?') may also minimize struggles over medication.

Promotion of optimal development

As is the case for adults, the mental health issues for infected children change over the course of the disease. There are an increas-

ing number of HIV-infected children who remain relatively symptom-free for long periods of time. They may not know their diagnosis and their lives may be relatively unaffected by illness. However, they may be very stressed by the illness of a parent, by substance abuse in the family, by disrupted placements and ruptured attachments, or any of the other problems which so often plague the families at highest risk for HIV (see below). Interventions for these problems and attention to promotion of the child's optimal development may be of more relevance in his or her mental health care than a narrow focus on HIV (Rosen *et al.* 1997; Ryan *et al.* 1997).

Educational issues

Part of optimal development is capacity for adequate school functioning. All too often, the various systems that should serve the HIV-infected child—the family, child welfare agencies, foster agencies, school and health care institutions—fail to assure that the child's education needs are met. Given the prevalence of HIV-related encephalopathy, neuropsychological problems and multiple medical appointments that interfere with school attendance, HIV-infected children are at high risk for school-related problems. HIV-infected children require regular psychoeducational evaluations—to monitor possible deterioration. Teachers may not always know about a child's HIV infection, given rules of confidentiality. They may misinterpret frequent absence and potential lack of motivation as reflecting a lack of interest or commitment to school. HIV-infected children may require considerable special education resources. As their health deteriorates, home-based education may be necessary (Haikie *et al.* 1991). It is important to the general well-being of these children that as normal an education experience as possible, including social experiences, be maintained.

Issues in adolescence

For HIV-infected children who live to adolescence, the normal developmental challenges of this stage, including puberty, sexuality and the desire to 'fit in' or be 'normal' are seriously complicated by HIV disease. The detrimental effects of HIV on growth and pubertal development pose significant challenges for the growing number of congenitally infected young people living into their teenage years. Nevertheless, as congenitally infected children move through adolescence and become sexually active, they require significant support in managing the complex issues of integrating healthy sexual development with their HIV infection. Open and honest communication around patterns of sexual behaviour, disclosure to sexual partners and strategies for the prevention of the spread of HIV are essential.

Therapeutic support for the child and family as death approaches

With disease progression, children must confront the physical and mental decline associated with AIDS. As they approach late stage illness, they and their families must confront the terminal

nature of the disease. Often, families are overwhelmed at this stage and have difficulty communicating with the child about issues related to prognosis and death. Sensitive mental health intervention by clinicians with an ongoing relationship with the child and their family can provide a place for a child to express the inevitable anxieties and fears about separation from family members and dying, and to help the child, if old enough, to communicate their wishes about medical treatment. Special attention must be paid to issues in pain management at this stage, particularly for young children with limited ability to communicate information to health care providers effectively (Havens *et al.* 1999).

As children approach the end of life, they may experience confusion and great anxiety. Parents or other adult family caregivers, and perhaps even medical and nursing staff, frequently find communicating with the child about the approach of death so difficult and overwhelming that they avoid it. Despite this, dying children need a venue in which the impending death can be discussed. They require an opportunity to express their thoughts and fears, and to receive reassurance. For many pre-adolescent children, separation from family, and especially from a primary attachment figure, is the most worrisome aspect of death. A therapist may be able to draw on elements in the family's spiritual or religious belief system to sustain hope of continuity of attachment between the deceased and surviving family members (Ryan *et al.* 1997; Havens *et al.* 1999).

Psychopharmacological management in HIV-infected children and adolescents

Psychopharmacological management of psychiatric disorder, delirium and dementia in HIV-infected children is often a necessary component of adequate treatment. However, it is complicated by drug–drug interactions with antiretroviral medications used to treat HIV disease (an issue in all HIV-infected children undergoing such treatment) and potential central nervous system impairment secondary to HIV infection (a particular issue in those children with advanced HIV disease). Guidance with psychotropic medications in paediatric HIV tends to be analogous to geriatric psychopharmacology, where dosage should be initiated at doses lower than standard treatment and titration upward should be slow and carefully monitored.

When evaluating children with behavioural syndromes who are treated with antimicrobial, antifungal and/or antiviral agents, potential neuropsychiatric side-effects must be included in the differential diagnosis, because many drugs commonly used in the management of HIV disease have such side-effects. When planning pharmacological treatment of HIV-infected children on antiretroviral medication, potential drug interactions must be taken into consideration (Sahai 1996). Of particular importance in drug interactions is the family of cytochrome P450 isoenzymes, which are responsible for the metabolism of many psychotropic medications and antiretrovirals, especially the protease inhibitors. Other HIV-related medications, including antimicrobial and antifungal medications used in treatment

and prophylaxis, also interact with cytochrome P450 isoenzymes. It is important when initiating treatment with psychoactive medications to review the metabolism of the medication(s) with the entire treatment regimen to identify interactions and contraindications. Unfortunately, the paediatric psychopharmacologist treating HIV-infected children is often in unexplored and undocumented territory, so treatment should proceed cautiously and with frequent monitoring (Heylen & Miller 1996a,b; Fauci *et al.* 1999; Oleske *et al.* 1999).

In a case series, Havens & McCaskill (1999) described the psychostimulant treatment of 12 HIV-infected children and adolescents, eight with ADHD and four with HIV-related dementia. Two-thirds of the children tolerated psychostimulants with good efficacy as measured by the Efficacy Index of the Clinical Global Impressions. The maintenance dosage of methylphenidate ranged from 0.2 to 1.2 mg/kg, and the one child on dexamphetamine required 0.6 mg/kg. Four of the 12 children treated (three out of the ADHD sample) experienced adverse side-effects precluding their continuation of the methylphenidate. While the neuropsychiatric adverse effects argue for caution in the psychostimulant treatment of this population, such treatment should not be withheld when clinically indicated. Two out of the three children who could not tolerate methylphenidate were managed with clonidine. The successful use of clonidine in the treatment of behavioural symptoms in a preschool-aged child with HIV encephalopathy was also described in a case study (Cesena 1995).

Acquired HIV infection in adolescence

The fact that a large number of HIV-infected adults learn of their diagnosis in their 20s suggests primary HIV infection occurs during adolescence (Centers for Disease Control 1999). There are several groups of adolescents who are at particularly high risk for HIV infection. These include teenagers living in poverty in inner-city environments where substance abuse is endemic; adolescents with substance abuse problems; gay and bisexual youth; youth with psychiatric disorders; and homeless and street youth. Adolescents acquiring HIV are at risk for a range of mental health problems related to their specific risk factors for HIV infection, premorbid conditions, and ramifications of having the disease itself. Risk factors for HIV infection in adolescence are described below as well as the corresponding mental health issues.

Inner-city racial and ethnic minority teenagers

In economically depressed areas of inner cities, teenagers of colour living in poverty have been overrepresented among AIDS cases, particularly young heterosexual females (Centers for Disease Control 1999b,c; New York City Department of Health 1999). Many inner-city adolescents engage in unsafe sexual behaviour, such as inconsistent contraceptive use and concurrent substance use. Risk factors that have been associated with ado-

lescent risky sexual behaviour include poverty, stress, family disruption, exposure to substance use, and early onset of sexual activity (Hogan & Kitagawa 1983; Hofferth *et al.* 1987; Walter *et al.* 1991). Early onset of sexual intercourse among adolescents of colour is well documented. Studies of inner-city youth have estimated sexual initiation at a mean age of 12–14 years (Brooks-Gunn & Frustenberg 1989; Orr *et al.* 1989; Keller *et al.* 1991; Paikoff 1995), with more than half of high school students having engaged in sexual intercourse prior to graduation (Kann *et al.* 1998). Engaging in sexual activity before the age of 15 has been related to unprotected sex, multiple partners, exposure to sexually transmitted diseases (STDs) and pregnancy (Walter *et al.* 1991; Smith 1997). Immaturity of the reproductive organs and immune systems of adolescents increases their risk of contracting STDs including HIV (Morris *et al.* 1993); adolescents now account for one-third of STD cases reported nationally (Kann *et al.* 1998). High rates of unprotected intercourse and STDs are both linked to an increased risk of contracting HIV (Wasserheit 1992).

Substance use

Drug use also tends to begin early in ethnic minority inner-city youth, often before the age of 14; in one study, 13 and 14 year olds reported using an average of three to four different drugs (Adger 1992). As adolescents mature, the proportion who experiment with sex and drugs increases. Substance use is considered to be part of a cluster of problem behaviours that occur during adolescence (Jessor & Jessor 1977) and therefore is likely to be related to behaviours that put adolescents at risk for HIV disease. For example, substance use increases the risk of HIV both directly, in the case of injected drugs, and indirectly, through disinhibition leading to unsafe sexual behaviours. Roger *et al.* (1998), in the REACH study of HIV-infected adolescents, reported that 14% of females and more than 25% of males reported drinking alcohol during the past 3 months, and 7% of females and 20% of males reported using hard drugs during that same period.

Homelessness

Many HIV-infected adolescents are homeless or living on the streets (Clatts & Davis 1999). In the USA, according to the US General Accounting Office (1989), it is estimated that 1–2 million youth are living on the streets. Many of the youth spend their time in and around bus terminals and known cruising areas (both heterosexual and homosexual). On the streets, with no employable skills and with their bodies as their only commodity, many homeless girls and boys often become part of the street economy and turn to prostitution in order to survive. Many of them are gay, lesbian or bisexual. Many use drugs and alcohol to cope with working in the sex trade and manage the constant stresses of day-to-day living on the streets (Hunter & Schaecher 1992). A vicious cycle is then established as they begin to trade in risky sex for drugs (Hunter & Schaecher 1992; Hunter &

Haymes 1997), increasing their risk for poor health outcomes, such as hepatitis, tuberculosis, STDs and HIV infection.

Gay and bisexual youth

Among 13–24-year-old males, 51% of all AIDS cases in 1998 were among young men who have sex with men (Centers for Disease Control 1999); gay and bisexual youth are overrepresented in this group (Centers for Disease Control 1999). Gay and bisexual male youth are at risk for HIV infection, not only because of the high prevalence of HIV among potential sexual partners, but also because heterosexism and homophobia and, for youth of racial and ethnic minority, racism make the process of identity development for gay and bisexual youth extremely difficult. Difficulties with identity development have been associated with risk behaviour in gay and bisexual youth, and therefore with HIV infection itself (Rotheram-Borus *et al.* 1995; Rosario *et al.* 1997).

An essential part of adolescence for all youth is the development of a personal and social identity, which includes the development of sexual identity (D'Augelli 1996; Hunter 1996; Hunter & Mallon 2000). Most self-identified gay and bisexual youth come into awareness of their sexual orientation in early adolescence. For gay youth, the process of developing a sense of self, coming out, and finding a supportive group of peers is extremely difficult and, for those who become infected, is further compounded by the stigma of HIV/AIDS itself.

Recent school-based studies have found high rates of suicide among gay, lesbian and bisexual youth (Garofalo *et al.* 1998; Remafedi *et al.* 1998). Youth who choose not to hide their sexual orientation or whose sexual orientation is discovered are often faced with negative responses: verbal harassment, sexual assault and sometimes violent reactions from family, friends, peers or strangers (Hunter & Schaecher 1987; Hunter 1990). Having limited options when they need support, many of these young people turn to alcohol and drug use as a means to cope with isolation and rejection.

Youth with psychiatric disorders

A number of research studies have found that self-esteem, self-efficacy and mental health are directly related to early onset of sexual activity, unsafe sex and the inability to change behaviours in HIV prevention programmes (Hofferth *et al.* 1987; Rotheram-Borus *et al.* 1991, 1995; Walter *et al.* 1991). Among non-clinical samples of urban teenagers, higher rates of depression were associated with early sexual activity (Smith 1997). Adolescents with psychiatric disorders are at increased risk for HIV infection because of impaired judgement, poor problem-solving ability, impulsivity, low self-esteem, self-destructive behaviours, drug and alcohol use, increased sexual activities and poor interpersonal relationships (Brown *et al.* 1997). Thus, many youth engaged in risk behaviours associated with their HIV-infection because of premorbid mental health problems (Hoffman *et al.* 1999).

Psychosocial issues for HIV-infected adolescents

In working with all HIV-infected youth, a solid understanding of adolescent development is critical (Hoffman *et al.* 1999). It has been well documented that adolescent development is characterized by substantial physical growth, cognitive change and transformation, as well as social and cultural challenges. During this period, youth are adjusting to physical, emotional and sexual maturation, ranging from the onset of puberty and the emergence of secondary sexual characteristics to the achievement of full maturity. This is a period that elicits a wide range of emotions (Brooks-Gunn & Paikoff 1993), as youth must master a series of developmental tasks in order to proceed to the next stage of development. These tasks include development of self-esteem and interpersonal skills, as well as the management of social and sexual roles. Mastery of these tasks is essential for an adolescent's well-being. Furthermore, as youth move through this period towards adulthood, their basic developmental and psychosocial needs include being valued as a member of a group, receiving social support, participating in caring relationships, acquiring skills to cope adaptively with everyday life, and believing in a future with real opportunities (Hamburg 1990). For youth who enter this period under adverse circumstances with prior deprivation or for whom there is any interference with the developmental process at this stage, this period can be problematic, with negative behaviours such as school drop-out, drug abuse, early or unintended pregnancy, mental health problems and suicide (Hamburg 1990).

Many HIV-infected adolescents have already experienced significant hardships prior to their diagnosis, including poverty, violence and abandonment (Balfer *et al.* 1988; Falloon *et al.* 1989; Ryan *et al.* 1997). They are at high risk for mental health problems and difficulties negotiating adolescent developmental tasks. HIV infection itself can then pose another challenge to each area of adolescent development.

Development of a healthy self-identity is challenged by HIV infection for many adolescents. Clinical reports indicate that many HIV-infected adolescents see themselves as infectious people, feel contemptuous of themselves for this reason, and thus struggle with low self-esteem (Hunter & Schaecher 1992; Hunter & Haymes 1997). A normative adolescent development task is a healthy separation and individuation from parents. For HIV-infected youth, the process of developing an adult identity gets distorted and delayed. Reliance on parents or other adult family members for health care may lead to regression and difficulty seeing oneself as a young adult.

For young people, disclosing their status to others can be traumatic. They have to decide who to tell and when, if they have that choice. Many HIV-infected youth fear rejection from family, peers and friends more than they do the illness itself (Wiener *et al.* 1998). For gay youth, disclosing their HIV status can be threatening because it may mean coming out as gay; for others, disclosure of drug use or pregnancy may be the issue.

While HIV among young gay men of racial and ethnic minority is still increasing (Valleroy *et al.* 2000), the face of the

HIV/AIDS epidemic is changing, with more heterosexual young females becoming infected. Clinical data reveal that many adolescent girls with HIV infection are identified during screening for pregnancy or when they give birth (Rotheram-Borus *et al.* 1996). While the challenge for them is the same as for other youth living with HIV (e.g. coping with a potentially fatal illness and the stigma of HIV/AIDS disease) these girls must also cope with the social stigma and burden of teenage pregnancy. The role of motherhood at an early age generates stress, for which the young mother lacks coping and parenting skills in order to deal with the multitude of issues which arise and which often lead to negative consequences. Even though she may be physically mature enough to have baby at this time, social, emotional and cognitive development are still underway. Adolescent girls will need to access and negotiate a health care system, not only for themselves but, if they are pregnant or have a baby, for the child as well. Teenage HIV-infected parents must deal with issues of illness, death and child custody at a time when they are only just developing more basic coping skills.

All infected youth, whether they have physical symptoms or not, will need help in understanding the nature of the virus, their illness and the importance of adhering to medical regimens. However, many adolescents are still largely in concrete stages of cognitive development and have difficulty understanding the full implications of their infection. They may deny the presence of the disease and its symptoms (Hunter & Schaefer 1992). Furthermore, many are not ready for the responsibility of caring for their health, particularly adhering to medication regimens. For adolescents, impulsivity and the desire to fit in with peers often leads to poor adherence to medication for many chronic illnesses including asthma and diabetes. Unfortunately, the HIV medication regimens are particularly arduous. HIV-infected adolescents are at particular risk for non-adherence and poor health care (Wiener *et al.* 1998).

Psychiatric disorders

While it has been recognized that HIV-infected adolescents are at risk for experiencing many stressful events as they negotiate this period of their lives, and that many of the factors that placed them at risk for HIV infection in the first place also place them at risk for future psychiatric disorders and problems with psychosocial functioning, the literature on psychiatric aspects of HIV disease in adolescents, as in children, is extremely limited. Clinical reports suggest that HIV-infected adolescents are at high risk for mental health problems (Ryan *et al.* 1997; Wiener *et al.* 1998). Case studies of HIV-positive adolescents indicate a high prevalence of anxiety, depression and bipolar disorder (Hoffman *et al.* 1999). Studies of HIV-infected adolescents reveal rates of affective disorder ranging from 25 to 44% and histories of sexual abuse ranging from 26 to 50% (Kissinger *et al.* 1997; Pao *et al.* 2000). It is also important to note that the mental health issues described above for perinatally HIV-infected children (e.g. central nervous system and neuropsychological ef-

fects of HIV disease, issues of death and dying, etc.) are also present for adolescents.

Regardless of mode of transmission, one of the major goals in working with youth who live with HIV is to encourage a better quality of life by helping them develop strategies to deal with their illness and the stressful life events that they experience and will encounter in the future, and by helping them develop a support system. Eventually, these young people may have to address specific planning around death and coping with the end-stage disease.

Secondary prevention among HIV-infected youth must also be addressed, so that these youth do not reinfect themselves or infect others. Issues for young people with HIV/AIDS, such as sexual behaviour, communication and negotiation, are very important in secondary prevention. HIV prevention education must address the underlying reasons for unsafe behaviours and focus on ways of motivating youth to engage in preventive behaviours (Hunter & Haymes 1997).

Mental health issues in children living with parental HIV illness

Mental health issues related to familial HIV illness

Children and adolescents, both infected and uninfected, are often also 'affected' by HIV disease in a family member. The uninfected children of HIV-infected parents are typically ignored by health care systems, even though they are at significant risk for their own mental health problems. The mental health issues associated with HIV illness in families evolve over the dynamic course of HIV illness, which moves through specific predictable psychosocial stages, roughly paralleling the natural history of the disease (Havens *et al.* 1996). These stages begin with diagnosis of HIV infection and continue through illness progression, late-stage illness, death and reconfiguration of the family with the children in new care arrangements.

Children may exhibit a variety of responses to parental HIV diagnosis, illness or loss at any stage in this process. These responses may be characterized as one or more of the following:

- 1 normative responses requiring supportive counselling and/or increased access to existing social supports;
- 2 responses complicated by developmental histories of poor or disrupted attachment and/or trauma (particularly common in children also affected by parental drug addiction), indicating a need for individual and/or family psychotherapy; and
- 3 exacerbations of pre-existing psychiatric disorder or precipitations of new onset disorder, in which syndrome-specific treatment must be among the interventions (Ryan *et al.* 1997; Havens *et al.* 1999).

Issues in differential diagnosis within the stage model of HIV illness will be reviewed below.

Mental health care of children through stages of HIV illness in the parent

Diagnosis and disclosure of HIV

When a diagnosis of HIV infection is made, it typically engenders anxiety about health and anticipatory grief for a potentially foreshortened future. When the diagnosed individual is a parent, these issues are compounded by concerns about the care of children in the future and by questions of communication with children and adolescents about HIV.

Infected parents frequently withhold information about their HIV diagnosis from their children. Most do not tell children prior to early or mid-adolescence (Mellins & Ehrhardt 1994). Even in the absence of direct communication, many children and teenagers develop their own suspicions about the parent's health problems from clues such as medications, symptoms or multiple medical appointments. Children may experience a great deal of distress, suspecting that a parent is struggling with HIV-related illness, yet because they are not 'supposed to know' they remain unable to reach out for adult support and reassurance.

Disclosure of a family member's HIV status to a child is often misunderstood as a discrete event that can be accomplished as a single communication. It is more appropriately handled as an ongoing process, with new information provided with any change in parental health status. Not only the content of the information communicated to the child but also the emotional tone with which it is conveyed will have an effect on the young person's understanding of the meaning of the information (Havens *et al.* 1996).

Moreover, the child's developmental level may limit ability to absorb complex affectively laden material. A school-aged child will normatively cope with difficult information about a parent's illness by denial, and may opt 'not to know' this threatening fact much of the time. Under stress, the school-aged child may revert to magical thinking that the virus can be wished away. Adolescents do not normatively defend themselves against knowledge of parental HIV by magical thinking or absolute denial, but may rigidly compartmentalize this information so as not to have to face it (Ryan *et al.* 1997).

Parents and other adult caregivers of the HIV-affected child should be counselled about the importance of developmentally appropriate communication about the parent's health. The child's need for the information and readiness to receive it must be accorded priority in deciding what information to communicate and when to disclose it. It is important for the adult to be honest, while respecting the child's coping mechanisms, including adaptive denial. The family's established style of communication about emotionally charged information may not be sufficiently flexible to allow for complete disclosure, but may be able to tolerate communication of part of the truth without specifying the precise diagnosis ('Mommy has an infection in her blood. She's taking medicine to keep her healthy'). Adults should be counselled to provide children with realistic reassur-

ance about the parent's health, and about their own future care and security. HIV-negative children may worry that they themselves are infected because their parent is, and should be assured that they and their siblings are uninfected. In cases where there is uncertainty about a child's serostatus or where additional reassurance is indicated, HIV testing can be very helpful.

Other therapeutic issues that arise for children and adolescents learning about their parent's HIV diagnosis include fear for the parent's health, and anxiety about potential separation from or loss of their parent. Shame and a sense of social isolation caused by the stigmatization of HIV are also common responses. Because the child's self-esteem is often dependent on identification with the parent, the HIV diagnosis may be felt by the child as detracting from his or her own self-worth. It is important to explore carefully with children their understanding of the meaning of parental illness and to provide ongoing support to help them cope effectively with parental HIV infection (Ryan *et al.* 1997).

Progression of HIV illness

As parental HIV disease progresses, children are confronted with deterioration in the parent's ability to function and separations because of hospitalizations. At this stage, children and adolescents manifest one or more normative emotional and behavioural responses to parental illness progression. In general, the distinction of normative from problematic responses is the extent of the response and its effect on the child's functioning. For a toddler, some increase in separation protest may be normative, while a more intensified inability to separate would be problematic; some increase in tantrums is to be expected, while extremely disruptive behaviour is a warning sign. Similarly, school-aged children may experience a minimal to moderate decline in school performance, but a precipitous decline is an indicator of more significant difficulty in coping with the parent's illness.

The importance of communication with children and adolescents about parental illness and its impact on family life increases as HIV disease progresses. Normative emotional and behavioural responses can be complicated when children experience a parent's physical, cognitive or functional decline without accurate information about illness and prognosis. The normal sadness, anger and/or anxiety experienced by children living with an ill parent can be exacerbated by the need to manage these feelings without support from adults who are unable to allow open communication about their illness.

Given the high-risk backgrounds of many HIV-affected families, children's responses to the parent's illness may also be complicated by underlying psychiatric disorder, developmental difficulties in the child's attachment to parent, and/or difficulties in family environment. When working with families affected by both drug use and HIV, it is important to assess carefully children presenting with symptoms in response to parental illness; the attribution of symptomatology to HIV-related stressors alone is often clinically inappropriate (Havens *et al.* 1996).

With the pressure of increasing parental illness, the child or adolescent may experience and express intense ambivalence toward the parent, particularly if the risk factor for the parent's HIV infection is understood by the child to be a negative behaviour (for example, drug use or selection of a drug-abusing partner). In these circumstances, the child or adolescent may be both sad and anxious about the parent and angry. This is often the case when children perceive that the behaviour which impaired past parenting (e.g. drug use) is leading to further erosion in capacity as illness progresses and perhaps ultimately to abandonment of the child when the parent dies an early death. Extreme ambivalence toward the parent is perhaps the most difficult psychotherapeutic issue in working with HIV-affected children because it greatly complicates the bereavement process (Rosen *et al.* 1997; Ryan *et al.* 1997).

Permanency planning

With HIV progression in the parent, caregivers may require counselling about planning for the placement of children following parental death. Communication about HIV illness and permanency planning tend to be closely intertwined, with difficulties in one area being reflected in the other. Family-based permanency planning that actively involves the children, particularly teenagers, is more likely to have a successful outcome than that which excludes the affected young people. Effective permanency planning can be undermined by active substance abuse and untreated psychiatric disorder in family members, as well as by family dynamics related to substance abuse.

Optimally, parents with progressive HIV illness have begun the permanency planning process prior to the final stage of parental HIV illness and other adults are available to provide care and support for affected children. However, some parents, particularly those struggling unsuccessfully with mental illness and/or substance abuse, present to medical care settings in end-stage AIDS without having addressed these issues. In clinical experience, these are usually the most disorganized families with the highest burden of psychiatric and substance abuse disorder. In these families, careful attention to the mental health needs of the children and adolescents is essential. Both the lack of family preparation and factors associated with that lack of preparation flag increased risk for mental health problems in these children.

Bereavement and family reconfiguration

Death of a parent in childhood ruptures the child's parental attachment before the child has completed the developmental tasks necessary for functioning as an independent adult. A wide array of emotional and behavioural problems may be observed over time following the loss: irritable mood in younger children and sadness in older ones; behavioural difficulties ranging from increased tantrums and fighting with siblings to conduct disorders; and decreased school performance (Rutter 1966; Kranzler *et al.* 1990). Studies of long-term sequelae, in particular depres-

sion in adulthood, have reported mixed findings, probably because of numerous confounding variables. A positive relationship between the parents prior to the death and a strong surviving parent to keep the family intact have been identified as protective against elevated risk of mental health problems (Harris *et al.* 1986; Kranzler *et al.* 1990). Among the predictors of complicated bereavement are child emotional and behavioural factors predating the loss, including prior emotional difficulties, emotional lability and poor impulse control (Kranzler *et al.* 1990). Many of the factors associated with complicated bereavement in childhood are present in HIV-affected children and adolescents, including emotional difficulties and negative relationships with parents prior to loss and absence of a surviving parent to provide adequate parenting after death.

Grieving HIV-affected children and adolescents most commonly move into reconfigured families with extended family members also mourning the loss of the loved one. In countries with well-developed health services, the social and concrete service supports available to the families by virtue of the parent's AIDS diagnosis generally diminish or disappear following the parent's death. Generally, children and adolescents orphaned by AIDS are moving from one situation of poverty to another, with the responsibility for the care of these children falling on financially limited and often overwhelmed extended family members. In those cases where children and adolescents move into non-relative foster care, they must make the difficult adaptation to new family members and often very different family lifestyles.

An important issue that may occur in the assessment of a bereaved child is differentiation of illusory phenomena related to grief from hallucinations. Children and adolescents frequently experience visual or auditory perceptions of a deceased parent in the period immediately after the death, or sometimes for months or years following. It is important to differentiate illusory phenomena associated with bereavement from hallucinations associated with a psychotic or affective disorder. The more benign perceptions may involve the parent calling the child's name or appearing in a familiar location in the home or neighbourhood. Particularly when the family's religious or cultural context provides reinforcement for such experiences, these perceptions of the deceased parent may be comforting to the child. When the child lacks cultural supports for these experiences, they may cause confusion. It is often helpful to probe gently with the grieving child to determine whether they are experiencing such perceptions and, if so, to reassure the child and assist him or her to understand the experience.

Education for the grieving child and counselling for his or her adult caregivers are very useful in many families. It is helpful to distinguish the usual course of mourning by adults (a sustained period of dysphoria, followed by a gradual return to normal mood) from that more typical of children, especially pre-adolescents (immediate periods of dysphoria punctuated by apparently normal play or socializing, with periods of grieving throughout the developmental trajectory). When a child's deceased parent has been absent or otherwise deficient in their role

with the child, adult caregivers may be puzzled by the child's mourning over the loss: they need an explanation that the loss of inadequate parenting may in fact complicate rather than minimize the child's grieving process.

Mental health issues related to parental substance abuse

For children with drug-abusing parents, risk factors for mental health problems cluster in two areas. The first area relates to the sequelae of parenting deficiencies associated with parental substance abuse (neglect, abuse, discontinuity of attachments and disruption of placement); the second to the biological risks associated with parental drug addiction (prenatal drug exposure, heritable parental psychiatric disorder).

Neglect, abuse and disrupted attachment associated with parental drug addiction

One of the most devastating effects of substance abuse is the erosion of parenting capacities essential to children's development and well-being. Children living with substance-abusing parents are at increased risk for neglect, abuse, exposure to domestic violence and disruption of attachments (Rodning *et al.* 1989; Kelley 1992; Singer *et al.* 1992), all of which have been shown to increase children's risk for mental health problems (Cicchetti & Carlson 1989; McLeer *et al.* 1994; Pelcovitz *et al.* 1994).

Biological risks associated with parental drug addiction

Prenatal drug exposure

Several studies have described the developmental and behavioural problems of children exposed to prenatal drug abuse (Coles *et al.* 1993; Griffith *et al.* 1994; Wilens *et al.* 1995). Methodological problems in much of the research on drug-exposed children limit definitive conclusions regarding the link between specific drug exposures and behavioural or cognitive outcomes (Hutchings 1993; Gonzalez & Campbell 1994). However, it is clear that maternal drug use during pregnancy with its associated problems, such as inadequate prenatal care, premature birth and low birth weight, may act to increase children's risk for developmental, cognitive and mental health problems.

Heritable psychiatric disorders

Adults with substance abuse disorders have high rates of psychiatric comorbidity, particularly affective and anxiety disorders and childhood histories of ADHD (Regier *et al.* 1990; Carroll & Rounsaville 1993; Haller *et al.* 1993). Children born to adult substance abusers are at increased risk for mental health problems because of the heritable nature of these psychiatric disor-

ders (Weissman *et al.* 1984; Goodman & Stevenson 1989; Biederman *et al.* 1990).

HIV illness commonly strikes families already struggling with substance abuse and its associated problems, including impairment of parenting capacities and psychiatric disorder. When a child's parent is substance abusing and HIV-positive, the HIV disease may play a less significant part in the child's mental health problems than do issues related to the substance abuse.

Conclusions

Almost 20 years into the HIV epidemic, HIV/AIDS continues to affect millions of children and adolescents worldwide. In the developed world, medical advances both in antiretroviral treatment and prevention of vertical transmission has decreased morbidity and mortality in infected children and in their infected family members. In the developing world, the cost of antiretroviral treatment and health infrastructure inadequacies make widespread implementation of treatment advances difficult, leaving millions of children and adolescents without parents and at risk for their own HIV infection and illness. While clinical trials are underway, there is no currently available vaccine against HIV (D'Souza *et al.* 2000). Continued targeted prevention efforts, more equitable distribution of health care resources and meaningful therapeutic interventions to address the mental health consequences of individual and/or familial HIV disease are essential elements in the uphill fight against HIV/AIDS.

Psychiatric Aspects of Specific Sensory Impairments

Peter Hindley and Tiejoo van Gent

Introduction

Sensory impairments alone do not increase children's vulnerability to mental health problems. However, the consequences of being sensorially impaired in a world orientated to the needs of hearing and sighted people do increase children's vulnerability. Understanding why and how that is the case throws light onto both normal development and psychopathology. In this chapter, we focus primarily on children with the most severe sensory impairments. In addition, we discuss the effects of otitis media with effusion (OME) and the mental health of hearing children of deaf parents. Given that 90–95% of deaf children and 99% of blind children are born into hearing and sighted families, the response of their parents is likely to be particularly important. For deaf children (meaning severe hearing impairment, HI), the major challenge is accessing meaningful communication. For many, visuospatial language will be the most effective route. For blind children (meaning severe visual impairment, VI), the challenge is how to access information relating to non-verbal communication and spatial orientation. For many children this will be accomplished by building a narrative picture of the world. Children with multisensory impairment (MSI) face challenges that are often greater than the sum of the HI and VI because sensory information needs to be integrated. Their main difficulties lie in accessing experience *per se* and that experience often has to be mediated through adults.

Hearing impairment

Epidemiology of hearing impairment

In the UK, approximately 1.2 in 1000 children have permanent bilateral HI of moderate or greater severity (Davis *et al.* 1995). In most cases, the HI is a result of genetic causes (Gorlin *et al.* 1995) or severe prematurity. Congenital rubella is a less frequent cause than it used to be; the introduction of vaccination for meningitis is likely similarly to reduce its role as a cause of deafness. Acute otitis media is probably the most common reason for consultation with GPs in the preschool years (Haggard & Hughes 1991). It is usually a time-limited condition that does not cause HI, but the complication of OME can lead to fluctuating HI. Approximately 10–30% of 2–7-year-old children will have fluctuating HI from middle ear disease (Haggard & Hughes 1991).

HI is often accompanied by other impairments, particularly in vision, motor function (resulting from brain damage) and intelligence (Freeman *et al.* 1975; Sinkkonen 1994). These additional impairments are least likely when the HI is genetically determined. An important exception is Usher syndrome, the co-occurrence of sensorineural deafness and VI caused by retinitis pigmentosa. The occurrence of additional impairments means that early screening for them is essential.

Cultural aspects

Meadow-Orlans & Erting (2000), in their comprehensive introduction to a sociocultural view of deafness, suggested that deaf culture had three characteristic elements: a primarily visual experience of the world; membership of an oppressed minority; and the use of sign language. However, the move towards more inclusive forms of education is changing the situation. Because most deaf children have hearing parents, membership of the deaf community is mainly acquired outside the family. To varying degrees, deaf people are effectively bilingual and bicultural (Padden 1996), identifying with both their sign language community and the spoken language community—in addition to subcommunities according to ethnicity or sexual orientation (Parasnis 1996).

Sign languages

Sign languages appear to develop naturally wherever groups of deaf people come together (Groce & Whiting 1988). They differ according to national groups, not necessarily relating to the dominant spoken language. British Sign Language (BSL) and American Sign Language (ASL) have little in common at a lexical level, whereas ASL and Langue des Signes Françaises (LSF) do. Nevertheless, all sign languages have in common the expression of semantic and grammatical concepts by movements of the hands, face and upper body. Most sentence structure follows a topic–comment construction, and most sign languages use a system in which verbs or subjects are represented by a limited number of hand shapes or classifiers (Sutton-Spence & Woll 1999).

The educational status of native sign languages has changed dramatically in the last 20 years with the development of bilingual/bicultural programmes in Sweden (Heiling 1995), USA (Strong 1995), UK (Young 1999) and many other countries. At the same time, the introduction of cochlear implants (see below) has led to increasing tension between the deaf community and

the audiological establishment (Hindley 1997). The study of sign language provides insights into the ontology of language (Stokoe 1998) and the neuropsychological processes that underpin language function (Corina 1999). The latter are similar to those of spoken language except that the brain areas involved in proprioception are also involved (Corina 1999).

Deaf children of deaf parents

The language development of deaf children of deaf parents is comparable to that of hearing children (Caselli & Volterra 1989; Pettito & Marentette 1991). Deaf parents tend to have greater sensitivity to the early communicative efforts of their infants than do hearing parents of deaf infants (Smith-Gray & Koester 1995), and deaf infants are more likely to use bodily movements than auditory signals to attract their mothers' attention. In turn, deaf mothers are more likely to perceive these signals as attempts to communicate and so reciprocate.

Deaf mothers use a variety of methods to gain their infant's attention (Harris 2001) and to make communication salient and contingent upon the child's activity. These include signing in the child's signing space, moving objects into the child's visual field before signing and waiting to obtain the child's visual attention before signing. Deaf parents adapt their signs in ways that are reminiscent of hearing parents' spoken 'motherese' (Erting *et al.* 1989; Masataka 1992). They show greater sensitivity in regaining their child's attention (Koester *et al.* 1998) and greater capacity for repair and discourse maintenance (Prendergast & McCollum 1996). This seems to improve the children's development.

Deaf children of deaf parents appear to outperform both deaf children of hearing parents and hearing children on false-belief tasks (Courtin & Melot 1998). This may be a consequence of early exposure to visual perspective-taking (a central feature of sign language). Braden (1994), reporting a meta-analysis, noted that deaf children of deaf parents have the highest mean IQ (108) of all groups of deaf children. Their educational achievements are also superior (Meadow 1968; Balow & Brill 1972).

Hearing parents of deaf children

The vast majority of hearing parents of deaf children will not have had prior contact with deaf people and experience considerable shock on realizing that their child is deaf (Freeman *et al.* 1975; Stein & Jabaley 1981). However, when they have had prior suspicions, there may also be an initial feeling of relief when the diagnosis is confirmed (Gregory 1991). In areas where deafness is conceptualized in cultural terms, they then have to come to terms with their child as different, not disabled (Young 1999). Many parents come to embrace this positive construction of deafness but many struggle with the notion as much as with disability (Hindley 1999). The use of cochlear implants (electro-assistive devices that transmit a signal direct to the cochlea) with younger children is raising parental expectations about their children's potential to develop spoken language, and

thereby clashes with the 'culturally different' concept. The family response reflects their coping skills and their social network (Danek 1988). However, many parents come to rely increasingly on professional networks (Quittner *et al.* 1990). Neonatal screening for life-threatening conditions has raised concerns that it may increase parental anxiety, with a deleterious effect on parent-infant relationships (Martineau 1993); this does not seem to apply to neonatal screening for deafness (Watkin *et al.* 1998).

Interaction between deaf children and hearing parents

Deafness affects the interaction between parents and their children (Brinich 1981; Vaccari & Marschark 1997; Marschark 1993). Although the mechanisms involved remain unclear, two seem to be involved: the emotional impact of deafness on the parents' perception of the child (Schlesinger & Meadow 1972); and the consequences of deafness for communication between child and parents. Schlesinger & Meadow (1972) suggested that parental depression following diagnosis can lead to decreased parental interaction. Meadow-Orlans (1995) found that mothers of children with HI experienced greater emotional distress than fathers, perceiving their children as inattentive.

Hearing mothers of deaf infants are less responsive than either deaf mothers of deaf infants or hearing mothers of hearing infants (Spencer & Meadow-Orlans 1996). This diminished responsiveness seems to stem from a lesser sensitivity to the deaf infants' visual signals (Spencer *et al.* 1992; Prendergast & McCollum 1996; Harris 2000) and is likely to have implications for the children's language development.

Parents of deaf children also tend to be more directive and controlling in their interactions with their deaf children when compared with hearing:hearing dyads and with deaf:deaf dyads (Marschark 1993). This could derive from difficulties in managing divided attention (Harris 2000) but could also be a response to the children's delayed language development (see below). Interestingly, despite these interactive features, deaf children do not show an increased vulnerability to anxious attachments (Greenberg & Marvin 1979; van Ijzendoorn *et al.* 1992; Hadadian 1995).

Language development in deaf children

There are two features of the language that hearing parents use with their deaf children (Marschark 1993). First, hearing parents tend to simplify both their spoken and signed language and, in the case of sign language, drop important function signs. As a result, communication is frequently impoverished. Secondly, interactions between deaf children and hearing parents tend to be shorter, less complex and contain fewer questions and self-references.

Much the same applies to teacher-child interactions (Wood *et al.* 1986; Power *et al.* 1990). Teachers tend to be more controlling, use more conversational repair strategies and initiate fewer

interactions. This controlling style was associated with fewer questions from pupils and less elaborated answers from them.

In a meta-analysis of early intervention programmes, Meadow-Orlans (1987) found that preschool-age deaf children enrolled in oral language programmes had spoken language some 2–3 years behind their hearing peers; very few had gone beyond the 10-word stage at 2.5 years. Two-thirds of the children that Gregory studied in the 1970s were using some form of sign language by the time they reached late adolescence, and one-sixth had such poor language that they could not participate in the study (Gregory *et al.* 1995). Deaf children using spoken language appear to have particular difficulty in understanding wh-questions, relative clauses and embedded questions (De Villiers *et al.* 1994). This may lead to poor understanding even when their spoken language is reasonable. Geers & Nicholas (1997) found that ‘heuristic’ communication functions (questions and answers rather than repetitions and imitations) at age 3 predicted better language development at 5 years in deaf children.

Two recent developments are affecting the course of deaf children’s spoken language. First, early ascertainment (below 6 months) is associated with better receptive and expressive spoken language development (Yoshinaga-Itano & Apuzzo 1998). Secondly, the use of cochlear implants also leads to significant gains in language development for some children (Meyer *et al.* 1998).

Children exposed to gesture but not to formal sign tend to develop their own gestural systems, often called ‘homesign’. These appear to convey second language learning advantage when formal sign language is encountered later in life (Morford 1998). When deaf children are presented with signed versions of spoken language, their expressive signing increasingly approximates to native sign language, particularly in the use of spatial grammatical principles (Supalla 1991). When deaf children of hearing parents receive good-quality sign input, their sign language development mirrors spoken language development in hearing children in sequence, but not always rate (Marschark 1993).

Some early intervention programmes provide mentorship from a deaf person; their support with respect to communication and to cultural awareness about deafness seems to foster the children’s language development (Watkins *et al.* 1998; Young 1999).

Cognitive development

Historically, deafness has been seen as an opportunity to study cognitive development in the ‘absence of language’ but this fails to appreciate the relevance of sign language (Marschark & Everhart 1997). The possible risk factors for cognitive development in children with HI include restriction of experience (both as a result of deafness *per se* and because of residential schooling); the effects of signing rather than spoken language; central nervous system damage; and lack of exposure to sound (Marschark 1993). The last could have an effect because of its effect on the integration of distal and proximal events (Campbell 1998).

An increasing awareness, from the 1950s onwards, of the effects of language on cognitive assessment led to the development

of specific non-verbal tests (Snijders Oomans, Leiter, Hiskey Nebraska) for children with HI, as well as the performance scales from instruments such as the Wechsler Intelligence Scale for Children (WISC). Nevertheless, even on non-verbal tests deaf children tend to show small but significant deficits when compared with same-age hearing children (Marschark 1993). Zwiebel (1987) found that genetically deaf children of hearing parents showed deficits, whereas deaf children of deaf parents had mean IQs that were significantly above hearing norms. Overall better language is associated with better cognitive performance. Subtest performance suggests that deaf children rely more than hearing children on visuo-perceptual thinking and visual memory, and less on abstract thinking.

Deaf children lag behind hearing children by approximately 2–4 years in their development of conservation. Language seems to have an important function in allowing explicit and implicit acquisition of categories and concepts (Marschark 1993); bootstrapping processes in deaf children may also be impaired (Campbell 1998).

HI seems, in addition, to be associated with deficits in short- and long-term memory, perhaps because of the lesser reliance on temporal sequential strategies (Marschark 1993). Linguistic creativity seems to be impaired if assessed through inappropriate spoken language tests, but not perhaps if assessed using sign language.

Academic achievement in deaf children

Deaf children significantly underachieve, especially in reading and writing (Gregory & Powers 1998), and also in mathematical concepts (Nunes & Monero 1998). It is probably relevant that most deaf children learn to read and write in what is effectively a second language. For some deaf children there is no basic problem with phonological coding but there is restricted vocabulary knowledge and syntactical ability. Their reduced working memory capacity (Marschark 1993) and diminished experience of the interaction among the semantic, syntactic and pragmatic components of spoken language (Campbell 1998) may be influential.

Approaches to improving deaf children’s reading and writing skills include accessing reading through sign language (Hoffmeister *et al.* 1997; Prinz & Strong 1998) and presenting spoken language by presenting phonological code in the form of hand shapes presented alongside the face (Campbell 1998). Hoffmeister *et al.* (1997) suggested that detailed knowledge of ASL syntax enhances children’s meta-linguistic skills and so enables them to decode English. However, many children with HI need further ‘bridging’ skills (Prinz & Strong 1998) such as enhancing recognition of phonological code (Campbell 1998) and recognizing letter–word patterns through the use of finger spelling and sign initialization (Padden & Ramsey 1998). Marschark (1993) suggested that the best outcomes for literacy in deaf children occur when children experience both signed and spoken language in early intervention programmes.

Social and emotional development

Deaf infants appear to show the same range of emotional states as hearing infants (Snitzer Reilly *et al.* 1989) but, as they develop, they tend to have smaller emotional vocabularies and are less good in recognizing other people's emotional states (Greenberg & Kusche 1989, 1993). Lederberg & Mobley (1990) found that deaf children showed less social initiative, less compliance, creativity and enjoyment in their interactions with their mothers and more misbehaviour. Harris (1978) found that deaf children of deaf parents showed less impulsive, and more reflective, cognitive styles than deaf children of hearing parents.

Although preschool friendship patterns do not differ between deaf and hearing children (Lederberg *et al.* 1986), deaf preschool-age children are more likely to use linguistic and non-linguistic visual communication with their deaf than with their hearing peers (Lederberg *et al.* 1986). As deaf children pass through the early years of mainstream school there are few initial peer difficulties (Hindley 2000) but later on they are increasingly likely to be socially isolated. Interventions based on promoting integrated activities rather than social skills appear to have short-term positive effects on deaf-hearing peer relationships (Antia *et al.* 1993).

Gregory & Mogford (1982) found that deaf children's play was less well elaborated than that of hearing children. Spencer & Deyo (1993) found that imaginative play was closely related to language level but Spencer & Meadow-Orlans (1996) suggested that maternal sensitivity rather than children's language predicts the emergence of representational play.

It has been suggested that deaf children will have difficulty in passing false-belief tasks because of delayed language and a lack of conversations about mental states (Gale *et al.* 1996; Peterson & Siegal 1998). Because deaf children of deaf parents appear to develop theory of mind earlier (Courtin & Melot 1998), it is likely that conversational experience is the relevant risk factor. However, methodological concerns (e.g. giving false-belief tests through interpreters) mean that there is some uncertainty regarding the validity of the theory of mind findings in children with HI.

Visual impairment

Severe VI is estimated to affect 81 in 100 000 children in industrialized societies (Bryars & Archer 1977), with over one-third of these completely blind (Cullinan 1987; Baird & Moore 1993). VI is more common in developing countries (Chirambo *et al.* 1986; Bard & Moore 1993), mainly because of retinal deficiency, measles and other acquired causes.

Over the last decade there has been growing awareness of cortical blindness (Jan & Freeman 1998). Children with cortical blindness can present with puzzling pictures of apparently inconsistent or variable visual functioning; also there may be significant improvements over time in visual functioning.

Additional impairments are very common among children with VI. In a clinic-based study, one-half had intellectual impairments and two-fifths had other disabilities, such as cerebral palsy, epilepsy and HI (Hill *et al.* 1986). Additional impairments are common, even in general population samples (Jan *et al.* 1977). As with children with HI, screening for associated problems is crucial.

Cultural aspects

The notion of a sociocultural perspective on blindness is a relatively recent development. Fogel (1997) suggested that the central experience of blindness involves construction of the world as a narrative rather than a gestalt, and that this constituted essential strength of the blind person. The only published study of the interaction between a blind mother and her blind infant (Rowbury 1991) suggested that, when compared with a hearing dyad, the blind mother used more spoken language and touch to maintain contact with her baby.

Family response to visual impairment

Jan *et al.* (1977) found that one-third of parents reacted with shock and disbelief to the diagnosis of VI (usually in infancy); one-half said that they did not want to have any more children. Some parents experience considerable distress, and it has been suggested that parental depression can lead to decreased interaction between child and parent (Fraiberg 1977; Warren 1994). The process of communication between children with VI and their parents may sometimes be affected adversely but positive interaction has also been found (Als *et al.* 1980).

It appears that the presence of VI affects the quality of language used by parents. In one study (Kekelis & Andersen 1984), parents were more directive and made more imperative statements and more requests. They also made fewer elaborations and fewer statements about events and people in the here-and-now. They may also be less contingent in their interaction with their children (Webster & Roe 1998).

Groenveld (1993) warned that multiple professional involvement with families of babies with VI could adversely affect parents' intuitive parenting style. However, that need not occur (Sonksen *et al.* 1991), although it is important to make appropriate use of the families' existing social networks and their inherent coping skills (Nixon 1994).

Language development

It is noteworthy that many blind people use gestures with spoken language in the same way that hearing people do (Iverson 1998). For children with VI but without additional impairments, language probably develops at about the usual time (Landau 1997; but see Adelson 1983 and Dunlea 1989 for a contrary view). However, there is evidence that they are delayed in their use of referential language such as 'I' and 'You' (Warren 1994). It is unclear whether this is as a result of difficulties in

processing visuospatial information (Mulford 1980) or a more profound difficulty in understanding interpersonal relationships because of a lack of visual interaction (Hobson *et al.* 1997). Longitudinal studies of the early development of children with VI suggest that attachment formation may be significantly affected but there is a lack of systematic research (Warren 1994). In a small-scale study, McAlpine & Moore (1995) found that children with VI were significantly delayed in their understanding of theory of mind. Failing false-belief tasks correlated with severity of VI and was not related to mental age. Given the child's dependence on gaining information through language, maintaining a stream of language appears important (Recchia 1997); it is important that this should be responsive to the child's activities and interests (Rowland 1983; Peters 1994).

Cognitive development

A commonly adopted strategy in assessing cognitive functioning in children with VI is to use just the verbal scale or to rely on adaptations of verbally loaded scales, such as the Stanford–Binet (Davis 1980). However, it is desirable to assess non-verbal skills in addition (Warren 1994), through the use of VI-appropriate performance items (Ohwaki *et al.* 1960), developing VI-appropriate aptitude tests such as the Blindness Aptitude Test (Newland 1979), or using a specific intelligence test designed for children with VI—the Intelligence Test of Visually Impaired Children (ITVIC; Dekker & Koole 1992). The ITVIC is explicitly based on Thurstone's (1938) model of intelligence and has been extensively assessed and normed. Factor analysis has revealed four main factors: orientation, reasoning, spatial ability and verbal ability. Of these, only the spatial ability factor correlates with degree of useful vision.

The degree of VI (in the absence of other disabilities) does not have a significant effect on cognitive skills apart from spatial ability. There is some suggestion that specific aetiologies may play a part with retinoblastoma being associated with both significantly raised and diminished IQ scores (Warren 1994). Retinopathy of prematurity has generally been associated with lowered IQ, this is most likely a reflection of concomitant central nervous system damage.

Warren (1994) reviewed the development of classification in children with VI. He concluded that development in both areas 'generally proceeds along a normal path'. However, he added that there is considerable within-sample variability and that IQ, visual experience and the range of the children's experience with the materials in the test will all have an effect. His comments should act as a caution to those using standardized tests with children with VI to ensure that the test materials themselves are within the children's experience. It appears that the development of abstract concepts is delayed in children with VI, but Warren pointed out that the studies do not exclude IQ and age as possible confounding factors.

As with deaf children, there has been considerable interest in the development of conservation in children with VI. They appear to develop conservation of weight and substance between 8

and 11 years and conservation of volume between 12 and 14 years (Warren 1994). Development of conservation of volume is clearly affected by degree of VI. Other important factors include IQ, institutional setting and direct experience of the materials used.

VI does not appear to have significant effect on either short-term or long-term memory. There is a debate as to whether or not visual imagery facilitates language learning with children with VI. It appears that there is considerable individual variation, visual imagery enhancing learning for some and interfering with learning for others (Warren 1994). There is a debate as to whether or not VI affects cognitive style. Some research suggests that the presence of VI leads to a more global (diffuse and unstructured) rather than articulated (structured) cognitive style (Warren 1994) but this is disputed by other research. VI does not appear to have an effect on children's creativity. Finally, research into the processing of phonological and tactile information in children with VI suggests that the two are separate but interdependent (Warren 1994). This is particularly important with respect to the reading of Braille.

Academic achievement

Research into the academic achievements of children with VI is far more limited. Warren cited one study (Coker 1979) that suggested that children with VI, in both public and special schools, match the academic achievements of their sighted peers up to 8–9 years of age. From this point onwards children in mainstream schools fell behind, whereas children in special schools maintained progress with sighted peers. In contrast to studies in sighted children which found positive correlations between internal locus of control and academic achievement, one study of children with VI has found the reverse—that external locus of control correlated with higher academic achievement (Jones & McGhee 1972). Freeman *et al.*'s (1991) long-term follow up of the grown-up children and young people in their original study found better than expected academic outcomes, with 76% having completed secondary education and 19% having attended or attending university.

Braille reading appears to develop as a result of a range of converging processes. Warren (1994) suggested that phonological decoding and tactile–spatial decoding function separately but interdependently. Millar (1997) suggested a complex process involving phonological, lexical and syntactic processes interacting with progressively organized hand movements which provide spatial referencing cues and verbal information.

Social and emotional development

Studies of the social and emotional development of children with VI have come to widely divergent conclusions about the impact of VI (Fraiberg 1977; McGurk 1983; Hobson *et al.* 1997). Mulford (1983) found that by the ages of 5–6 most blind children had established a range of verbal and non-verbal communication strategies for establishing referential communication.

Preisler (1995; 1997) noted that children related much more to adults; they extended their interaction with peers in structured play but continued to have difficulty in free play settings (Rogers & Puchalski 1984); and expressed feelings of loneliness. Freeman *et al.* (1991), in their follow-up of children with VI into adult life, found half had a romantic relationship and 20% were in partnerships, all with sighted people.

Multisensory impairment

Epidemiology

Best (1983) estimated that 1 in 100 000 children have MSI but this is likely to be an underestimate. In the past, congenital rubella has accounted for one-third to one-half of cases (Trybus 1985) but this has fallen as a result of universal rubella immunization in many countries. Genetic conditions, such as Usher syndrome, and brain abnormalities associated with very low birth weight are now likely to account for the majority. Additional impairments are very common, with intellectual impairment in one-third to one-half and brain abnormalities in one-quarter (Trybus 1985).

Cultural aspects

In areas where there is high incidence of Usher syndrome, such as in the Cajun community of Louisiana, USA, deaf-blind communities have formed. A similar community has formed in Seattle, Washington, primarily through migration. Miner (1999) provided essential guidance on therapeutic techniques when working with deaf-blind people (see also the deaf-blind website: www.deafblind.com).

Impact of multisensory impairment

MSI is one of the most devastating (Adler 1987) and least understood (McInnes & Treffry 1982) of handicapping conditions. However, its impact on children and their families is influenced by the severity of the sensory impairments and the nature and severity of associated impairments (Jenkins & Chess 1996). Responses to sensory losses may include feelings of anxiety, isolation, denial, resentment or distortion of body image. Children with MSI demand a tremendous amount of effort and adaptation of approach from their parents (Freeman 1975, 1985). In the case of Usher syndrome, many parents appear devastated and unable to imagine the future life of their child when they are informed that their already deaf child may well go progressively blind (Miner 1995). More frequently than in the examination or treatment of children with HI and VI, the clinician will encounter dependency needs. The differential diagnostic problems are the same as for children with VI and HI, but with a particular concern not to miss sensory impairments when there is a complex multicausal neuropsychiatric syndrome combined with serious communicative problems.

Psychiatric aspects of hearing impairment

Most studies have shown that the rate of psychopathology is increased in children with HI compared with the general population, although the majority do not have a mental disorder (Hindley 1997). However, comparisons across studies are difficult because only three used a clinical interview with the child (Rutter *et al.* 1970; Hindley *et al.* 1994; van Gent, in preparation); only four were based on the general population (Rutter *et al.* 1970; Freeman *et al.* 1975; Sinkkonen 1994); and only three used instruments specifically designed for deaf children (Hindley *et al.* 1994; Vostanis *et al.* 1997; van Gent, in preparation).

The range of psychiatric disorders is the same as in hearing children (Hindley *et al.* 1994) but deaf children are exposed to a range of additional risk factors including communication problems, central nervous system disorders, physical health problems and intellectual impairment (Kammever & Hütsch 1988a, 1988b; Hindley 1997). This may explain why pervasive developmental disorders are more common amongst deaf children (Table 50.1). Although there is a greater proportion of disruptive than emotional disorders amongst children referred to specialist services (van Gent & Hendricks 1994; Hindley & van Gent 2000), high rates of emotional disorders are found in a school population of deaf children in comparison to hearing children (van Eldik 1998). Findings are contradictory on whether disorder is more common amongst children with HI in mainstream or special schools. Smith & Sharp (1994) found that deaf children in mainstream schools were particularly likely to be bullied. On the other hand, deaf children in residential schools are vulnerable to abuse (Sullivan *et al.* 2000).

Psychiatric assessment

Deaf children rely on visual communication. When interviewing them, the room needs to be uncluttered and well lit but without a bright light, such as a window behind the interviewer. Lip-reading requires a clear view of the lips; bushy beards and moustaches can cause problems. No more than 25% of spoken language is seen through lip patterns alone (Conrad 1979). Deaf people have to make educated guesses when lip-reading (Beck & de Jong 1990), and a strong foreign accent can make that more difficult.

When clinicians have limited signing skills, their efforts to engage signing deaf children can blunt their capacity to detect subtle affective signals, thereby missing affective disorders (Hindley *et al.* 1993). It is better to engage a professional sign language interpreter, preferably with experience of child mental health and with an opportunity to meet the child prior to the interview and for debriefing afterwards. This is particularly important because the interpreter will have the child's eye contact and may have picked up subtle emotional cues (Turner *et al.* 2000). The coexistence of deafness and psychiatric disorder can lead clinicians to

Table 50.1 Prevalence of psychiatric disorders in children and adolescents with hearing impairment (HI) and hearing controls.

Study	Number of children with HI	Range of HI	Prevalence of disorder	
			HI group (%)	Control (%)

*Profound: severe to profound, early onset hearing impairment.

†Moderate to profound acquired hearing impairment.

an unwarranted assumption that deafness explains all—the phenomenon of ‘diagnostic shadowing’ (Kitson & Thacker 2000).

Psychological assessments

Caution is needed in interpreting psychological test findings in deaf children because most tests have been validated exclusively in hearing populations. A knowledge of developmental and cultural aspects of deafness is also helpful (Orr *et al.* 1987; Blennerhassett 2000).

Autism and related disorders

Two studies of deaf children attending audiology clinics found autism and related disorders to be more common than in hearing children. Juré *et al.* (1991) estimated a prevalence of 5.3% and Rosenhall *et al.* (1999) 3.5%. In the latter study, intellectual impairment did not account for the raised rate. One of the assumed causes of an increased prevalence of autism in deaf children is a common underlying cause arising from brain damage caused by agents such as intrauterine rubella (Chess 1977) and cytomegalovirus (Stubbs 1978; see van Gent *et al.* 1997).

The age of diagnosis of autism is frequently later in deaf children (Juré *et al.* 1991), in part reflecting ‘diagnostic shadowing’ (see above). This is despite the fact that the basic impairments associated with autism are qualitatively different from what is seen in other deaf children. Nevertheless, poor language skills stemming from deafness may be associated with delayed but not impaired imaginative play. Unusual communication patterns and passivity are more common in deaf children with intellectual impairment who do not have autism. Also, even clinicians with good signing skills can have difficulty in detecting language

disorder in sign. Further, some deaf children with autism show significant improvements in social functioning when educated in signing environments (Juré *et al.* 1991; Roberts & Hindley 1999).

Disruptive behaviour

The overrepresentation of HI children with disruptive behaviour among those referred to clinics may partially reflect referral patterns. However, there may also be associations with brain pathology that occur with some types of deafness (Kelly *et al.* 1993). In a longitudinal study of children affected by congenital rubella, Chess *et al.* (1971) and Chess & Fernandez (1980) found that early impulsiveness in those with deafness alone disappeared as the children acquired language and self-control skills. By contrast, impulsiveness persisted in deaf children with additional impairments. Oppositional behaviour can be an expression of underlying feelings of impotence, anxiety or sadness, or an expression of frustration with difficulties of communication (Kelly *et al.* 1993). Symptoms of distractibility and overactivity may reflect a distracting visual environment, or poor language matching in the classroom leading to boredom (Hindley & Kroll 1998), or undetected intellectual language impairments, seizure disorders or the side-effects of drugs (Kelly *et al.* 1993).

Emotional disorders

The underrepresentation of emotional disorders in children with HI seen in the specialist services runs counter to the epidemiological evidence. Using the Child Behaviour Checklist (CBCL; Achenbach 1991), van Eldik (1998) found significantly higher scores on the anxious/depressive scale among deaf

teenagers than among hearing peers. Emotional problems may be missed because poor signing skills prevent parents and teachers recognizing the mood disturbance.

The display of emotion used to illustrate narratives in sign must not be confused with an affective disorder. The latter is pervasive and persistent, whereas the former changes rapidly and is congruent with the narrative (Roberts & Hindley 1999). Behavioural problems that have distinct beginnings and endings, with no clear response to changes in circumstance may derive from depression (Kitson & Thacker 2000).

Schizophrenia and other psychoses

Psychotic disorders are not more common in deaf young people (Kitson & Thacker 2000). Because the syntax of sign language is very different from spoken language, disorders of thinking can be misattributed (Evans & Elliott 1987; Jenkins & Chess 1996). Equally, accurate assessments of thought disorder and abnormal experiences can be difficult (Kitson & Thacker 2000). Nevertheless, phenomena such as clang associations and flight of ideas have been clearly identified in deaf adults with psychotic disorders (Fraunhofer & Kitson 1991; Kitson & Thacker 2000).

Intervention

In the early 1960s, Rainer & Altschuler (1966) described the then revolutionary service for deaf adults in New York State; and more recently Sleeboom-van Raaij (1991) offered her experience in setting up a similar unit in the Netherlands. Specialist services for children and adolescents with HI and their families are still few but are better developed in the Netherlands, Sweden and the UK than in most other countries. In the Netherlands an inpatient and outpatient service was started in 1993. In the UK, an outpatient service was started in 1991 and a national inpatient unit opened in 2001. Sweden has a national outpatient service. All these services emphasize the importance of the socio-cultural model of deafness, consultation with the deaf community and parents of children with HI, and a combined team of deaf and hearing professionals. Hearing professionals are expected to achieve high levels of sign language proficiency (Hindley & van Gent 2000).

After initial assessment, the same range of outpatient treatments are provided as for hearing children and their families (Hindley 2000). Treatment often has to be organized nearer to the child's home because of the distance to the specialized service. Because of their scarcity, specialized services are often brought in as consultants to local clinics (van Gent 1999).

Elliott *et al.* (1987) described specific pitfalls in the psychotherapy of children with HI as well as the value of deaf therapists. Interpreters in family and group therapy may become incorporated into transference relationships (Harvey 1989; Hoyt *et al.* 1981). Medication may involve effects that impede communication because they influence the skills needed for signing or lip-reading (Sleeboom-van Raaij 1997). Also, children

with HI are sometimes unable to describe the effects and side-effects of the medication prescribed. The inpatient treatment of children with HI usually involves a highly structured programme tailored to the individual child within a small and well-organized community and the wider deaf community (teachers, social workers, etc.).

Specialist or generic services

Specialist services exist in only a few countries and, where present, may not be geographically accessible to all. Specialist services for deaf children do not fit neatly into tiered models of services. Unlike other specialist services, their specialism is not in a particular group of disorders, but in communication—a fundamental aspect of all service provision. Two considerations should guide referral to specialist services: the communication needs of the child and the complexity of the case. Where there are no specialist services, clinicians will need help with signing from interpreters but should also be prepared to use non-verbal means of communication.

Otitis media with effusion

Otitis media with effusion can lead to transient, but sometimes severe, conductive hearing impairment. Early reports suggested that this could result in impaired language skills and behavioural difficulties (McGee *et al.* 1982; Chalmers *et al.* 1989). However, the weight of evidence now indicates that although the recurrent hearing impairment may lead to some minor impairments in language functioning, it less often causes a serious language disorder (Haggard *et al.* 1990; Bennett & Haggard 1999).

Hearing children of deaf parents

Knowledge on the development of hearing children of deaf parents is relatively limited (Meadow-Orlans 1995; Singleton & Tittle 2000). The most comprehensive report is an anthropological study of 150 grown-up children of signing deaf parents (Preston 1994). Most deaf parents are competent and caring but they experience stresses as a result of being deaf in a hearing world (Singleton & Tittle 2000). Hearing children of deaf parents are at the centre of interaction between deaf and hearing cultures. Although use of sign language is a central component of being deaf and often a source of pride, some deaf people see their sign language as less valued than spoken language and may experience shame when using sign outside their deaf community. This may lead some to choose not to use sign with their hearing child and to rely on inadequate spoken language. In other circumstances hearing children are drawn into the role of communicator/interpreter for their parents. These experiences can be seen as adverse, 'parentifying' the child at an early age, but to others these experiences lead to 'greater adaptiveness, resourcefulness, curiosity and "worldliness"' (Singleton & Tittle 2000). Deaf parents may have difficulty in accessing information about parenting, and their own childhood within a hearing family may

not have provided them with good models of parenting. This may lead to their feeling unconfident or incompetent as parents (Singleton & Tittle 2000). In some respects, the experience of deaf parents of hearing children can be compared to that of parents raising children from ethnic backgrounds different from their own (Singleton & Tittle 2000). Some lessons about 'cultural brokering' may be relevant.

Most of the grown-up hearing children of deaf parents studied by Preston (1994) acknowledged some difficulties in their childhood but attributed these as much to the hearing society's response to their parents as to their parent's failings. Their roles as interpreters and advocates were linked to experiences that were both fulfilling and hurtful. In a similar vein, many described loyalties that were divided between their deaf parents and their hearing grandparents.

Little is known about the psychological well-being of hearing children of deaf parents but perhaps a characteristic pattern should not be expected. Clinical experience suggests that emotional difficulties may be more common than in children with HI but whether this applies to non-referred children is not known.

Mental health aspects of cochlear implantation

Advocates for cochlear implants in congenitally deaf children argue for 'the unique possibility of restoring some hearing to the deaf' and claim long-term postoperative gains with respect to hearing, language and scholastic achievements at school (Van den Broek *et al.* 1998). Critics (including most organizations for the deaf) express ethical objections on the grounds that the implants constitute a serious invasion, and denial, of the cultural identity of deaf people and they query both the consistency and validity of the supposed benefits (Hindley 2000). Adequate psychological evaluations have yet to be undertaken but they are much needed.

Adult psychotherapy

A community survey of deaf adults (Checinski 1993) has suggested that the rate of psychiatric disorder is increased, with perhaps one-third experiencing an episode of depression. In London, referral for depression and for anxiety disorder have increased recently, as a result of improvements in service provision (Kitson & Thacker 2000). In line with our clinical experience with adolescents, there has been some increase in drug use (Austen & Checinski 2000) and abuse (Vernon & Daigle-King 1999) amongst deaf adults.

Psychiatric aspects of visual impairment

Epidemiology

Jan *et al.* (1977) studied a heterogeneous total population of blind and partially sighted children and young people aged 0–20

years, using questionnaires and interviews and a neighbourhood control group matched for age and sex. Of 86 children with VI, 57% showed psychiatric or cognitive disorder. Mental retardation or a developmental disorder was present in one-third of the children, and the psychiatric diagnoses spanned adjustment reaction, personality disorder and behaviour disorder. More children with VI were prescribed more psychotropic medication, and more had sleep and nutritional problems.

Van Hasselt *et al.* (1986) found that male adolescents with VI had higher mean scores than sighted controls on the parent, teacher and self-report versions of the CBCL (Achenbach & Edelbrock 1983). Those attending a residential school had higher mean scores than those attending a mainstream day school. In a study of preschool-age children with severe VI and mental retardation, one-third of the group showed social withdrawal, lack of relationships with other children, self-injurious behaviour and/or poor compliance at bedtime (Kitzinger & Hunt 1985). Ollendick *et al.* (1985) noted a pattern of fears in adolescents with VI that reflected the dangers they faced in their everyday world. Huure & Aro (1998), in a study of adolescents with VI in mainstream schools, found an increased rate of loneliness and difficulties making friends, but not of depression, compared with controls. Thus, the evidence suggests that VI is accompanied by a raised rate of psychopathology that, to some extent, follows a possibly slightly different pattern from that found in sighted children (although there were marked similarities in the study by Schnittjer & Hirshoren 1981).

Yoshida *et al.* (1998) found an excess of emotional disorders in young adults with VI but there have been reports of increased depression and anxiety among adults who became blind at a later age (De Leo *et al.* 1999). Also, blind people may be at a greater risk of developing chronic post-traumatic stress disorder because of their difficulty in reconstructing a mental image of the initiating traumatic event (McFarlane 1988).

As with HI, psychiatric disorder in children with VI is more likely when there are additional impairments. Probably, congenital blindness has a more pervasive effect on psychological development but acquired VI may lead to a greater sense of loss for both parents and children (Jan *et al.* 1997). Early visual experience can have a positive effect on the acquisition of skills such as Braille reading (Sampaio & Philip 1995). Although VI can have a powerful impact, children vary in their response, and there is no such thing as a 'blind personality' (Vander Kolk 1987).

Psychiatric assessment

The assessment of children with VI and their families is comparable to that of children with HI, except that it does not involve the need for an interpreter. Given the impact of VI on early mother-child interaction, a careful account of this period should be obtained from parents. Early sleep difficulties (Tabandeh *et al.* 1998) may reflect circadian cycle disturbances stemming from lack of visual feedback (Sasaki *et al.* 1992) or perception of social cues relating to sleep (Sadeh *et al.* 1995).

Separation anxiety may be increased in young children with VI (Burlingham 1972; Fraiberg 1977), and in adolescence over-protection may make the development of personal and sexual relationships more difficult (Scholl 1974).

The psychiatric interview should take place in a room adapted to the child with VI. Obstacles should be few, lighting should be good if the child has any vision, and children need to be given time to explore and adapt to the new environment (Hansen *et al.* 1982). The clinician must be prepared to have much more physical contact than with sighted children, to take the time to describe and respond to questions about the contents of the room and the toys, and about the purposes and procedures of the assessment (Jenkins & Chess 1996). Many children with VI use touch and oral manipulation to become familiar with toys and test objects. Clinicians must be aware of their own reactions to the child with VI; one study showed that there was a tendency to make a more favourable assessment of cognitive and social capacities when the blind child used gaze direction (Raver-Lampman 1990). In view of the frequency of additional impairments, it is essential that clinical appraisal should include an adequate physical assessment.

Psychological assessment

Blindness affects children's variety of experiences, their ability to get about, and their control of the environment (Lowenfeld 1948). These need to be considered when interpreting test findings (Warren 1977). A focus more on the functional skills used and on style of problem-solving may be as informative as scores on tests designed for sighted children (Hansen *et al.* 1982). Such tests can be useful, however, if used to assess patterns of performance (Groenvelde & Jan 1992). There are some tests specifically designed for use with children with VI (e.g. the Reynell-Zinkin; Reynell 1979). Others have been translated into Braille or large print, but appropriate modifications of standard tests may allow them to be used (Van Hasselt & Sisson 1987), although care is needed in relation to implications regarding comparisons with standardization data (see Sergeant & Taylor, Chapter 6). As with children with HI, the testing of children with VI tends to take somewhat longer than that of sighted children.

Autism and related disorders

Children with severe congenital VI not infrequently show autistic-like features (Cass 1998); one-quarter did so in the study by Brown *et al.* (1997). These features include echolalia, pronominal reversal and delayed emergence of symbolic play (Fraiberg 1977), and stereotyped behaviours, or 'blindisms', such as repetitive body-rocking, hand-flapping, toe-walking, eye-pressing, rubbing or poking, eye flicking with fingers and light gazing. The latter may derive from early lack of sensory experiences (Jan *et al.* 1977), giving rise to compensatory self-stimulation (Warren 1984). The autistic qualities may also

reflect failures in psychological perspective-taking (Hobson *et al.* 1999). Autistic patterns are much more frequent when VI is accompanied by mental retardation (Brown *et al.* 1997) and they may also stem from brain pathology associated with some forms of VI (Chase 1972).

In summary, autism in children with severe VI may reflect shared risk factors but also VI may give rise to 'blindisms' that carry a somewhat different meaning. They may be influenced by interventions and usually gradually disappear but may reappear with anxiety, lack of sufficient stimulation or in new stressful situations.

Interventions

There are far fewer specialized psychiatric inpatient and outpatient services for children and adolescents with VI than for those with HI. The usual range of therapeutic modalities are applicable but styles of therapist-child interaction may need some modification (see Fraiberg 1977; Van Hasselt *et al.* 1983; Warren 1984; Erin *et al.* 1991; Sisson 1992). Therapists must appreciate that VI will impair children's ability to perceive communicative cues conveyed through posture and facial expressions and they must be willing to translate their responses into words. Also, VI may alter the child's use of directed gaze, facial expression and posture to convey feelings. The presence of a guide dog sometimes complicates matters, if it becomes protective of its owner through awareness of negative emotions. In insight-directed therapy, the child may express contradictory feelings and desires regarding dependence and independence, when memories of helplessness and of the significance of the VI re-emerge (Johnson 1989). Therapists may take a more active protective attitude than they would towards sighted children. Particularly in the final phases of treatment, intense separation anxiety may recur, reflecting early fears of losses. Parenting a child with VI can be extremely stressful and approaches to reduce parental stress have been developed (Kirkham *et al.* 1986; Van Hasselt *et al.* 1987; Webb 1990). As with children with HI, careful monitoring of the effects and side-effects of medication is very important in relation to possible influences on sensory functioning.

Adult outcome

Freeman *et al.* (1991) followed the heterogeneous sample of children with VI previously studied by Jan *et al.* (1977) into early adult life. Mannerisms had almost disappeared (except in those with multiple handicaps), and several individuals who exhibited stereotypies when they were alone were able to control this behaviour in public. A worse psychiatric outcome was found in those with mental retardation and in those whose vision deteriorated. It was striking that one-third of the women and one in nine of the men reported that they had been sexually molested or abused. Also, nearly three-quarters said they had been cruelly teased at school. Misunderstandings tended to be worse for the partially sighted students, whose visual abilities were more

difficult to comprehend. There was a strong tendency for the partially sighted to want to pass as normal. Employment outcomes were poor, with three out of five out of work.

Conclusions

Our knowledge of the developmental pathways of sensory impaired children, and of their differences from hearing and sighted children, continues to grow. However, on the whole, we know more about the effects of HI than of VI, and services for children with VI are less well developed than for those with HI. This is impeding both our understanding of psychopathological factors and our care of these young people. Uncertainties remain about the optimal balance between specialist and local services. Until recently, the main psychological focus has been on the effects of HI and VI on key developmental experiences and on the effects of society's response to sensory deficits. These remain important but opinions are divided on the extent to which sensory impairments should be viewed as a cultural difference rather than as a disability. The improvements that are likely in medical interventions, such as cochlear implants, will make resolution of this issue both more difficult and more important. There is also a growing awareness that some of the psychopathological problems found in children with HI or VI stem from associated neurodevelopmental impairment or cognitive deficits. An integrated approach to mental health issues will continue to be crucial.

Implications for the Infant of Maternal Puerperal Psychiatric Disorders

Maureen N. Marks, Alison E. Hipwell and R. Channi Kumar

Introduction

Maternal psychopathology in the puerperium is associated with increased risk for subsequent impairments in cognitive, social and emotional development in offspring. There are multiple pathways to these effects: physiological, genetic and environmental. We describe associations observed between maternal psychopathology and subsequent infant outcome and concentrate attention on links between these associations and the maternal environment provided for the infant by the mentally ill mother. This environment will depend not only on the nature of her disorder but also on a variety of other environmental factors, some of which in turn may be causes or consequences of maternal psychopathology.

Maternal mental illness

The extent to which maternal psychopathology might have an impact on the child will depend not only on primary diagnosis but also on other characteristics of the illness, e.g. comorbidity, severity of illness, the course of illness during pregnancy and after the infant's birth and the timing of the infant's exposure to it (Rutter 1989).

Mother's parenting style

Associations between maternal mental illness and the mother–infant relationship and/or infant development may be the indirect consequence of disturbances in the mother's parenting style (Bornstein 1995) rather than mental illness *per se*. An important contributor to a how a mother parents her child will be the parenting she herself received as a child. Research across generations has demonstrated significant concordance between mothers' 'working models' of their own early relationships and their children's security of attachment (Fonagy *et al.* 1991; for a review of studies see Fonagy *et al.* 1994). There is also evidence for intergenerational continuities in a number of behaviours, e.g. smoking, antisocial behaviour, aggression, social withdrawal and violence by young men to their partners. Whereas intergenerational associations such as these may sometimes be related to parenting practices (Patterson & Dishion 1998), other factors could account for or mediate them, such as genetic transmission of temperamental traits, or continuities of social conditions (e.g. poverty), across generations (for a discussion of these issues see Patterson 1998; Rutter 1998).

The child's father

A husband or partner can sometimes influence the course of maternal postnatal psychiatric illness (Brown *et al.* 1990; Marks *et al.* 1992, 1996) and it is likely that he will have some effect on infant development, either directly through his relationship with the child, or indirectly via his relationship with the infant's mother (Egeland *et al.* 1988; Cabrera *et al.* 2000). Family structure, in particular the place of the infant's father in the family, is also likely to be important (Marks & Lovestone 1995; Lamb 1999).

Social adversity

The presence of social stress not only increases the likelihood of maternal mental illness, but also exacerbates negative parent–infant interactions (Hamilton *et al.* 1993) and has a direct impact on infant function (Adrian & Hammen 1993). Poverty in particular is linked with depressed mood in parents, conflict between the parents, more negative parental interactions with offspring, an increase in emotional and behavioural problems in children (Conger *et al.* 1994) and a negative impact on their academic performance (Brody *et al.* 1994).

Infant factors

The infant's outcome will depend to some extent on the infant's inherent characteristics. There are gender differences in infants' vulnerability to environmental adversity. Male infants appear to be more vulnerable to death by injury (accidental or non-accidental) and by homicide (Marks 1996); to the impact of maternal postnatal depression (Sharp *et al.* 1995); and to elicit more adverse parental responses (Murray *et al.* 1993). In an examination of findings in some studies, but not in others, that boys seem to be more adversely affected by parental divorce than girls, Zaslow (1988, 1989) has commented on some methodological problems. Outcome measures may not be sensitive to girls' possible adverse responses and the context within which outcome has been assessed may have contributed to the differences observed (e.g. in the divorce studies, when post-divorce family form is taken into account, it is remaining with a mother who does not remarry that is the most adverse outcome for boys).

The infant's temperament can also have an impact on the parent. Research has shown how infant characteristics influence

parental behaviours (Papousek & Papousek 1997). Infant factors may also influence the mother's mental health (Field *et al.* 1988; Whiffen & Gotlib 1989; Murray *et al.* 1996).

Genetics

Clearly, any or all of the above may be influenced directly or indirectly by genetic factors and the task of future research will be to delineate how genes and environment interact (see Rutter *et al.* 1997 for a discussion of current key findings and future research strategies). There is no doubt that psychiatric disorders in parents are associated with increased risk of psychiatric illness in their children. The evidence suggests that there is a genetic component to the development of schizophrenia and bipolar disorder but that depressive illnesses in offspring are largely determined by environmental factors. Even when there is good evidence that genes play a part, associations are weak and often diagnoses of offspring are not the same as those of the parents; the non-specificity suggests that influences other than genetic ones are likely to have contributed. More recently, it has become evident that environmental experience can sometimes alter genetic material. Caldji *et al.* (1998) found that maternal care of neonatal rat pups altered the genetic expression of behavioural responses to stress and that this alteration was then passed on to the next generation.

Pregnancy

Few systematic prospective studies have examined either the prevalence or course of substantial mental health problems during pregnancy, or the risk for relapse in women with prior psychiatric histories who discontinue medication when they become pregnant. Nevertheless, it is known that women who experience clinically significant psychiatric symptoms during pregnancy are at risk of inadequate antenatal care, poor nutrition and obstetric complications (Gotlib *et al.* 1991; Steer *et al.* 1992; Perkin *et al.* 1993; O'Hara 1995; Orr & Miller 1995). Altshuler *et al.* (1998) also suggested that the potential impact of hypothalamic–pituitary–adrenal dysregulation associated with maternal depression on fetal well-being may be of theoretical concern.

The maternal psychological state, particularly in the later stages of pregnancy (Hedegaard *et al.* 1993), may have a significant impact on the physical outcome for the newborn. Maternal anxiety, perceived stress, and life-event distress have been shown to be associated with lower infant birth weight and reduced gestational age at birth (Lobel *et al.* 1992; Wadwa *et al.* 1993; Lou *et al.* 1994). Maternal anxiety in the last trimester of pregnancy has been found to be associated with increased risk of emotional and behavioural problems in the children when they are 4 years old (O'Connor *et al.* in press). Recent evidence (Gitau *et al.* 1998; Gitau *et al.* 2001) has suggested that there may be two possible mechanisms by which these characteristics of maternal mood during pregnancy have their effect on the fetus:

- 1 by direct transport of cortisol across the placenta; and
- 2 by impaired blood flow through the uterine arteries.

One of the possible major hazards for the fetus of mothers who have histories of severe psychiatric illness or who experience an episode of illness during pregnancy is exposure to psychotropic medication. At present studies are few and limited in terms of sample size, fetal outcome measures and period of follow-up (for a review see Altshuler *et al.* 1996). For women treated with antipsychotic medication, there is some evidence of an increased risk of congenital abnormalities when phenothiazines are administered in the first trimester, but for high-potency neuroleptics, such as haloperidol, or the newer antipsychotic drugs, such as clozapine, little is known. There are case reports of mostly transient (lasting up to 10 days) perinatal syndromes in neonates of mothers who took neuroleptics in pregnancy (e.g. motor restlessness, tremor, hypertonicity, abnormal movements). There is no evidence for any association between fetal exposure to tricyclic antidepressants and congenital abnormalities, suggesting that these are relatively safe drugs for pregnant women, although neonates have shown withdrawal syndromes (jitteriness, irritability, convulsions). With regard to serotonin selective reuptake inhibitors, fluoxetine has also been found, on the basis of preliminary data, to be relatively safe. The data for sertraline, paroxetine and fluvoxamine are either insufficient or non-existent. Likewise, there is little information available about monoamine oxidase inhibitors. First trimester exposure to lithium is associated with an increased risk of cardiovascular malformations. While there have been case reports of neonatal toxicity in infants exposed to lithium, a study of bipolar women maintained on lithium during pregnancy found no evidence for this. First trimester exposure to benzodiazepines and to carbamazepine increases the risk of a congenital malformation.

The clinician has to weigh up the potential risk to the fetus from drug exposure with the risk to mother and infant of not medicating a seriously ill mother or of discontinuing medication. The relative risks of *in utero* exposure to psychotropic medication compared with the risks of untreated psychiatric disorder are still unclear and further research is urgently needed (Oates 1997; Cohen & Rosenbaum 1998).

Postnatal period

Psychiatric disorders occurring postpartum may or may not have aetiological links with childbirth and may or may not be exacerbated by childbirth. Diagnoses such as postpartum depression and postpartum psychosis are frequently referred to in clinical practice and in psychiatric research investigations, but neither DSM-IV nor ICD-10 (World Health Organization 1992) refer to them as formal diagnostic categories, although DSM-IV provides for a postpartum *onset* specifier for mood disorders and for brief psychotic disorder. Many episodes of postpartum depression begin during pregnancy or even before pregnancy (Gotlib *et al.* 1991; Marks *et al.* 2000) as do episodes of bipolar disorder (Brockington *et al.* 1990). Other disorders occurring in

the puerperium, some of which may constitute a relapse of a previous disorder (e.g. anxiety disorders) or may be associated with an increase in severity of symptoms (e.g. obsessive-compulsive disorder) and some of which have long-standing and chronic courses with no increase or decrease in symptoms (e.g. schizophrenia), tend not to be given the label postpartum, but none the less are likely to have an impact on the mother's parenting of her child.

Thus, postpartum illnesses are defined by their temporal proximity to child-bearing. In general, symptomatology and clinical course are similar to illnesses occurring at other times. On this basis, Brockington (1996) dismissed the scientific value of the concept of postnatal depression but argued the case for a 'pure' postpartum psychosis as a specific disease entity when episodes of the illness occur only after childbirth and recur after subsequent pregnancies. A similar case could be made for depressions or other illnesses that occur only in the context of childbirth.

Unipolar (non-psychotic) depression

Inconsistencies in the time frame used to delineate the postpartum period—ranging from 4 weeks to 6 months after delivery—make the literature on the impact of postnatal depression on the child difficult to interpret. Studies have fairly consistently reported rates of depression of 12–16% during the 6–12 weeks after delivery (O'Hara & Swain 1996). A range of psychosocial risk factors for postpartum mood disorder have been identified, including prior postpartum depression (Wisner *et al.* 1993), depressive symptomatology during pregnancy and family or personal histories of major depression, as well as stressful newborn-associated events such as health problems and infant irritability (Kumar & Robson 1984; Gotlib *et al.* 1991; Beck 1996; Murray *et al.* 1996; O'Hara & Swain 1996).

In the last decade there has been considerable research into the impact of mothers' depressions on their children (for overviews of research to date see Murray & Cooper 1997; Radke-Yarrow 1998). Weinberg & Tronick (1998) summarized the extent to which the quantity, quality and timing of depressed mothers' social and affective behaviour with their infants are compromised in ways that are associated with impairments in infant functioning. In the first few months of life, infants of depressed mothers have been shown to have difficulties engaging in social and object interactions, and show less positive and more negative affect, lower activity levels, and greater physiological reactivity as evidenced by higher heart rate and cortisol levels than the infants of non-depressed control mothers (Campbell & Cohn 1991; Field 1995). They may also show compromised ability to regulate their affective and behavioural states which are present from the newborn period, often in the form of irritability and inconsolable crying (Zuckerman *et al.* 1990). This suggests that prenatal factors (e.g. neuroendocrine changes associated with the mothers' depression) may have had an impact on the infant's behaviour. In addition, there is growing evidence from prospec-

tive studies that the adverse effects on social, emotional and cognitive development continue well after the mother's symptoms have remitted (Stein *et al.* 1991; Murray 1992; Campbell *et al.* 1995; Sharp *et al.* 1995; Murray *et al.* 1999). Murray (1992) demonstrated that children of mothers with postnatal depression were less likely to form secure attachments to their mothers at 18 months, performed worse on object concept tasks, and showed more mild behavioural difficulties. Whereas this study reported no overall effect of depression on more general measures of cognitive development, postnatal depressive disorders seemed to have potentiated the adverse effects of low social class. Field *et al.* (1988) demonstrated that infants of depressed mothers generalized a withdrawn and avoidant interactional style to other adults, which clearly has implications for the child's social development.

There is fairly consistent evidence that male infants may be at greater risk from maternal depression than females. On a measure of general cognitive functioning, Sharp *et al.* (1995) reported that the 4-year-old boys of postnatally depressed women were performing at a mean of 1 SD lower than that of boys of well mothers but no such differences were found for the girls in that study. In a recent follow-up of the same children at the age of 11 years, the same finding was reported (Hay *et al.* 2001). Boys of women who have experienced an episode of postnatal depressive illness also appear to be at risk of subsequent behavioural and emotional difficulties. During the transition to school, for example, teachers have described these children as showing signs of hyperactive and distractible behaviour. In contrast, the girls whose mothers had been depressed in the postnatal period were not only perceived as extremely well behaved, but more prosocial and diligent than the control group girls (Sinclair & Murray 1998). While there is insufficient research to draw any conclusions about the mechanisms that might be involved in these observed differences within clinical samples, the fine-grained observations of early mother–infant interactions in non-clinical samples have suggested that males rely more on maternal support to regulate their affective state and take longer to repair 'interactive errors' than female infants in interaction with their mother (Weinberg & Tronick 1998). Thus, these social demands that may be characteristic of male infants in the postnatal period are likely to be especially difficult for mothers to cope with if they are also feeling depressed at this time, and may set in train a pattern of relating that is maintained over time despite remission of the mother's symptoms.

Although studies of postnatal depression have reported significant differences in mother and infant functioning on the group level, it is clear that the behaviour of depressed mothers is heterogeneous and therefore will be experienced by infants in a variety of ways. Some depressed mothers disengage and withdraw when they are with their infants, others may become intrusive and overtly hostile during interactions, whereas others are able to mobilize a normal range of behaviour and affect (Lyons-Ruth *et al.* 1986; Cohn & Tronick 1989). Cohn & Tronick (1989) reported that, in turn, the infants' affective states are

specifically related to their mothers' style of interaction. These investigators found that the infants of withdrawn depressed mothers spend most of their time fussing and crying, whereas the infants of intrusive depressed mothers rarely cried but avoided looking at, and interacting with, the mother. The infants of depressed mothers who were able to respond within the normal range behaved similarly to control group infants. These results highlight the need to consider the mother's affective style in addition to her diagnostic status, which is likely to have specific implications for therapeutic intervention.

Weissman & Paykel (1974) and Frankel & Harmon (1996) noted the disparity between the mother's perception of her ability to parent and the quality of the mother–infant interaction. They highlighted the need to address difficulties in the mother–infant relationship in the course of therapeutic intervention rather than aim to treat the mother alone. This need is further indicated by the reciprocal nature of interactions and the infant's active role in shaping relationships (Weinberg & Tronick 1994). Furthermore, 'the infant who functions well can be used as a therapeutic ally to increase the mothers' sense of competence as a parent' (Weinberg & Tronick 1998, p. 59).

Anxiety disorders

More recently, researchers have begun to recognize the postpartum period as a time of increased vulnerability to symptoms of anxiety such as panic and obsessionality (Metz *et al.* 1988; Sichel *et al.* 1993; Cohen *et al.* 1994; Northcott & Stein 1994; Williams & Koran 1997). In a prospective study, Cohen *et al.* (1996) reported that 90% of patients with panic disorder (some of whom had experienced a reduction in symptoms during pregnancy) were actively symptomatic in the first 1–3 months postpartum. The 10% of patients remaining well were taking anxiolytic medication. Furthermore, Wisner *et al.* (1999) reported that women who develop postnatal depression are more likely to experience disturbing aggressive obsessional thoughts or images than women whose depression occurs outside the postpartum period. There was also a significant association between aggressive obsessions and checking compulsions that were primarily focused on the baby.

Relatively little is known about the impact of maternal anxiety in the postnatal period on infant functioning. Most studies have focused on older children, and on panic disorder to the exclusion of other anxiety disorders. However, as with depression, there may be important developmental effects on children. Mullen *et al.* (1993) found that 10–15% of children in their US sample were described as 'inhibited' and predisposed to be irritable as infants, and shy, fearful and introverted at older ages. Children of mothers with panic disorder also have a higher rate of insecure attachment to the mother than non-clinical samples (Manassis *et al.* 1994). Eighty per cent of the preschool-age children in this study were classified as insecurely attached to their mother, with 65% being judged as 'disorganized'. The mothers of securely attached children differed from mothers of insecure

preschool-age children in reporting fewer depressive symptoms, fewer stressful life events and an increased sense of parenting competence. However, this study was based on a relatively small sample in which the children ranged in age from 18 to 59 months. In addition, there were some methodological problems as a result of modest reliability coefficients for the attachment ratings and observers who were not 'blind' to maternal diagnosis. These findings must therefore be considered as preliminary and treated with caution.

More longitudinal observational studies are clearly needed to confirm some of these initial findings and to evaluate the importance of these risk factors in the development of psychopathology.

Affective psychosis

The rate of postpartum relapse in women who suffer from bipolar illness has been estimated at 33–50% (Reich & Winokur 1970; Kendell *et al.* 1987; Marks *et al.* 1992), and many of these women present with postpartum psychosis. Although postpartum psychosis can present with delirium-like symptoms and confusion that distinguish it from a typical manic episode (Brockington *et al.* 1981), several follow-up studies of women with postpartum psychosis noted recurrence of episodes of bipolar disorder (Benvenuti *et al.* 1992; Videbech & Gouliaev 1995) or schizoaffective illness (Klompouhouwer & Van Hulst 1991).

Postpartum psychosis is considered a psychiatric emergency that typically requires inpatient treatment with mood stabilizers and antipsychotic medication in order to avoid placing the mother and infant at risk of harm. Rates of infanticide associated with untreated puerperal psychosis have been estimated to be as high as 4% (Davidson & Robertson 1985).

Compared with well women, those experiencing an episode of psychosis in the postpartum period tend to demonstrate poorer quality caregiving at the time of the illness (Kumar & Hipwell 1994), although there may be substantial improvement with recovery (Thiels & Kumar 1987). Preoccupation with hallucinations and psychotic ideation, blunting of affect, increased irritability, etc., may lead the parent to be unresponsive to the child's emotional and physical needs. The form of disturbance in caregiving has been found to vary according to whether the episode is schizoaffective, manic-depressive, or a severe form of unipolar depression. Hipwell & Kumar (1996) found nurses' ratings to differ significantly according to diagnostic status, mothers with schizophrenic symptoms being rated the most impaired, followed by those with manic, bipolar and, finally, depressive symptoms.

It is somewhat counterintuitive therefore that adverse effects on the developing child have not been consistently demonstrated. McNeil *et al.* (1988) reported that, compared with the children of well controls and mothers with a history of psychosis but no symptoms postnatally, the children of puerperally psychotic mothers were no more impaired on measures of attach-

ment to the mother and maternal perceptions of infant temperament at 1 year. Furthermore, at the age of 6, there were no differences on measures of cognitive development and mental disturbance. Similar negative findings had previously been reported by Grunebaum *et al.* (1975) when comparing the developmental quotients of 1 year olds admitted to hospital with their mentally ill mothers, with those infants of well mothers. There have even been reports of superior functioning in some children of psychotic mothers (Kauffman *et al.* 1979). In contrast, DeMulder & Radke-Yarrow (1991) reported that two-thirds of 24 children of mothers with bipolar illness in their study showed insecure patterns of attachment when they were aged 15–52 months of age, most of whom were classified as insecure-disorganized. This proportion was significantly more than the 42% of insecurity reported for the offspring of mothers with unipolar depression or no mental health problems. However, 13 of the fathers of these 24 children were diagnosed as having unipolar depression, and the mothers with bipolar disorder were significantly more impaired in terms of their functioning during the child's lifetime than the mothers in the other groups.

Although some reports suggest that there is little detrimental effect of puerperal affective psychosis on infant development, many of the infants in the index groups had experienced significant separations from their mother during her illness. Hipwell *et al.* (2000) suggested that the absence of adverse outcome in these children may well arise because the infant's exposure to the maternal illness was limited, rather than because there were genuinely no detrimental effects. In this study, there was no excess of insecure attachment in the 1 year olds of mothers experiencing postpartum mania, in spite of the early interactions being rated as poor. By contrast, infants of unipolar depressed mothers whose interactions were rated as much less impaired were more likely to be insecurely attached. Examination of clinical management suggested that infants of mothers with manic symptoms were more often separated from their mothers and cared for by nursing staff than were infants of women with unipolar depressive episodes who may therefore have been less protected from the adverse effects of the mother's illness. However, there was also evidence that those suffering from manic episodes made a more complete recovery than those with depression, and the different infant outcome in these two groups could reflect current maternal functioning, rather than the protective effects of separating mother and infant. Another explanation may be that infants of mothers with bipolar illness show a different developmental course from the offspring of women with unipolar disorders such that emotional and affective difficulties are not apparent until later in childhood, when the direct and indirect effects of exposure to the mother's illness have become chronic. Using an accelerated longitudinal research strategy to examine the developmental pathways of 22 children whose mothers had been diagnosed with bipolar illness, Radke-Yarrow *et al.* (1992) reported that during the preschool period (age 1.5–3.5 years) the children of mothers with bipolar disorder appeared to be competent and without problems; they were able to separate from their mother without anxiety and related easily with a

stranger. But, by middle to late childhood, children exposed to maternal bipolar illness demonstrated significant symptoms of depression and anxiety. This early 'maturity' in the preschool phase may have represented a precarious method of coping with chaotic mothering.

One of the major hazards for children of mentally ill parents is that resulting from discontinuity of care because of separate admission of the mother to hospital. Alternative care that is both stable and personalized, e.g. from the child's father or grandmother, is sometimes preferable to that provided by a highly disturbed mother. However, separation from the mother frequently involves placements with a series of unfamiliar foster parents (see Rushton & Minnis, Chapter 22) and this can have profound effects on the development of attachments and serious consequences for the children both during childhood and as adults (Bowlby 1973; Rutter & Quinton 1984; Brown 1988). The role of the other parent (Webster 1990) or extended family is therefore crucial in providing continuity of care and the necessary support to the mother so that her hospitalization can be kept short.

Schizophrenia

For women with schizophrenia, rates of relapse or symptomatology do not appear to be exacerbated by childbirth (McNeil 1986; Davies *et al.* 1995). In contrast to the acute episodes of psychotic relapse that are typical for women with a history of bipolar illness, outcome studies from mother-and-baby units that admit women with chronic schizophrenia with their infants for treatment and assessment show that the prognosis for their ability to care for their infant is poor, particularly if they are single and have no social support to assist in providing consistent care for their child (Appleby & Dickens 1993; Davies *et al.* 1995; Kumar *et al.* 1995). The best predictor of the ability to parent successfully with a diagnosis of chronic schizophrenia appears to be the best level of functioning before the child was born (Oates 1996).

Children born to schizophrenic parents are at increased risk of impaired cognitive, sensorimotor and neurological development compared with the offspring of parents with other psychiatric disorders and with those of normal controls (Ragins *et al.* 1975; Fish 1977; Weintraub 1987; Wynne *et al.* 1987; Fish *et al.* 1992; McNeil *et al.* 1993; Sameroff *et al.* 1997). These differences have been found as early as the first few days or months of life and have sometimes been linked to obstetric complications and/or low birth weight (Mednick *et al.* 1971; Marcus *et al.* 1981; Yoshida *et al.* 1999).

One of the aims of studies of the offspring of parents with schizophrenia has been to determine early indicators of the development of schizophrenia in the children. The general conclusion of such studies has been that because impairments have appeared early in the infant's life they are probably largely genetically determined. However, the impairments may also have been in part a consequence of the intrauterine environment or the quality of parental care received by the developing infant.

Sacker *et al.* (1995) studied obstetric complications in schizophrenic cases identified in the British Perinatal Mortality Survey birth cohort. They reported that the increased risk of obstetric complications in those with schizophrenia may result from the physique/lifestyle of their mothers. Their mothers were more likely to have smoked, to have attended fewer antenatal clinics, to have had more previous pregnancies and to have been attended by untrained people at the birth. They concluded that the increased vulnerability of infants thought to have the potential to develop schizophrenia, obstetric insult and low birth weight may be an epiphenomenon of their mothers' chaotic lifestyles rather than a genetic characteristic. Further evidence for this is provided by Goodman & Emory (1992) who compared the prenatal care received by schizophrenic, depressed and control women. Having schizophrenia increased the likelihood of both receiving inadequate prenatal care and having obstetric complications.

Inadequacies in the prenatal environment are likely to continue postpartum. In the Stony Brook high-risk project (Weintraub 1987) the lifestyles of families with a schizophrenic parent were described as characterized by increased marital discord, family conflict, financial problems, and poorer ratings of family solidarity and household facilities compared with normal control families.

Goodman (1987), who assessed the children of schizophrenic, depressed and well mothers, from birth to 5 years of age, reported that the offspring of women with schizophrenia showed more deficits on social competence and had lower IQs than the other children. These deficits were linked to the child-rearing environment provided by their mothers. Schizophrenic mothers were rated as providing the poorest overall environment (less play stimulation, fewer learning experiences, less emotional and verbal involvement) and were also rated as less affectively involved and less responsive than well mothers.

Bergman *et al.* (1997) examined the interaction between parental psychiatric status and child maltreatment on neuro-motor functioning in the children of parents with schizophrenia, with other psychiatric diagnoses or with no psychiatric diagnoses. Children who had been maltreated performed worse than those who had not. There was no main effect of psychiatric diagnosis.

In summarizing the Israeli high-risk study, Marcus *et al.* (1987) provided data showing that the parenting provided by mothers with schizophrenia was an important factor in the child's psychosocial development and the subsequent development of illness in the offspring. Of the schizophrenic offspring who showed early neurobehavioural deficits in this study, 15/24 (63%) also received poor parenting compared to 4/26 (15%) of the offspring who did not show early behavioural deficits. Further, only children who had experienced poor parenting subsequently became schizophrenic.

Observational studies of the schizophrenic mother's parenting of her infant have reported that these women are more likely to be 'grossly disturbed and inadequate' (Sobel 1961; Ragins *et al.* 1975). Schizophrenic mothers touch and play less with their

4-month-old infants than controls (Garmezy 1974). Psychotic hospitalized mothers, particularly schizophrenics, have been described as being more likely to perceive their infants as passive creatures and to interpret their cues, such as smiles, as 'accidental grimaces' compared with mothers in a control group (Cohler *et al.* 1970). Separation from their infants during the acute phase of their illnesses may have contributed to these disturbed patterns of behaviour. By contrast, Schachter *et al.* (1977) observed schizophrenic mothers to be *more* responsive and affectionate, and to play more with their 14-month-old infants than did controls. However, all the participants in this latter study were informed of the study's hypothesis, which may have differentially increased anxiety and motivation among the schizophrenic mothers to perform well.

Gamer *et al.* (1976) investigated cognitive and emotional outcome in the infants of 15 women who had been hospitalized in the puerperium. These investigators found that infants of mothers with schizophrenia tended to perform worst on tests of object constancy at age 1 year. They were also less likely to approach their mothers and interact positively with them after a brief separation, which, it could be argued, is suggestive of insecure attachment to the mother. These infants were also more likely to have had multiple caregivers during the mother's illness.

McNeil *et al.* (1983) carried out a major longitudinal study of infants of mothers with histories of various kinds of psychotic illnesses. They found consistently less social contact between schizophrenic mothers and their infants in comparison with healthy mothers up to 6 months. Subsequently at 1 year, these children were more likely to show anxious attachment using a modified version of the Strange Situation Test (Ainsworth & Wittig 1969; Näslund *et al.* 1984), and were less likely to be afraid of strangers. At 1 year, their mothers also displayed greater tension and a higher frequency of vocal discrepancy (positive intonation combined with negative content) in a feeding and play situation. By contrast, Sameroff *et al.* (1982) reported no difference in attachment security between infants of mothers with schizophrenia and either those of mothers with non-psychotic depression or personality disorder or those of healthy controls.

McNeil *et al.* (1984) suggested that the infants of mothers with schizophrenia may contribute to non-optimal maternal behaviour as a result of being temperamentally more difficult and more reactive to stimulation. Other kinds of infant factors may also precipitate and/or maintain problematic interactional style. Gamer *et al.* (1976) reported that these infants were more inhibited. Similarly, Ragins *et al.* (1975) described infant characteristics such as less spontaneity and a lesser tendency to imitate, less responsiveness to verbal stimulation and heightened distress to separation from the mother than healthy control infants. However, these studies could not disentangle the bidirectional effects of disturbed mother-infant interactions.

The Finnish Adoptive Family Study of Schizophrenia (Tiernari *et al.* 1994; Wahlberg *et al.* 1997) assessed the interaction between genetic risk and rearing-family risk. Findings

suggested that the adult offspring of schizophrenics may have a genetically determined hypersensitivity to the family environment. They fared better than controls in an adequate family situation and worse than controls in a disturbed one. The findings have yet to be replicated but they suggest hypotheses for future research. For example, if a mother is suffering from schizophrenia, then it is likely that the family environment of her infant will be somewhat disturbed, either because the infant is more likely to be separated from the mother and placed in institutional care or given multiple alternative carers, or because her mothering skills are likely to be less than adequate in the first place, and it may be that this environment, as much as, or in interaction with, the infant's inheritance, is linked to impairments in subsequent development.

These studies demonstrated the need for further longitudinal observational studies of the mother–infant relationship when mothers have schizophrenia, starting during pregnancy, to disentangle the impact on the infant of the schizophrenic mother–infant relationship, and the environment she provides for her child, from those genetic factors which place the infant at risk.

Eating disorders

The literature on the impact of maternal eating disorders on the fetus and infant is sparse. Evidence is mixed whether maternal symptoms diminish during pregnancy but return to prepregnancy levels postpartum (Lacey & Smith 1987; Lemberg & Phillips 1989) or worsen during pregnancy and postpartum (Stewart *et al.* 1987). This may be because of differences in the course of symptoms associated with the type of eating disorder. A recent prospective study (Blais *et al.* 2000) found that women with bulimia showed a decrease in symptoms during the pregnancy and this decrease was sustained for the 9 months they were followed up. Women with anorexia also showed decreased symptomatology during the pregnancy but their symptoms had returned to prepregnancy levels by 6 months postpartum.

Although the evidence concerning the course of eating disorders during the perinatal period is mixed, having an eating disorder during pregnancy does appear to pose risk for the fetus. Perinatal deaths in women with eating disorders are six times the expected rate (Brinch *et al.* 1988), twice the rate of fetal loss in women with bulimia compared with controls (Mitchell *et al.* 1991) and a 10% lower birth rate in a mixed group of anorexia and bulimia (Blais *et al.* 2000). Newly born infants of women with eating disorders have lower birth weights and smaller lengths than control group infants (Waugh & Bulik 1999). The mothers of full-term infants who are small for gestational age are three times more likely to have eating disorders than mothers of premature infants and six times more likely than mothers of control infants (Conti *et al.* 1998).

It is not known whether these infants are at risk in the long term for impaired growth and its neurodevelopmental sequelae. Lacey & Smith (1987) raised concern that mothers with bulimia may try to slim their infants down during the first year of life, de-

spite their weights being in the normal range. However, this phenomenon was observed in only three of the 20 mothers in their study. Similarly, Woodside & Shekter-Wolfson (1990), in their sample of 12 mothers or fathers with anorexia or bulimia nervosa, described many examples of highly distorted parent–child relationships. Two of the parents had abandoned their children altogether as a result of their eating disorder, while in other families the children had become extremely involved in their parent's illness by cooking for them or dieting in response to parental weight loss. In some families the parent was wearing the children's clothes. Brinch *et al.* (1988) reported that 17% of a group of 50 mothers with a history of anorexia nervosa described their children as failing to thrive during the first year postpartum. However, the mothers were interviewed between 4 and 22 years after their children were born and these retrospective findings must be interpreted with caution. Nevertheless, other reports (van Wezel-Meijler & Wit 1989) also raised concerns about inadequate child nutrition and care within their samples of mothers with eating disorders.

In a controlled observational study of 1-year-old infants, Stein *et al.* (1994) found that mothers with eating disorders were more intrusive and expressed more negative emotion towards their infants during meals compared with controls. They were also more intrusive but not more negative during play. In addition, the infants of index mothers were lighter than those of controls; infant weight was related to the degree of conflict between mother and infant that was observed during mealtimes and to the extent of the mother's concern about her shape. A later study (Stein *et al.* 1996) also found evidence for growth faltering in the children of women with eating disorders. They compared children of women with eating disorders with those of women with postnatal depression and with those of controls. Infants of mothers with eating disorders were smaller (weight for length and weight for age) than infants in both comparison groups.

The mechanism whereby maternal eating disorder pathology affects the infant's growth is as yet unclear and there is a need for further research to elucidate the psychic or behavioural factors that are involved.

Substance abuse

A comprehensive and comparative review of adverse effects of different kinds of substance abuse is beyond the scope of this chapter. Instead, the general characteristics and effects of maternal substance abuse are illustrated by reference to selected studies of alcohol, opioid and cocaine abuse.

Maternal substance abuse is associated with increased rates of complications during pregnancy, labour and delivery and is believed to have a wide range of effects on the fetus and infant that are dependent on the dosage, timing and conditions of exposure (West 1986). Infants of substance abusers are at greater risk of sudden infant death syndrome (Kandall *et al.* 1993) and the children of addicted parents are at increased risk for later dysfunctional behaviours (Fergusson *et al.* 1998; Yates *et al.* 1998; Weissman *et al.* 1999).

A longitudinal prospective study carried out in Sweden by Aronson *et al.* (1985) shed some light on the risks involved for the fetus. The offspring of alcoholic mothers who had been reared by foster parents showed hyperactivity, inattention and poor motor skills, and were also found to have lower IQ scores than their controls despite showing no signs of fetal alcohol syndrome (Jones & Smith 1973). Streissguth *et al.* (1984) reported that the 4-year-old children born to heavy drinkers displayed attention and reaction time abnormalities compared with children born to light and infrequent drinkers. Similar findings have been reported in several studies (for an overview of research see Streissguth & Kanter 1997), although there is some discussion as to the existence of a threshold of safe exposure, or whether abnormalities of balance in particular are observed among 'social drinking' mothers (Streissguth *et al.* 1984; Barr *et al.* 1990). In O'Connor *et al.*'s (1987) study of primiparous middle-class mothers, an increase in attachment insecurity was observed among infants of moderate-to-heavy drinkers compared with the offspring of abstinent or light drinkers.

It is known that many infants who are prenatally exposed to opioids undergo some degree of withdrawal after delivery (for overviews of research findings see Mayes & Bornstein 1997; Kosofsky 1999) which may last up to 6 months and is manifested as irritability, high-pitched crying, tenseness of muscles, tremulousness, regurgitation (Kron *et al.* 1975) and also rejection of their mothers' attempts to console them (Strauss *et al.* 1975). Chasnoff & Griffith (1991) have also reported that cocaine-exposed neonates have low thresholds for overstimulation and significant difficulty with self-regulation when these thresholds are exceeded, which is likely to have far-reaching effects in a range of contexts if this difficulty continues over several years (Howard *et al.* 1989). In the early postnatal period therefore such infant behaviours are likely to be primarily associated with problems in infant-caregiver interaction patterns. However, Jeremy & Bernstine (1984) reported no differences in patterns of mother-infant interaction between the 4 month olds of mothers maintained on methadone during pregnancy compared with infants of control mothers. The mothers who abused drugs showed worse interaction and communication with their infants but this was related more to lack of current maternal resources than to drug use *per se*.

Substance-abusing mothers have also been described as being at high risk for difficulties in parenting, including child neglect and abuse (Lawson & Wilson 1979). Thus, there are separate and interactive implications for the child of maternal abuse, e.g. alcohol, during or after pregnancy because of the likely associations between alcohol consumption and maternal personality characteristics, physical and mental health, intelligence, social circumstances, multigenerational and/or multiple substance abuse, and the impact of being reared in a drug- or alcohol-seeking environment. It is clear that many kinds of psychological stressors are associated with the environments of children whose parents abuse drugs or alcohol, and it is particularly difficult to tease out the effects on the fetus from those occurring postnatally on the infant (for a discussion of these issues see

Kaltenbach 1994). A study that compared substance-abusing women in the context of high and low levels of social adversity found that women in the high adversity group had poorer scores on parenting attitude scales (Kettinger *et al.* 2000). In another study, the effect of maternal opioid use on parenting behaviour was accounted for by effects of comorbid personality disorder (Hans *et al.* 1999).

Studies of the effects of drug abuse are beset by numerous methodological difficulties, such as the confounding effects of nutritional deficits, concurrent infections, multiple drug use, differential effects of motivation and sample attrition, the chaotic lifestyle of substance-abusing mothers and other mental health problems such as clinical depression and anxiety or personality characteristics such as low tolerance to frustration and neediness for immediate gratification. It is therefore not possible to predict the developmental outcomes for these high-risk children until more is known about the additive and interactive effects of the multiple risk factors to which they are exposed.

Infanticide

The younger the infant, the more likely the risk the child will become the victim of homicide and the more likely the perpetrator will be a parent (Marks & Kumar 1993, 1996).

The characteristics and causes of the homicide of infants within 24 h of their birth (neonaticide) are very different from those of the homicide of children older than 1 day. Compared with parents who kill older infants, neonaticidal mothers are more likely to be young (under 20), single, and often still living at home with parents. The pregnancy is often the first, unintentional and concealed. The motivation to kill is usually because the child was unwanted (Resnick 1970) and the infant's death is more likely to have resulted from inaction rather than the violent action that often characterizes the killing of older infants: nearly half die from neglect (Marks & Kumar 1993). In addition, the mothers are rarely mentally ill (D'Orban 1979). Mothers who kill their neonates are treated comparatively leniently by the legal system in the UK; a major proportion are never indicted and those who are usually receive infanticide convictions (Marks & Kumar 1993).

The most frequent observation about women who commit neonaticide is that the pregnancy had been denied (Brozovsky & Falit 1971; Green & Manohar 1990). In some cases the woman may 'know' she is pregnant but to all intents and purposes behaves as if she were not. This state of affairs is usually the consequence of an unconscious belief: if you do not think about it, then the pregnancy will, magically, disappear. Sometimes the woman does not seem to acknowledge even to herself that she is pregnant. In either case the woman does not seek medical help and makes no preparation for the delivery. After the child is born and disposed, the mother returns immediately to her normal daily life.

The denial in these concealed pregnancies is sometimes so powerful that it seems also to influence the perceptions of other people as well as the pregnant woman. This may be related to the

fact that the biological manifestations of pregnancy sometimes become attenuated; for example, there may be reduced change in body contour, continuation of menstrual bleeding during pregnancy and no complaints of pregnancy such as nausea or increased urinary frequency. Brozovsky & Falit (1971) report a neonaticidal mother who during the pregnancy had convinced her physician, after a positive pregnancy test and at 5 months, that she was no longer pregnant.

The labours are often rapid: the woman thinks she has colic or menstrual pain and may interpret the contractions as a need to defecate and the delivery itself as a bowel movement. The arrival of the baby is thus experienced as a traumatic shock and puts an end to the denial and the woman is then confronted with the overwhelming fear that made the denial so necessary and effective in the first place. Anxiety of such intensity sometimes leads to ego disorganization, especially when the ego is less than resilient in the first place, which is typical of these women, and in this disorganized or dissociated state the woman kills the child or leaves it to die.

The overrepresentation of naive young women in studies of neonaticide may be in part a consequence of their naivety. It is generally considered that reported rates of neonaticide underestimate true rates. This is because many neonaticides remain undiscovered. It may be that more mature worldly women are more able to conceal successfully an unwanted pregnancy and dispose of the newly delivered infant in such a way that it remains undiscovered. Funayama & Sagisaka (1988) report 12 recorded cases of mothers in Japan who had carried out multiple neonaticides (three or more in each case). Eleven of the women were married and their ages ranged from 31 to 45 years.

Sakuta & Saito (1981) distinguished between two different kinds of neonaticide, which they described as the 'mabiki' and 'anomie' types. 'Mabiki' is a Japanese term that means 'thinning out' and is also used to refer to neonaticide when it is used as a form of population control, which was once culturally acceptable in Japan. The mabiki type of neonaticidal mother is typically married, has several children and does not wish to have more. In contrast, the 'anomie' type of mother is characteristically unmarried, this is her first child and the reasons for the infanticide are 'avoiding ill-repute' or 'loss of psychological support'. It may be that a similar, if less clear-cut, distinction also applies to neonaticides that occur in Western countries today.

Paternal neonaticide is rare. Kaye *et al.* (1990) reviewed four cases, one of which involved an infant with severe congenital abnormalities, two men with a psychiatric disorder (schizophrenia) and one man with an intellectual impairment.

In contrast with neonaticide, infanticide is usually attributed to either mental illness or child abuse; the parent who has killed his or her child is generally considered to be either 'mad' or 'bad'. In England and Wales there is an Infanticide Act, particular legislation which applies to a woman who has killed her child under 1 year of age. Implicit in this legislation is the idea that childbirth may sometimes have a destabilizing impact on mothers' minds, that the infant homicide may have occurred under these unsta-

ble psychological conditions, and that therefore there may be a case for diminished responsibility for the crime. In contrast, in Scotland and in the USA, mothers who kill their children are charged as for any other homicide offence with the possibility that the infanticidal mother can plead diminished responsibility within the usual terms of each country's homicide legislation. Despite these differences in legislation, in most Western countries the younger the infant, the greater the likelihood that the offence will be attributed to some form of mental illness and the perpetrator convicted of a less serious offence and given a lighter sentence. This is particularly so for mothers who kill their infants. In England and Wales most mothers who kill their infants are convicted of infanticide and given probation sentences. This is in contrast to fathers who kill their infants, who are usually given prison sentences (Marks & Kumar 1993). Despite there being no infanticide act in Scotland the outcome is similar. Most mothers who kill infants receive non-custodial sentences, either probation or hospital orders, and most fathers are sent to prison (Marks *et al.* 1996).

Studies in the USA have not examined differential sentencing of mothers and fathers but Crittenden & Craig (1990) reported that in Florida, the younger the infant, the more likely the offence will be ascribed to parental mental illness, and the less serious the conviction and lighter the sentence.

Public records provide limited information about the details surrounding these offences and so it is difficult to know if sentencing reflects the circumstances and severity of the crime. The Scottish Office computer records include the motive for the offence. Mothers are usually recorded as having killed their infant because of their mental state, whereas the most frequent attribution given to fathers is that of rage (Marks & Kumar 1996). However, it is impossible to assess how these motivations are ascribed and whether the difference between mothers and fathers is because of the circumstances surrounding the offence or to the effects of gender on the attributions about the causes of events.

In a systematic study of maternal filicides, D'Orban (1979) studied 89 women admitted to Holloway prison during 1970–75, who had been charged with the killing or attempted murder of 109 children. This constituted almost the total sample remanded in custody during the period in London and the south-east of England, since during that time all mothers charged with the killing or attempted murder of their children were remanded to Holloway for some period before trial.

D'Orban found that the most frequent category of perpetrator was that of the 'battering mothers': the mother had lost her temper with some aspect of the child's behaviour, e.g. the child's crying, feeding or incontinence. Only 14/89 women in D'Orban's study were psychotic at the time of the offence and he concluded that puerperal psychotic illness is a relatively rare cause of maternal filicide. However, about half the offences in D'Orban's study had been against children aged 1 year or more: they had occurred sometime after the postpartum period by which time the risk of maternal mental illness has substantially declined (Kendell *et al.* 1987; Cox *et al.* 1993). In addition, a fur-

ther proportion had involved neonaticide, which is unlikely to be related to either battering or mental illness.

In a later reanalysis of D'Orban's data (Marks & Kumar 1996), the relative contribution of mental illness to offences that occurred nearer the infant's delivery (when the mother was more likely to have a postnatally related psychological illness) was assessed. The effect of the time since delivery on the contribution of mental illness to the mother's impulse to kill was examined by comparing infants aged between 1 day and under 6 months old, with those aged between 6 months and under 1 year and those aged 1 year or more. Neonaticides were excluded from this analysis. The results indicated that maternal mental illness was more likely to be implicated in the killing of *older* children. Women who killed children between 1 day and under 6 months were most frequently categorized as 'battering' mothers, whereas mothers who had killed or attempted to kill older infants were most frequently categorized as mentally ill. Although maternal mental illness had contributed to some of the homicides of the younger aged infants, more often infants had been killed, or nearly killed, because the mother had suddenly lost her temper with the child.

Likewise, in Australia, Wilkey *et al.* (1982) concluded that the largest group of homicide of children were those occurring as the end result of non-accidental injury assaults. Similar results have been reported in studies in the USA. A study of all victims 12 years of age or less, during 1956–82, in Florida (Copeland 1985) found that 45% of all deaths were caused by fatal child abuse. This study notes that the younger the child the more likely the death was a consequence of child abuse; 91% of the child abuse fatalities occurred in children aged 3 or less, whereas non-child abuse cases were more evenly distributed throughout the age range. Copeland also found that male children were more likely to be child abuse fatalities.

Crittenden & Craig (1990) reported that children between 1 month and 5 years were more than twice as likely to be killed as a result of injuries inflicted by parents responding to noxious behaviour (e.g. incessant crying or disobedience) than were neonates or older children (52% compared to 17% of neonates and 21% of school-aged children). They also found that in 60% of children aged between 1 month and under 5 years there was evidence of present or past abuse or neglect, e.g. marks on the child's body, a service record of maltreatment or an eyewitness report. Only 7% of neonates and 10% of school-aged children had any evidence of abuse or neglect.

Although there are many individual case examples published, few studies have systematically examined the circumstances surrounding filicide where the parent's mental state was the main precipitating factor. McGrath (1992) studied a cohort of 115 women who were in Broadmoor Hospital, and who had killed their child, during 1956–69. For 46% of the sample the diagnosis was affective psychosis, and for 37% it was schizophrenia. Only 5% were categorized as having personality disorder. Seventy-five per cent had a history of previous psychiatric illness and 49% had attempted suicide at the time of the offence. In

many cases the claimed motivation was altruistic, to relieve the child of suffering, although only one victim had severe disability. However, Broadmoor is a high-security hospital to which only the more severely ill and dangerous patients are admitted and so the psychiatric characteristics observed in this sample are likely to be typical of Broadmoor's patient population in general rather than being peculiar to women who had killed their child.

The sample studied by D'Orban (1979) was more representative. In this study, 54% of mothers who had been categorized as having killed their child as a direct consequence of mental illness had a history of previous psychiatric illness requiring inpatient or outpatient treatment and 88% suffered from psychiatric symptoms prior to the offence. Two-thirds had attempted or contemplated suicide at the time of the offence. Usually the murder and suicides were simultaneous acts. In the majority, the conscious motive was primarily self-destruction, and the killing of the child was an extension of the suicide act. Less often the killing was a result of some delusional idea.

D'Orban (1979) reported that many of the women categorized by him as 'battering' also had psychiatric diagnoses, although these diagnoses were not implicated in the offence. Forty-seven per cent had personality disorder and a further 33% were depressed at the time of the offence.

A high proportion of women who have killed a child, as a consequence of abuse, are also likely to be suffering from some kind of psychiatric disorder, either depression or personality disorder, particularly the latter. In turn, it is the case that both personality disorder and depression are more likely to be associated with either high levels of hostility or a reduction in the capacity to inhibit the expression of hostility, or both. In fact, personality disorders are defined by these features: the DSM-IV criteria for personality disorder include abnormalities in cognition (ways of perceiving and interpreting), affectivity, interpersonal functioning and impulse control (American Psychiatric Association 1994). Individuals with personality disorder by definition experience difficulties in all areas of interpersonal functioning and these will apply in their relationships with their children as much as, if not even more so given the emotional intensity of family life, in any social domain. It would appear that while such diagnoses may not usually be directly linked to infant homicide, they are likely to contribute indirectly in that they may make the task of containing aggressive feelings, which all parents sometimes feel towards their infants, difficult, if not impossible for some.

In assessing risk to future children when a mother has killed a child, there are no studies that have followed up this client group to assess outcome in subsequent pregnancies. Each case therefore has to be considered individually, and the usual methods of assessing parenting and risk for the children applied as discussed in the parenting assessment section later in this chapter. As with assessing the risk of violence in psychiatric patients generally, there are difficulties in assessing the risk of filicide in a mentally ill parent. The risk of being killed by a parent as a direct

Table 51.1 Maternal psychiatric disorders. Some questions to ask when a woman with a history of mental illness becomes pregnant and decides to keep the baby.

<i>Pregnancy</i>	
Antenatal clinic	Has she booked in? Do obstetricians and midwives know of her psychiatric history?
Family doctor, health visitor and psychiatrist	Do they know she is pregnant? Have they seen her recently?
Social Services	Is a planning meeting necessary to discuss possible concerns about child protection? Does she need counselling and practical help, e.g. about housing? Does she need an allocated social worker?
Medication	Has it been reviewed since her pregnancy became known?
<i>Labour, delivery and early puerperium</i>	
Admission	Will she see staff she has met before? Is there a contact number for the liaison psychiatrist? Have arrangements been made, if needed, to call upon a psychiatric nurse to 'special' her, after delivery? Do the obstetric and paediatric teams know what medication she is taking?
Postnatal management	Is the baby staying with her or in a nursery? How long is the planned stay on the postnatal ward and where is she going from there? Has an assessment by a psychiatrist been organized? Are Social Services convening a child protection conference, and have they got all the relevant clinical data?
Discharge separately from baby	If she is being separated from the baby, has she been prepared for this and does she know her rights? What part are her partner and her family playing? Where is she going, and do receiving staff know about her needs? Who will organize access to the baby?
Discharge with baby	What level of supervision, if any, is needed? Have Social Services assessed her need for facilities such as day nursery, home help, etc.? Who will organize reviews of the child's welfare and what information is required for such reviews? Who is responsible for the mother's clinical management?

consequence of the parent's mental illness is unrelated to the child's age. Most parents with mental illness do not harm their children. When they do, the most frequent scenario involves a parent who is suicidal and who believes the child will also be better off dead.

Jacobson & Miller (1998) presented three examples of detailed, systematic and extensive assessments of future parenting risk when a mentally ill mother had killed someone previously: a neonaticidal mother, a 'battering' mother who had killed a 1-year-old child and a mother who had killed an adult friend during a psychotic episode. As a result of the assessments, all three were deemed to be at *low* risk for future child maltreatment and violence. This article well illustrates the highly complex and multifaceted issues involved in making assessments of parents at risk of filicide.

Clinical management

A particular feature of the management of perinatal women is the protection of the infant. From a practical clinical perspective, the prevention of possible harm to the child begins in preg-

nancy and depends upon effective liaison. The checklist of questions in Table 51.1 is intended as an *aide-mémoire*—it is neither comprehensive nor are all the items relevant to every patient. It has been prepared in the hope that going through such a list and acting upon the information available or lack of it may obviate some of the crises that occur on postnatal wards or at home after discharge from the obstetric unit.

Non-psychotic disorders

Most child-bearing women with mental disorders do not come to the attention of psychiatric services. Epidemiological and case register studies (Nott 1982; Oates 1989) show contact rates between 4 and 15 per 1000 deliveries, of which about 2 per 1000 represent admission (Meltzer & Kumar 1985; Kendell *et al.* 1987). The prevalence of depression after childbirth is at least 10% and therefore about 90% of depressed mothers remain exclusively under the care of their family doctors. To this number may be added cases of other pre-existing non-psychotic disorders, such as phobias and obsessive-compulsive disorders, many of which may also not have been referred for specialist assessment and treatment. The majority of postnatal depressions are

self-limiting and resolve within 6 months but, for about one-quarter of those affected, childbirth marks the beginning of chronic and persistent depression (Pitt 1968; Watson *et al.* 1984) and, for a similar proportion, the start of recurrent, remitting and relapsing depressive disorder (Kumar & Robson 1984). Studies of child-bearing women in the community have shown that about half of those meeting operational clinical criteria for caseness remain undetected by family doctors (Kumar & Robson 1984; Sharp 1992) or by health visitors (Briscoe 1986).

The first priority therefore is to improve the detection of women with non-psychotic postnatal psychiatric disturbances and a very significant step in this direction has been made by the development of screening questionnaires such as the Edinburgh Postnatal Depression Scale (Cox *et al.* 1987). Such methods allied with the introduction of systematic psychiatric liaison for obstetrics (Appleby *et al.* 1988; Cox *et al.* 1992) may greatly improve detection rates. However, an essential next step is to develop indices that will help in picking out women most in need of interventions, such as counselling (Holden *et al.* 1989), pharmacotherapy (Henderson *et al.* 1991; Appleby *et al.* 1997) or measures specifically targeted at improving the quality of interaction between mother and infant (Seeley *et al.* 1996; Cooper & Murray 1997).

The childbirth experience in the present context is best summarized as reflecting discontinuities of care. As the mother passes from family doctor to student midwife or to junior obstetricians for subsequent antenatal visits, then meets new faces in the delivery suite and subsequently in the postnatal ward where she must undergo checks from obstetricians and paediatricians before leaving hospital to go back into the care of the community midwives, health visitors and her family doctor, it is not surprising that changes in her mental state may be missed. Even when vigorous attempts are made to detect women at risk, or those already suffering with psychiatric problems in antenatal clinics and postnatal wards (Appleby *et al.* 1988), a significant proportion—nearly 30%—fail to keep clinic appointments. It is possible that many such non-attenders are also the most needy; they may be overwhelmed by the problems of coping with other small children without support from their partners or others and cannot contemplate travelling to a hospital clinic while feeling depressed and run down with an infant and toddlers in tow. There is a need for a co-ordinated policy of care based upon links between hospital and community primary health care services, Social Services and voluntary agencies. Such resources, to be effective, must also be capable of being delivered at home and the contribution of child psychiatrists to the development and shaping of these services seems indispensable.

Psychosis

Admission of a mother to a psychiatric hospital may mean separation from her infant at a time when their relationship is starting to develop. The practice of joint mother-and-infant admissions has become relatively widespread (Buist *et al.* 1990;

Margison 1990), especially in the UK, since it was first proposed by Main (1948). Joint admission was initiated as a consequence of the work of Bowlby (1977) who argued that prolonged separation of mothers and children may be detrimental to the psychological development of the child as well as to the ongoing process of attachment. However, later work (Robertson & Robertson 1971) has indicated that the quality of substitute parenting, rather than separation from the mother *per se*, may be the key factor which influences child outcome.

Studies carried out over the last 30 years have provided support for the feasibility of specialized mother-and-baby units in as much as the burden on nursing staff is manageable, there is no clearly increased risk of physical injury to the child and there appears to be no adverse effect on the mental health of the mother. Baker *et al.* (1961) reported that joint admission of mothers and babies resulted in shorter hospital stays, lower relapse rates and a greater likelihood of the mother adequately caring for her child. However, these findings have not always been supported by other studies (Glaser 1962; Bardon *et al.* 1968; Stewart 1989). Nevertheless, it is generally accepted that the mother's recovery is hastened by the practice of joint admission, as a result of either the continued contact with her infant and the associated confidence in her role as a mother or the particularly supportive and structured environment that is created by grouping women together with similar illnesses. The mother may learn by direct observation of other adult-infant interactions how to care for and play with her baby. Destructive, ambivalent and guilty feelings, obsessional thoughts and misinterpretations can be detected by staff and dealt with promptly. Joint admission may also facilitate attachment by allowing breastfeeding for infants whose mothers are taking certain psychotropic drugs. Mothers who become ill as a result of environmental difficulties but with no obvious problem in their feelings for their baby will also benefit from joint admission by the very fact that separation from the child and the ensuing effects on their relationship will only add to the crisis that brought them into hospital.

However, assessing the positive value of joint admission is complicated by variations in admission criteria between units. Systematic studies have yet to test the validity of claims about the benefits for the mother or, even more surprisingly, for the developing child. In the latter case, another methodological puzzle presents itself. In an attempt to ascertain the potential advantages and disadvantages for the infant of joint admission with a psychotic mother, how can one separate out the effects of the mother's illness from the fact that the pair have been placed in an institution with the influences of multiple caregivers or risks from other patients in addition to the child's own mother?

A feature of mother-and-baby units, like that of neonatal intensive care units, is that caregiving is carried out by a large number of different people, not all of whom are able to learn individual characteristics of a particular baby; their interventions therefore may not always be sensitive to the infant's current mood or activity and may interfere with the normal development of infant self-regulation (Minde & Benoit 1991). Grunebaum *et al.* (1975) described a study of seven infants of

mentally ill mothers who were jointly admitted to hospital, seven babies of mentally ill mothers not treated in hospital and 14 babies of normal mothers. Although the social development of the children in the former two groups was judged to be impaired at 18 months compared with controls, the 'joint admission' children attained markedly higher developmental quotients than the other groups, mainly as a result of higher scores on expressive language development. It was suggested that the infant's experience of multiple caregivers and heightened and varied environmental stimulation in the hospital proved to be beneficial to cognitive development at this time.

A number of factors may further heighten the risk of maladaptation of infants whose mothers become psychotic in the puerperium. These include the mother's own difficulties in establishing patterns of mutually responsive interaction with her infant because of heavy sedation from antipsychotic drugs; discontinuation of breastfeeding; and some degree of limited access to the baby as a result of staff concerns about safety and competence of care. Another important consideration that will indirectly affect the mother and infant's long-term outcome is the impact of their joint admission on the quality of the marital or familial relationship (Harvey & McGrath 1988; Lovestone & Kumar 1993), the concerns felt by the family about the baby's safety and the difficulty that the partner/father may experience in getting to know the newborn.

Assessment of risk for the infant must be the most important consideration in the provision of joint care. In community-based samples, researchers have repeatedly tried to identify factors arising before and after childbirth that could indicate mothers who are at high risk for child abuse or neglect. In one of the few prospective studies carried out, Gray *et al.* (1979) identified such a wide range of maternal characteristics and social problems potentially associated with risk for the child that clinical decision-making was not made any easier. Systematic measures of current and future risk among inpatient populations of mentally ill mothers and their infants, however, remain to be defined. A detailed psychiatric history would go some way of raising awareness about the functioning of particular patients who have shown violent or impulsive behaviour in the past or who have experienced command hallucinations or persecutory delusions. A measure that could formally assess characteristics such as maternal motivation and competence to care safely for the infant both during psychiatric illness and after remission of symptoms in an acute episode would clearly be invaluable from a clinical point of view. The development of measures such as the Bethlem Mother–Infant Interaction Scale that was devised in the course of clinical observation on a specialized mother-and-baby unit are likely to provide a useful adjunct in predicting caregiving difficulties from observations in the early weeks of joint admission (Hipwell & Kumar 1996; Kumar & Hipwell 1996). Such measures intended to assess risk should only be one part of the decision-making process of experts and their routine use could clearly have serious consequences where false-negatives or false-positives occur.

Joint care thus poses a number of specific problems: assess-

ment of risk, regulation of access and support in developing an appropriate mother–infant relationship. The practice of domiciliary care of carefully selected severely depressed or manic mothers has recently been shown to be a viable alternative to admission to a mother-and-baby unit (Oates 1988). In this study, the women were managed at home if they were free from active suicidal or infanticidal ideas, lived within reach of the base hospital in case of emergency, were not living alone and had the support of family and friends. The minimal disruption to the family and, the individuality of care provided by the community nurse, encouraging maternal self-confidence and autonomy in her own home, were described as particular benefits of this type of management. No major difference in the clinical recoveries of 17 patients who had been admitted previously with an episode of puerperal psychosis was reported, although these women felt their recovery had been faster when managed at home.

Assessment of parenting

Child psychiatrists may be invited to assess a mentally ill mother who is contesting actions by Social Services under child protection procedures. Most mentally ill mothers are competent parents and colleagues can manage adequately if appropriate support is provided. The difficulty lies in defining criteria and thresholds for what is deemed to be adequate in the context of maternal mental illness, not only currently, in the case of infants, but also stretching into the future as the child's needs change and develop. Conflict between the child's welfare and the mother's parental rights is explicitly recognized by the Children Act and this conflict can begin when a woman suffering from severe mental illness becomes pregnant. There are often lapses and delays in recognizing potential or actual risk to infants, and relatively little attention has been paid to detecting and evaluating threats to welfare that may apply, particularly in the case of infants.

Although there are methods and frameworks for assessing safety and adequacy of parenting and potential risk to older children (Steinhauer 1983; Adcock & White 1985; Kennedy 1991; Reder & Lucey 1995; Budd & Holdsworth 1996; Goepfert *et al.* 1996; Louis *et al.* 1997), the evaluation of risk to infants, in the presence of maternal mental illness, is less well established. There are several key areas that have to be addressed. These involve not only the mother's mental illness and its impact on her capacity to nurture her child, but also the social and physical environment within which mother and child are located (Rutter 1988). Parenting assessments need to be multidimensional and include an evaluation of the following.

- *Caregiving.* Attachment to infant, warmth, sensitivity and responsiveness, knowledge and expectations about children, attitudes to being a parent, commitment, competence and consistency in routine care, planning, safety and prevention of risk.
- *Social situation.* Social support, marital relationship, other relationships, violence in relationships, social adversity.
- *History of parenting.* Immediate past with other children and the mother's own experience of being parented.

- *Infant factors.* The baby's health, temperament, difficulties with crying, feeding, etc.
- *Psychiatric issues.* Severity and chronicity of illness, presence of delusions and hallucinations and whether the infant is incorporated in maternal psychopathology, insight about the illness and its impact on the infant, acceptance of and responsiveness to interventions and treatment, including compliance with medication.

Conclusions

Over the past 20 years there has been a convergence of interest by clinicians and researchers investigating the impact of maternal psychiatric disorders on parenting ability, and those whose primary focus of investigation has been the sensitivities of infants to the emotional states of their primary caregivers. This has led to a better understanding of some of the mechanisms involved in the effects of maternal psychopathology on the developing infant and has important and hopeful implications — parenting attitudes and behaviours can sometimes be changed — but highlights the need for the development and evaluation of strategies for early intervention for families at risk.

A review of the current literature on maternal psychiatric illness and child adjustment and development is complicated by the diversity of questions asked and methods used. The merits and drawbacks of a variety of procedures to assess mother–infant interaction were discussed by Melhuish *et al.* (1988), who concluded that an integration of methods is essential for future research and clinical practice. Ideally, highly detailed observations of short duration that describe the interactive roles and behaviours of mother and infant should be combined with longer observations in naturalistic settings that provide a more typical, although global, account. Such systematic assessments in the early postpartum months may then be placed in the context of long-term longitudinal investigations of developmental outcome for the child and its network of relationships.

Another major problem with almost all studies to date concerns the confounding of diagnosis with other predisposing factors, not only genetic, but also, for example, the downward social mobility that accompanies serious psychiatric illness (Yoshida *et al.* 1999) or pre-existing dysfunctional relationship patterns which can co-occur with, but independently of, diagnosis (De Mulder *et al.* 1995) or when the infant's and mother's temperaments have a poor fit, to name but a few. Then there is the possible impact of different management strategies, e.g. was the mother admitted to hospital, with her baby or not, or was she looked after at home? Not all children are affected by their mother having a puerperal psychiatric illness. When maternal postnatal depression has been found to have an impact on the infant it may be perhaps only when other factors are also present, e.g. when the mother's attachment to her infant is compromised (Kumar 1997) or the depression occurs in the context of pre-existing disturbed patterns of family relationships or when the baby is irritable. Relatively recently developed methods for the

design and analysis of longitudinal studies (Willet *et al.* 1998) allow for more sophisticated projects which would take into account not only factors such as those discussed above but also the changes over time that occur in individual behaviour. Multicentred studies to obtain adequate sample sizes together with the use of these newer methods of design and analyses would allow us to begin to disentangle effects and their mediators.

One of the most important clinical developments in the last decade or so has been the consequence of a shift in emphasis from parental rights to the rights of the child and parental responsibility in ensuring that these are adequately met. In the UK, the passing and implementation of the Children Act (1989) has resulted in important changes in practice. The key feature of this act is that the welfare of the child is paramount. This means that where there is conflict the child's needs take precedence over those of the parent.

The work of Bowlby and subsequent attachment theory research has had two consequences. On the one hand, it has highlighted the importance of the development of secure attachments to caregivers in infants for their later psychological development. On the other hand, in emphasizing the difficulties for the infant of separations from the mother, rather than the importance of the stability and quality of care, whoever the carer may be, mother and infant may have been kept together perhaps sometimes under inappropriate circumstances when the best outcome for the infant might have been separation as early as possible with view to placement in a permanent and stable situation.

There is always sympathy and concern for a woman who has a severe psychiatric disorder. Often she herself has been the victim of grossly inadequate parenting from which society failed to protect her. Under these circumstances the woman's carers may find it difficult to keep both mother and baby's sometimes conflicting needs in mind. A frequently expressed, and understandable, view is that all mothers need to be given a chance. A society that asserts and legislates for the primacy of the child's welfare ensures that it is the baby who is given a chance. This may be through therapeutic intervention aimed at helping a mother to better protect, care for and understand her child, or where necessary through separation and safe and secure placement. The improvement in, and systematization and testing of, methodology for assessing adequacy of parenting and risk to the infant, not only in the context of severe maternal mental illness but also in the community, will be an important next step.

Approaches to Treatment

Introduction

Identifying and treating children with psychiatric disorder on a one-to-one basis cannot be expected to produce a substantial reduction in the suffering from such disorders. There are several reasons. First, the number of children with clinically important psychiatric disorders far exceeds, sometimes by factors of 10–20, the ability of clinical services to assess and treat them (US Congress 1986; Boyle & Offord 1988). This is no doubt an overestimate because, even though community surveys indicate that the prevalence of one or more psychiatric disorders is about 20% (Costello 1989; Costello *et al.* 1996), many of these children would not necessarily require specialized mental health services. However, lowering the prevalence rate to include only those children with psychiatric disorders of sufficient severity and impairment to require clinical services (estimated at 10–12%) (Institute of Medicine 1994) would still produce numbers of children far exceeding clinical resources. Secondly, compliance is a troublesome issue. In families who begin treatment because their child has a mental disorder, 40–60% withdraw from treatment prematurely (Kazdin 1996). Further, many parents of children at high-risk for emotional or behavioural problems do not enroll in parent training programmes even when they are widely available (Cunningham *et al.* 1995, 2000; O'Donnell *et al.* 1995). Thirdly, the time interval, between parents seeking help and actually receiving treatment, may be considerable. The child, and his or her family, can be expected to suffer during this period, and the disorder and associated impairment may worsen and become more entrenched. Fourthly, although considerable progress is being made in discovering effective treatments for child psychiatric disorders (Kazdin & Weisz 1998), for many disorders, e.g. early onset conduct disorders, little evidence of effective treatments is available (Offord & Bennett 1994; Kazdin 1997).

The marked limitations of clinical work alone in alleviating the suffering from child psychopathology has motivated researchers, policy makers and even clinicians to examine carefully the possibilities of developing and evaluating prevention efforts (Institute of Medicine 1994; Durlak & Wells 1997). The finding that, for some disorders (e.g. marked antisocial behaviour in adulthood), there are recognizable childhood antecedents before the onset of adult disorder suggest that high-risk groups can be identified for prevention, so that risk modifications can be carried out (Loeber & Farrington 1997).

Definitions

Historically, prevention initiatives were classified as *primary*, *secondary* or *tertiary* (Caplan 1964; Cowen 1983). *Primary prevention* programmes aim at reducing the incidence or number of new cases of a disorder. The goal of *secondary prevention* is to lower the prevalence of disorder by early identification and effective treatment, while *tertiary prevention* centres on rehabilitation aimed at reducing the severity of the impairment associated with an established disorder. A major problem with this classification is that the distinction between the presence or absence of disorder (and thus between primary and secondary prevention) is blurred because determining the threshold for disorder is difficult and arbitrary when the frequency and severity of symptoms occur on a continuum (Offord 1987).

More recent conceptualizations have moved away from the determination of whether the prevention is primary, secondary or tertiary towards a classification system centring on who is offered the intervention (Institute of Medicine 1994; Offord *et al.* 1998). In a *universal* programme, all residents in a geographical area as large as an entire country, or a smaller setting (e.g. community or school) are offered the intervention. The individuals do not actively seek help, and no one, within the population, is singled out for the intervention. The setting itself may be a psychopathological high-risk one but, if the intervention is not targeted at specific children and youth, then the intervention is classified as universal. In a *targeted* programme, again potential recipients do not seek help, but rather individuals within the population are singled out for the intervention. Targeted interventions can be divided into two subtypes: *selective preventive* and *indicated preventive* (Institute of Medicine 1994). In *selective preventive* interventions, the target group is individuals or a population subgroup where there is an increased risk for developing a psychiatric disorder. An example would be the offspring of parents who are on social assistance (Offord *et al.* 1987a). In *indicated preventive* interventions, the high-risk group is identified on the basis of having mild symptoms or even a biological marker of an established disorder. An example of such a high-risk group would be children who have mild antisocial symptoms and, although they do not qualify for conduct disorder, are at increased risk for it (Lipman *et al.* 1998).

The trade-offs between universal and targeted programmes have been described in detail elsewhere (Offord *et al.* 1998). The advantages of universal programmes include the absence of

labelling or stigmatization, the inclusion of the middle class who demand that the programme be well run, and the sensitizing of the setting or ‘tilling the soil’ for targeted interventions. Some of the disadvantages of universal programmes are that they will have a small benefit to the individual, will be seen as being unnecessarily expensive, and may have their greatest effect on those at lowest risk, thus increasing inequality between the high- and low-risk subgroups within the population.

The targeted approach can address problems early on and is potentially efficient if the targeting can be done accurately. The disadvantages are several and include the possibility of labelling and stigmatization; the difficulties with ongoing screening including the cost and commitment; the challenge that the compliance with the screening manoeuvre will be least amongst those at highest risk; and the difficulty of targeting accurately. It is a formidable task to identify accurately individuals for targeted interventions (Bennett *et al.* 1998, 1999; Bennett 2000). Whereas clinicians are primarily interested in the positive predictive value of an early identification instrument (e.g. what proportion of children have a clinical disorder at follow-up), the policymaker is concerned not just with the positive predictive value but also with the sensitivity (e.g. what proportion of children who have the disorder at follow-up were identified by the screen earlier on) (Bennett *et al.* 1998; Lipman *et al.* 1998). There is always a trade-off between positive predictive value and sensitivity. An additional limitation of the targeted approach is that more cases of disorder will be attributable to the large number of persons at low risk, not the relatively small number at high risk. Data from the Ontario Child Health Study, a large community study of the prevalence and distribution of selected psychiatric disorders in children of 4–16 years of age (Boyle *et al.* 1987; Offord *et al.* 1987b), revealed that children living in families with an annual income under \$Can10 000 were at high risk for developing psychiatric disorders, the prevalence rate being 36.3%. However, only 7.3% of children in Ontario lived in families in this income category. Thus, economically disadvantaged children account for only 14.5% of those with psychiatric disorder. By contrast, children who lived in families with a higher annual income (\$Can25 000 or more) accounted for more than one-half (59%) of children with psychiatric disorder. The risk of psychiatric disorder was much lower in this relatively well-off population than in the poorest population, but the large number of children in the non-poor group means that their contribution to the population of children with disorder was far greater than that of the economically disadvantaged children. An implication of this finding is that one targeted programme, even if effective, cannot be expected to have marked beneficial effects at the population level.

Approaches

There are two quite different approaches to developing and evaluating preventive programmes. The first can be termed Preventive Science (PS) and this perspective was favoured in the In-

stitute of Medicine (IOM) report (Institute of Medicine 1994). A series of five steps were outlined in setting up a prevention programme:

- 1 identification of a problem or disorder;
- 2 the identification of risk and protective factors;
- 3 carrying out pilot efficacy studies;
- 4 launching and evaluating large-scale effectiveness trials; and
- 5 dissemination of the programme in a variety of community settings.

Usually, expert personnel from academic settings are in charge of such programmes, and participation by community members in planning and carrying out the studies is not emphasized.

The second contrasting model is termed the Collaborative Community Action Research (CCAR) model where community members are participants throughout the whole prevention initiative (Kelly 1988; Tolan *et al.* 1990). The resulting prevention programme will be community-specific, if not in terms of causes, almost certainly in terms of solutions, and the programme will not necessarily be suitable for dissemination to other communities. Because of the limitations of the design, the strength of the scientific evidence supporting the effectiveness of these programmes cannot be strong (Canadian Task Force on the Periodic Health Examination 1979). The advantages and disadvantages of these two approaches were reviewed recently (Weissberg & Greenberg 1998), with suggestions for melding the two approaches.

There are two somewhat different but overlapping groups of initiatives in the field of the prevention of child and adolescent psychiatric disorders (Institute of Medicine 1994). The first focuses on preventing specific psychiatric disorders, such as conduct disorder and depression. The second centres not so much on preventing illness but on promoting health, and enhancing competence across many domains including psychological, social, physical and spiritual.

This chapter first covers selected contributions of developmental psychopathology to prevention, and then moves on to review what is known about the prevention of three child and adolescent psychiatric disorders: conduct disorder, anxiety disorder and depressive disorder. Two risk situations (child abuse and children of divorce) are taken up next. Brief summaries are provided of prevention in low-income countries, the issue of environmental contaminants and barriers to prevention, and the chapter ends with concluding comments.

Selected contributions of developmental psychopathology to prevention

Developmental psychopathology, which emerged in the 1980s, is concerned with factors that influence the onset and course of emotional and behavioural disorders in children and adolescents (Stroufe & Rutter 1984). The hallmark of this field of inquiry is the integration of knowledge and research methodologies from several complementary disciplines, most notably developmental psychology, clinical psychology, psychi-

etry and epidemiology. Numerous significant contributions are now available that have important implications for prevention practice and research. In this section we summarize these contributions under four headings:

- 1 risk and protective factors;
- 2 multiplicity, specificity and timing;
- 3 theories of development and life-course studies; and
- 4 causal models.

Risk and protective factors

Developmental psychopathology has increased our understanding of the risk and protective factors associated with emotional and behavioural problems in children. A risk factor is a characteristic of the individual or his or her environment and must meet the following criteria:

- 1 the factor must be present prior to the onset of disorder; and
- 2 increase the likelihood of future disorder in individuals exposed to the factor, compared to those who are not.

A risk factor is considered causal when additional scientific criteria are satisfied. Ideally, evidence for causation is derived from experimental studies wherein exposure to the putative causal factor is determined in a bias-free manner using random assignment. However, when experimental evidence cannot be obtained for ethical reasons, or is not yet available, a ‘case for causation’ can be made using evidence of temporality; documentation of a risk increase when the putative causal factor is present; evidence of a dose–response relationship; specificity of cause and effect; consistency of findings between different studies conducted using different methods; and epidemiological and biological sense (Hill 1965; Kraemer *et al.* 1997).

Risk factors for psychiatric disorder can be either internal or external to the individual. A large number have been identified (Institute of Medicine 1994) and they can be grouped into five levels:

- 1 individual characteristics (e.g. gender, temperament);
- 2 parent and family factors (e.g. psychopathology, marital discord, socioeconomic status);
- 3 peer group characteristics (e.g. deviance);
- 4 school characteristics (e.g. leadership, academic); and
- 5 community or neighbourhood qualities (e.g. ‘poor’ neighbourhoods, social support).

It is essential to distinguish causal risk factors from correlates, markers and non-causal risk factors for disorder (Kraemer *et al.* 1997; Offord & Kraemer 2000). Prevention interventions that focus on causal risk factors will have a high likelihood of achieving their intended goal—a reduction in the incidence or severity of a future disorder. Interventions that focus on correlates, markers or non-causal risk factors have little or no impact on disorder. For example, correlates of disorder may be associated with disorder but may contribute little or nothing to its occurrence. In fact, the disorder may cause the correlate. Markers, which are fixed variables such as race or gender, are not modifiable and should not be the focus of intervention. Non-causal risk factors for disorder are modifiable variables that precede disorder

		Conduct disorder (CD)		
		Present	Absent	
Early aggressive symptoms	Present	4 (a)	7 (b)	
	Absent	6 (c)	83 (d)	
		10	90	100

$$\begin{aligned} \text{Odds ratio} &= (a)(d)/(c)(b) = (4)(83)/(6)(7) = 332/42 = 7.9 \\ \text{Population attributable risk} &= \frac{\text{Rate of CD in population} - \text{Rate of CD among those without symptoms}}{\text{Rate of CD in the population}} \\ &= \frac{10/100 - (6/89)}{10/100} \\ &= \frac{0.1 - 0.0674}{0.1} \\ &= 0.326 \text{ or } 33\% \end{aligned}$$

Fig. 52.1 Measures of risk (data hypothetical for illustrative purposes only).

der but, if they are not causally related to disorder, changing them will have no impact on outcomes.

Protective factors precede the occurrence of disorder and can reduce its likelihood in the presence of a risk factor or situation. Again, it is important to distinguish causal from non-causal protective factors. Characteristics of the individual, the nature of their relationships with others and environmental characteristics have been proposed as possible causal protective factors (Rutter 1985; Rae-Grant *et al.* 1989; Weissberg & Greenberg 1998). However, two problems continue to plague this area: the first concerns what distinguishes a risk factor from a protective factor; the second concerns their mechanism of action or how a causal protective factor reduces or ameliorates risk. Despite this lack of clarity, substantial evidence exists that only a proportion of children exposed to conditions of adversity develop psychiatric symptoms (Werner & Smith 1982; Rutter 1985). Further work is needed to understand the processes that lead to variation in outcome in this group of children.

The strength of the relationship between a risk factor and future psychiatric disorder can be expressed using measures such as the odds ratio and population attributable risk. Simply put, the odds ratio tells us the increase in risk associated with a particular factor. It is defined formally as the likelihood of the outcome in those exposed to a risk factor compared to those not exposed (Streiner & Norman 1996). In contrast, population attributable risk helps us understand the contribution of a specific risk factor to the occurrence of a specific disorder in the population. The formal definition is the percentage of all cases of disorder in a population that are attributable to a specific risk factor (Kelsey *et al.* 1996). The higher the percentage, the more important the risk factor, if it is indeed causal.

Figure 52.1 shows some hypothetical study results relating the presence of antisocial behaviour symptoms in childhood to conduct disorder in adolescence. The odds ratio for disorder in adolescence given the presence of early antisocial symptoms is 7.9, so children with early symptoms are almost eight times

Fig. 52.2 The prevention model.

more likely than children without to develop conduct disorder in adolescence. The population attributable risk for these data is 33%. This means that if we could eliminate early aggressive behaviour symptoms in this population, the proportion of children with conduct disorder in adolescence would be reduced by approximately one-third, if indeed early aggressive behaviour symptoms are a causal risk factor for conduct disorder.

Figure 52.2 provides a simple model that links risk and protective factors to the design of programmes to prevent psychiatric disorder in children and adolescents. Four components—a causal risk or protective factor, a prevention intervention, a proximal outcome and a distal outcome—make up the model and are explained in the following. Under ideal circumstances, the prevention intervention consists of a set of actions that decrease the effects of a causal risk factor or increase the effects of a causal protective factor and, consequently, causes the proximal outcome to occur. The proximal outcome is a causal risk or protective factor that is known, or assumed, to cause the distal outcome to occur. The distal outcome might be the incidence of one or more psychiatric disorders. For example, social skills training is a competence-enhancing prevention intervention that is offered to young children to prevent conduct disorder. Figure 52.2 can be used to illustrate the theory behind this prevention strategy—how it is thought to exert its effect. The risk factor being addressed is poor social skills, the proximal outcome targeted by social skills training is an increase in prosocial skills, e.g. sharing and taking turns. The underlying logic is that by teaching children prosocial behaviours, and how to apply them in particular social situations, responses characterized by externalizing behaviour symptoms (a risk factor for conduct disorder, the distal outcome) will be minimized or eliminated.

Another example of a prevention intervention strategy is parent management training for parents with poor parenting skills (Webster-Stratton 1991). The objective is to reduce or eliminate this causal risk factor for conduct disorder in a group of parents who have it. The intervention teaches parents ways to improve how they monitor their children's behaviour and respond to aggression and non-compliance. Improved parenting skills are the proximal outcome, which in turn are thought to decrease the risk for conduct disorder.

Multiplicity, specificity and timing

Developmental psychopathology has increased our awareness of three important aetiological principles: multiplicity, specificity and timing. First, the onset of psychiatric disorder in children and adolescents is multifactorial in nature (Institute of Medicine 1994). The risk of disorder is thought to depend on the number

of causal risk factors present and to accumulate over time (Yoshikawa 1994). Very little risk increase is evident when only one or two factors are operating. However, when three or more factors are present the risk of disorder is increased significantly. Secondly, there has been very little progress in demonstrating the specificity of causal risk factors—that certain risk factors are associated with one disorder and not another. In contrast, most of the evidence suggests the existence of common causal risk factors for multiple outcomes—a lack of specificity. For example, parental psychopathology has been shown to be a causal risk factor for conduct disorder, depression and anxiety disorders (Institute of Medicine 1994). Thirdly, the influence of a particular causal risk or protective factor depends upon timing or the developmental stage of the individual. For example, poor parenting is thought to exert much more of an influence in younger than in older children (Reid & Eddy 1997).

Theories of development and life-course studies

Theories of child development aim to explain how cognitive, emotional and behavioural characteristics emerge and evolve over time. Developmental psychology has focused primarily on understanding the processes of normal development, whereas clinical psychology, psychiatry and epidemiology have been concerned with the onset and clinical course of emotional and behavioural disorders. Developmental psychopathology has shown that longitudinal studies of representative populations, which identify individuals early in life and follow them up into adulthood, are needed to understand the aetiology and outcome of child and adolescent psychopathology. Several excellent reviews of the major longitudinal studies are available elsewhere (Institute of Medicine 1994; Loeber & Farrington 1997). Collectively, these studies have produced a number of findings that have had a major influence on the field.

Longitudinal studies have shown that there are both continuities and discontinuities in the onset and persistence of psychiatric symptoms and disorder (Rutter 1995). For example, for some individuals there is a high level of stability in clinically important antisocial behaviour symptoms across the life-course (Moffitt 1993; Loeber & Farrington 1997). However, it is also evident that children with high levels of symptoms early in life may not possess them in adolescence and/or adulthood (Nagin & Tremblay 1999).

Longitudinal studies have also introduced the concept of developmental trajectory and helped us to understand its relationship to possible causal risk and protective factors (Kellam & VanHorn 1997). The result has been a shift away from research models that focus on identifying increases in the rate of future discrete events to new approaches that describe and explain differences in the rate of growth of a particular emotional or behavioural trait over time. Figure 52.3 illustrates this concept using hypothetical data. The rate of decline of externalizing symptoms following entry to elementary school is compared between groups of children who have been classified according to their parents' level of parenting skills. As can be seen, the down-

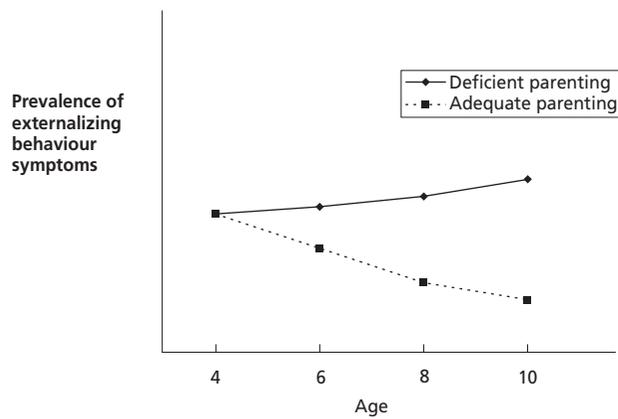

Fig. 52.3 Developmental trajectories (data hypothetical for illustrative purposes only).

ward slope is greater for children whose parents have adequate parenting skills; very little change is evident for children whose parents are deficient. This difference in the rate of change reflects the different developmental trajectories of the two groups of children.

Longitudinal studies have helped us understand that the links between an early risk factor and future psychiatric disorder may be indirect and depend upon other mediating variables. A recent study (Fergusson & Horwood 1998) showed that the link observed between early conduct disorder symptoms and two important adolescent psychosocial outcomes (educational attainment and unemployment) may be mediated by certain behaviours in adolescence (peer affiliations, substance use, truancy and problems with school authority).

Causal models

A major challenge facing child mental health researchers concerns how causal risk and protective factors work to exert their influence on child psychiatric disorders. Causal chains or pathways have been used as a simple way to explain the sequence of events associated with the onset and persistence of disorder. For example, one causal pathway into conduct disorder proposes that early learning problems lead to disruptive behaviour symptoms which result in problems in school, association with a deviant peer group, school failure and antisocial behaviour (Oford & Fleming 1996). However, several authors have called for a deeper analysis of the role that specific risk factors have in producing disorder (Baron & Kenny 1986; Baronowski *et al.* 1997; Holmbeck 1997). They have distinguished mediating factors from moderating factors and provided useful examples to illustrate why we need to increase the clarity and consistency with which these concepts are operationalized in the design and analysis phase of studies. A mediating factor is a variable that links an independent variable to an outcome: the independent variable causes the mediator, which then causes the outcome

(Shadish & Sweeny 1991). For example, marital conflict may exert its effect on psychiatric symptoms through an effect on the quality of parenting. Moderating factors, on the other hand, interact with or moderate the influence of an independent variable on outcome so the effect of the independent variable on the outcome depends upon the level of the moderating factor present. Family structure (e.g. intact vs. divorced) might moderate the relationship between marital conflict and psychiatric symptoms, with the relationship being present for divorced families but not for intact families.

Two final points concern the dynamic nature of variables with respect to their role as a mediator or moderator; and the limits to intervention impact that are imposed by mediating variables. The evidence suggests that a specific variable may act as a mediator in one instance and a moderator in another. For example, in one context poor parenting skills may mediate the relationship between an independent variable and the occurrence of psychiatric symptoms. However, in another context, poor parenting skills may interact with the independent variable. In this instance, the influence of the independent variable depends upon the level of parenting skills present.

The strength of the association between a mediating variable and an outcome will limit the impact of an intervention. This is because most interventions exert their influence through a mediating variable (Baronowski *et al.* 1997). Social skills and parent management training programmes exert their influence on conduct disorder by modifying proximal risk factors that are thought to be causal (poor social skills or poor parenting skills). However, although these risk factors are correlated with future conduct disorder, the relationship is not one-to-one. Consequently, the magnitude of the link between each one and future conduct disorder places an upper limit on the impact of intervention on conduct disorder.

Prevention of psychiatric disorders

In this section, a selective summary is presented of what is known about effective strategies to prevent conduct disorder, anxiety disorder and depressive disorder. Most of what is known concerns conduct disorder and antisocial behaviour and has been derived from studies of programmes designed to measure the competence of the child, the parent, or both. Relatively few programmes that target the prevention of specific psychiatric disorders have been tested to date. For each programme reviewed the following issues are discussed: the target population; whether the programme was universal or targeted; whether the intervention was designed to prevent a specific psychiatric disorder or to exert a more generalized competence-enhancing effect (cognitive, emotional and/or behavioural-social); the domains addressed; the findings to date, including the strength of the research design. Almost all of the prevention strategies reviewed here have been evaluated in randomized controlled trials. This design, when executed rigorously, provides the greatest number of safeguards against biased estimates of programme effective-

ness (Jadad 1998). For simplicity, for conduct disorder, age is used to organize the programmes into three groups (the under 5s; ages 5–11; and older than age 11).

Conduct disorder

Programmes for children under 5

Nurse home visitation has been shown to prevent antisocial behaviour in a programme designed for poor unmarried pregnant women. Olds *et al.* (1998a,b) followed up children at age 15 whose mothers received home visits by a nurse (during pregnancy and up to the age of 2), as part of the Elmira randomized trial of nurse home visitation. When these adolescents were compared to children who had not received the full programme of home visitation, the authors found (based on youth self-report) lower rates of arrests (56% reduction), convictions and violations of probation (81% reduction), running away (60% reduction), lifetime sexual partners (63% reduction) and alcohol consumption (56% reduction). Parents also reported lower rates of behaviour problems associated with alcohol and other drugs (56% reduction) for these adolescents. This same preventive intervention initiative is reviewed in more detail in the section on child abuse.

Findings from the Perry Preschool Project show that compensatory preschool education exerted an effect on the incidence of antisocial behaviour (Schweinhart & Weikert 1988, 1989). The programme was designed in the 1960s for poor black 3- and 4-year-old children and aimed to improve academic and social outcomes. The intervention was 2 years in duration and included a daily preschool programme (90-min classes, 5 days per week) and a weekly home visit provided by highly trained teachers. The preschool component was designed to promote academic, social and physical development. The home visits were designed to help parents reinforce the preschool curriculum. Programme effectiveness was evaluated in a randomized controlled trial and the children were followed up into adulthood; 58 children were assigned to the experimental group and 65 to the control group. Early results showed that initial IQ gains in the experimental group were lost. However, long-term follow-up at ages 19 and 27 showed important differences on measures of antisocial behaviour including fewer lifetime arrests (31% in the experimental group vs. 51% in the control group) and a substantially reduced rate of being arrested five or more times (5% in the experimental group vs. 35% in the control group). Cost-benefit analyses have demonstrated that the benefits of the programme exceed the costs (Barnett 1998).

The Carolina Abecedarian Project also evaluated the effects of compensatory preschool education in an extremely high-risk group of children born to poor African-American mothers (Campbell & Ramey 1994). The intervention began in the first year of life and was very intensive. The birth-to-age-5 programme included a range of services offered through a daycare centre: daycare curriculum to enhance cognitive, language, perceptuomotor and social development; medical care; social

services; some home visits; parent groups and toy lending. Once the child entered primary school, the intervention consisted of a home-school resource teacher who assisted parents with supplementary individualized educational activities for the child to do at home. This was delivered through 15 home visits per year, beginning in kindergarten and ending in grade 2.

The Abecedarian approach was evaluated in a randomized trial, in which the outcomes of four groups of children were compared:

Group 1: birth to age 5 programme plus kindergarten to grade 2 programme ($n=25$);

Group 2: birth to age 5 programme only ($n=22$);

Group 3: kindergarten to grade 2 programme only ($n=21$);

Group 4: no programme ($n=22$).

The results showed that children who received the full programme did better than children in the other three groups on measures of IQ and school achievement. The results also showed that intervention before age 5 in this high-risk group was more effective than intervention in the early school years. IQ and school achievement in children who received the birth-to-age-5 programme only were superior to those of children who received the kindergarten to grade 2 programme only, when they were followed up at age 8 (conclusion of the programme) and age 12. Unfortunately, antisocial outcomes were not assessed. However, given the nature of the intervention and the positive effects found on academic outcomes, this intervention would appear to hold promise as a prevention strategy for antisocial behaviour.

In summary, there is evidence that prevention strategies offered before age 5 to extremely high-risk groups of poor predominantly black children are effective in preventing antisocial behaviour. The focus of these programmes is on risk and protective factors related to early family supports, parental caregiving skills and child cognitive outcomes. At present, the mechanisms by which these programmes exert their effects are not entirely clear and there is a need for a more coherent conceptual and theoretical basis for these types of programmes (Yoshikawa 1994; Ramey & Ramey 1998). In general, it is thought that early intervention increases school readiness through a set of developmental priming mechanisms (Ramey & Ramey 1998). The effect is to increase the ability of the child to meet academic expectations and to adapt behaviourally to the school setting. This in turn sets in motion a series of mediating mechanisms that protect against a wide range of negative health and social outcomes.

Finally, there is a need to evaluate these approaches in other populations of children. The results to date have been collected on small samples of extremely deprived African-American children, particularly in the case of compensatory education strategies. Consequently, the magnitude of benefit that can be expected in populations at less extreme levels of risk and material deprivation is not known. It seems likely that the benefit will be less than that observed to date. Further evidence of costs and effects is therefore needed to guide policy decisions about the provision of these types of programmes to other groups of children.

Programmes for children aged 5–11

Most of the programmes evaluated for children in this age group have been offered through schools to groups of children at elevated risk for conduct disorder and antisocial behaviour. Four types of strategies are reviewed in this section:

- 1 single-factor approaches;
- 2 multicomponent approaches;
- 3 competence-enhancement approaches; and
- 4 school development approaches.

Prevention strategies that focus on a single risk or protective factor in a single context have been evaluated in randomized trials and shown to have small to moderate effects on antisocial symptoms. An evaluation was carried out of a violence prevention programme for elementary school children in a randomized trial involving 7 and 8-year-old students in 12 elementary schools (Grossman *et al.* 1997). The intervention, called Second Step, consists of 30 social skills lessons that address anger management, impulse control and empathy and are provided in the classroom by the teacher. Observational measures showed a moderate reduction in aggressive behaviour and an increase in prosocial behaviour 2 weeks after the conclusion of the intervention; some effects persisted 6 months later. No effects were found on teacher and parent reports of behaviour.

The Good Behaviour Game (GBG) is another single-component strategy and consists of a classroom management strategy (Kellam *et al.* 1994) wherein the teacher divides the classroom into teams, and monitors the rate of disruptive events (physical disruption, verbal disruption, out-of-seat without permission, non-compliance). Any team whose number of disruptive events does not exceed four during the game period wins a reward. Over time, the frequency and duration of the game period is increased; at the same time, the teacher begins to initiate the game without announcements and delays the provision of rewards to winners. The GBG approach has been evaluated in a randomized trial. Schools were randomized to provide the GBG or not for 6 and 7-year-old students. Results at the end of the school year for 6 and 11-year-old students suggest that children from classrooms who received the GBG had lower levels of aggressive behaviour and that the effect is more pronounced for males with high levels of aggressive behaviour at the outset.

Peer mediation is another single-component strategy. In this approach students are trained in conflict mediation skills and then assigned to act as peer-mediators on the school playground. Their job is to identify conflict in the early stages, to intervene within 10s and to carry out mediation according to a standard protocol. This approach has been shown to be effective in resolving playground conflicts; physically aggressive playground behaviour was reduced by 51–65% and the effects were maintained at a 1-year follow-up (Cunningham *et al.* 1998).

Multicomponent strategies that address multiple risk and protective factors operating at several levels have also been designed and evaluated to determine their impact on behavioural maladjustment and antisocial behaviour. The Montreal Longitudinal Experimental Study evaluated a targeted intervention

for high-risk kindergarten males (Tremblay *et al.* 1995). The intervention was designed to address two risk factors for conduct disorder: one at the child level (social skills training) and one at the family level (parenting skills). All boys in 53 Montreal schools who scored above the 70th percentile on the Social Behaviour Questionnaire and whose parents were French-speaking and had less than 14 years of formal education were randomized to one of three treatment groups.

1 A 2-year intervention programme consisting of school-based social skills training and home-based parent training sessions. In the parent training component, parents were taught how to monitor their child's behaviour, give positive reinforcement, to discipline effectively without using harsh or punitive strategies and to manage family crises. The maximum number of sessions was 46 over the 2-year period; the mean number attended was 17.4. Social skills training was taught in a lunchtime session at the boy's school by members of the study professional team. Small groups included two study boys and six prosocial peers; 9 sessions were held in year 1 and 10 sessions in year 2.

2 An attention-control group.

3 A control group.

Overall, the intervention seems to have had little or no lasting effect beyond the elementary school period. Initial results in elementary school showed that intervention boys did better on measures of school adjustment. However, by age 15, 6 years after the conclusion of the programme, intervention group members were not different from that of the control group. Gains, measured in terms of whether the boy was in an age-appropriate regular class, disappeared after age 13. Teacher-rated disruptive behaviour did not differ between the two groups over the follow-up period to age 15. The intervention group reported statistically significantly fewer delinquent acts, but there was no difference between intervention and control boys when juvenile court records were compared over the follow-up period from age 10 to 15.

The Tri-Ministry Helping Children Adjust Project was designed as a universal programme to address three risk factors for emotional-behavioural maladjustment in childhood: poor reading skills, poor social skills and poor parenting skills (Boyle *et al.* 1999). The initial intervention plan called for a reading partners programme, a social skills programme and a parent management programme, alone or in combination, to be provided to children at entry to primary school. However, consistent with other investigators, the uptake of the parent management programme was very poor and this programme element had to be dropped after the first year of the evaluation. Consequently, three programme groups were compared in a randomized trial: reading partners alone, social skills training alone and a combination of both reading partners and social skills training. Sixty schools were selected from 11 school boards in a defined geographical area and were randomly allocated to receive one of the three programmes or the control condition. Programme duration was a minimum of two school terms. The results, after 1.5–3.5 years of follow-up, showed that the effects of the intervention were modest at best. Playground

observations revealed statistically significant increases in prosocial behaviour and there was some evidence that externalizing symptoms were reduced (Hundert *et al.* 1999).

Fast Track is another multicomponent approach. It was designed specifically to address risk and protective factors for antisocial conduct problems (Conduct Problems Prevention Research Group 1999a,b). The intervention model focuses on multiple levels (child, family, school, peer group, community) and factors (academic skills, social skills, parenting skills, family support) and includes a universal and targeted component. The programme begins in grade 1 and is planned to continue through middle school. The universal programme is offered at the classroom level to all children in the school and consists of the Promoting Alternative Thinking Strategies (PATH) curriculum that teaches skills in self-control, emotional awareness and social problem-solving. The targeted component consists of the following.

- 1** A weekly 2-hour enrichment session for high-risk children (selected on the basis on high levels of externalizing behaviour symptoms) and their families. The sessions include parent groups, child social skills training and academic tutoring and are held on Saturdays or in the evening.
- 2** Home visits held approximately every other week in grade 1. The purpose is to provide individualized help and to support generalization of the skills learned in the enrichment session.

Fast Track is currently being evaluated in a large randomized trial involving 54 schools in four geographically distinct sites in the USA. The unit of allocation is the school. Results based on outcomes at the end of grade 1 showed the following.

- 1** In the high-risk sample, positive effects were found on children's social, emotional and academic skills, peer interactions, social status, conduct problems and special education use. Parents also reported positive effects on parenting outcomes (less physical discipline needed; greater parenting satisfaction; more appropriate and consistent parenting; more warmth/positive involvement and more involvement with the school).
- 2** In the full sample, the universal social skills programme combined with the targeted intervention for the high-risk children resulted in statistically significant effects on peer ratings of aggression, hyperactive-disruptive behaviour and observer ratings of classroom atmosphere.

It is too early to tell whether the Fast Track approach will translate into clinically and policy significant reductions in conduct problem rates as the children move into adolescence and adulthood. Moreover, the approach is extremely intensive and cost-effectiveness analyses are needed to determine whether the cost is justified in relation to the benefits achieved. Finally, it is possible that the apparent early benefits will be lost when adolescent outcomes become available, as was the case in the Montreal Longitudinal Experimental Study. As already noted above, the results of the Montreal study showed little or no lasting effect beyond the elementary school period as, at age 15, no between-group differences were found on measures of teacher-reported disruptive behaviour and court reports of delinquent behaviour.

Competence-enhancing intervention strategies have also shown effects on antisocial behaviour. The rationale is to promote social competence rather than reduce psychopathology. The Seattle Social Development Project consists of three components that aim to improve child bonding to their family and school and, consequently, social competence:

- 1** teacher training in classroom instruction and management;
- 2** child social skills development in grade 1 and drug resistance skill development in grade 6; and
- 3** parent training.

The programme is offered from grades 1–6. The results of a non-randomized controlled trial showed that, at age 18, adolescents who had participated in the programme self-reported fewer delinquent acts (19% reduction), less heavy drinking (40% reduction), fewer sex partners (19% reduction) and pregnancies (35% reduction) compared to control students (Hawkins *et al.* 1999).

The Social Competence Promotion Program for Young Adolescents is another approach to competence enhancement (Weissberg & Greenberg 1998). The programme consists of 45 classroom sessions designed to promote a set of social competencies: self-control; stress-management; responsible decision-making; social problem-solving; and communication skills. Self-reported antisocial and delinquent behaviour was shown to be reduced among middle school students who received this programme for 2 years, compared to others who received no training or less than 1 year of training. Both of these strategies would benefit from further evaluation in a randomized trial design to minimize the influence of bias on estimates of effect size, in particular overestimates of intervention effectiveness (Jadad 1998).

Finally, school development strategies have been applied in elementary schools and may have a role to play in reducing the rate of antisocial behaviours. The School Development Program developed by Comer *et al.* is made up of three components.

- 1** A school planning and management team composed of school administrators, teachers, support staff and parents who identify school problems and develop and implement appropriate solutions.
- 2** A mental health team responsible for prevention initiatives and addressing the needs of individual teachers and students.
- 3** A parent programme that involves parents in all aspects of school life, including problem identification and the design and implementation of solutions.

This approach differs from the other methods already described in that it consists of a mechanism (or process) to support change. The specific content of the programme is not defined, but left up to the school management and mental health teams. The overall goal is to modify and enhance school policies and programmes so that school climate is improved, positive behaviours are promoted and negative health and social outcomes are prevented or minimized. The Comer approach has been evaluated in a non-randomized controlled study. Children who attended schools using the approach had superior educational outcomes to children attending non-programme schools

(Comer 1985). Again, further evaluation in a randomized design is needed.

In summary, over the past decade a number of promising conduct disorder prevention approaches have been developed and applied in the elementary school setting. Clearly, this is an important venue for prevention programmes. Schools have a central role in behavioural and social development and it is well recognized that they function *de facto* as the primary mental health care service for children and adolescents (Mortimore *et al.* 1988; Sylva 1994; Hoagwood & Erwin 1997).

The single-component approaches have the advantage of being simple and rather straightforward to implement. However, when evaluated against our understanding of the aetiology of conduct disorder this model is clearly weak and unlikely to have a major impact on the incidence and severity of disorder. Multicomponent approaches, which address multiple risk and protective factors at the level of the child, family, peer group, school and community, are consistent with current causal models. However, this programme approach is complex and expensive, and the magnitude of benefit in relation to cost is uncertain at this time (Hundert *et al.* 1999).

Competence-enhancement approaches have the advantage of targeting multiple risk and protective factors. However, the impact of this approach depends upon the strength of the link between the mediating factors targeted (social skills, self-control, coping and stress management) and the occurrence of disorder. School development approaches make theoretical sense because they address the environmental supports needed to support and sustain adaptive behaviours (Bronfenbrenner & Morris 1998). However, this is a relatively new area with respect to rigorous evaluation of promising strategies.

Programmes for children over 11

Prevention programmes in older children are less prominent for conduct disorder because the emphasis is primarily on treatment in this age group. Two programmes are summarized here, one that shows promise and one that has been shown to be ineffective.

The PATHE programme (Positive Action Through Holistic Education) is a school development model that has been applied in this age group and shown to influence antisocial outcomes. The programme consists of organizational change strategies and the provision of services to high-risk students as follows.

- 1 A school team responsible for reviewing and revising school policies and for supporting shared decision-making between school and community agencies and parents.
- 2 Development of school and classroom goals (academic and behaviour) followed by staff training in how to implement them through classroom management strategies and student participation.
- 3 School-wide academic innovations.
- 4 School-wide climate innovations.
- 5 Mental health and academic services for high-risk students.

This approach has been evaluated in a non-equivalent comparison group design. Student reports suggested that the programme results in fewer delinquent acts, lower rates of drug use and school suspensions (Gottfredson 1986). Further work on this promising school reform strategy is warranted.

Finally, the Cambridge Somerville Study deserves comment. In this programme, which was initiated in the 1930s, boys around the age of 11 were randomized to be assigned or not to a social worker (McCord 1992). The role of the social worker was to build a close personal relationship with the boy and to provide assistance to both the boy and his family. Follow-up in adulthood (when participants were 40–50 years of age) showed that the treatment group boys had worse outcomes (convicted of a crime; death before age 35; received a diagnosis of alcoholic, schizophrenic or manic-depressive) than the controls, and that the treatment had in fact been harmful. The reasons why the programme failed are not entirely clear.

Anxiety disorders

The literature on the prevention of anxiety disorders is sparse (Spence 1994). Although there has been a discussion of various universal interventions that could be used in the prevention of childhood fears (e.g. classroom-based intervention for prevention of fears of the dark) (Robinson *et al.* 1991), no well-controlled experiments have been conducted. There is literature on the prevention of fears in specific situations, such as attending the dentist and subsequent avoidance of dental treatment (Melamed *et al.* 1975a,b; Milgrom *et al.* 1992); preventing fear and anxiety relating to medical procedures (Jay *et al.* 1987); test anxiety (Tryon 1980; Van der Ploeg-Stapert & Van der Ploeg 1986); and facilitating the transition to a new school (Felner & Adan 1988).

A programme addressing this latter issue, entitled the School Transition Environment Project (STEP; Felner & Adan 1988), focused on children making the transition from elementary to high school, and included three components: organizing the physical plan of the school into units with homerooms, the availability of a 'homeroom' staff member who can provide counselling for academic and behavioural problems, and the provision of a co-ordinated liaison between teaching and school counselling staff. The overall aims of the programme were to increase meaningful relationships between pupils and staff, and to create smaller environments within the overall larger school environment. Evaluations of the STEP programme, using a randomized controlled design, showed that programme participants compared to control children had greater improvements in academic performance and self-esteem, better school attendance and lower drop-out rates. A particular strength of the programme is that its positive effects have been replicated in various school settings with children from different backgrounds. Although this intervention is not designed specifically to prevent fears or anxiety disorders in the students, it illustrates an approach aimed at reducing the severity of a stressor experi-

ence in order to prevent the development of emotional and behavioural difficulties.

A randomized controlled trial aimed at preventing the onset and development of anxiety problems in children, the Queensland Early Intervention and Prevention of Anxiety Project (Dadds & Spence 1997), screened 1786 children representing all children between 7 and 14 years of age in grades 3–7 in eight preselected primary schools in the metropolitan area of Brisbane, Australia. These children participated in a complicated and extensive four-stage screening procedure using both teacher nominations and children's self-report. Children who met criteria for DSM-IV anxiety disorder, but were not rated as the most severe in terms of impairment, were included in the study as were those who did not meet criteria but had features of anxiety disorder, or were particularly shy and sensitive based on parent reports. Children exhibiting primarily externalizing problems were excluded. Of the 1786 children screened, 121 (6.8%) entered the trial. Children selected were allocated to the intervention and control groups on the basis of school. Schools matched on size, sociodemographics and socioeconomics were randomly assigned to the intervention or control groups.

The intervention was based on *The Coping Koala: Prevention Manual* (unpublished data) and consisted of 1–2-h sessions with the children over 10 weeks with group sizes ranging from 5 to 12 children. Children were taught strategies for coping with anxiety using a cognitive-behavioural approach. In addition, parent sessions were conducted at weeks 3, 6, 7 and 9 and focused on child management skills, and how to employ these skills to manage their child's anxiety. Attendance at the intervention sessions for the children themselves was approximately 80%, while parents attended approximately 58% of the sessions. By the 6-month follow-up, only five children had withdrawn from the trial: two from the intervention group and three from the control group. At that follow-up, children in the intervention group had lower rates of anxiety disorder than those in the initial group and, of those who had features but not full disorder, at pretreatment ($n=33$) 56% progressed to a diagnosable disorder in the control group at the 6-month follow-up compared with 16% in the intervention group. The authors concluded that the intervention was successful both in reducing rates of disorder in children with mild to moderate anxiety disorders, and preventing the onset of anxiety disorders in children with early features of the disorders. A 2-year follow-up (Dadds *et al.* 1999) revealed that at 1 year the rates of anxiety disorder were similar in the intervention group (37%) and the control group (42%), but at 2 years the rates had diverged, as they did at the 2-month follow-up, with rates of anxiety disorders in the experimental and control groups of 24 and 37%, respectively. Severity of pretreatment diagnoses, female gender and parental anxiety predicted poor initial response to intervention, but pretreatment severity was the only predictor of chronicity at 2 years. This preventive intervention is promising in that it showed that a school-based targeted intervention for children can produce sustained reductions in anxiety problems. How-

ever, the labour-intensive four-stage screen is a barrier to wide adoption of the programme.

Depressive disorder

There are no examples of universal programmes that have been shown to be effective in preventing the onset of depressive symptoms or depressive disorders (Harrington 1997). Suggestions of which risk factors could be addressed in universal programmes include the provision of good-quality parenting, prevention of bullying, and increasing social competence and positive attitudes. There are several targeted programmes, both of the indicated and selective types, that have focused on depressive disorder aimed at preventing future depressive symptoms.

In one indicated targeted intervention (Jaycox *et al.* 1994), school-aged children, 10–13 years of age, were identified on the basis of self-reports of both elevated levels of depressive symptomatology and parental conflict. The 143 children were assigned to one of three 12-week treatment conditions (cognitive treatment only, social problem-solving skills only, or both) or to one of two control groups (waiting list and no participation). The cognitive component emphasized challenging negative beliefs about the self, present circumstances and the future, and the social problem-solving skills component taught children goal-setting, perspective-taking, information-gathering, developing action alternatives, decision-making and self-instruction. Because at post-test no important differences were observed between the three treatment conditions, they were collapsed into one group, as were the two control groups. The results revealed statistically and clinically important differences in the reduction and prevention of depressive symptoms in the treatment compared to the control groups, both at the end of treatment and at the 6-month and 2-year follow-ups (Gillham *et al.* 1995). Because the differences between the treatment and control groups widened over time, it suggests that the intervention may have immunized children against future depressive episodes. Weaknesses of the study include the very poor response rate in both the intervention and control schools. Of the approximately 900 children in the initial pool in the intervention schools, 174 (19%) returned consent forms, and in the control schools the numbers were 88 (13%) of 700. Further, there was no evaluation of the psychometric properties of the screening procedure.

Three additional indicated targeted interventions were carried out, using randomized controlled trials, by the same group of investigators. In the first two (Gillham *et al.* 1995), educational interventions ranging from three lectures on the symptoms, causes and treatment of depression in the first study to five sessions designed to increase the daily rate of their pleasant activities in the second study did not produce positive results. In the third study (Clarke *et al.* 1995), the quality and power of the intervention were increased. Of 1652 adolescents screened in two stages, 150 were identified as experiencing depressive symptoms but did not meet the criteria for depression, and they

agreed to participate in the study. The intervention consisted of a 15-session cognitive-behavioural intervention (three sessions per week for 5 weeks) and data were collected at post-treatment and at follow-up at 6 and 12 months. The preventive intervention emphasized training adolescents in cognitive-restructuring skills to allow them to reduce mild levels of negative cognitions before they reach depressive symptoms of clinical proportions. Overall, the total incidence of either major depression or dysthymia at follow-up was 14.5% for the treated group and 25.7% for the control group—a statistically significant difference.

Beardslee *et al.* (1993, 1996, 1997a,b) have been involved for several years in selective type targeted prevention programmes, where children aged 8–15 are identified, on the basis of having a parent with a recent episode of affective disorder, as being at increased risk for depressive disorder themselves. Children were randomly assigned to one of two psychoeducational interventions (clinician-facilitated or lecture group discussion), both of which were designed to prevent childhood depression and other related problems through decreasing the effects of risk factors and promoting resiliency. The two interventions were similar in content but differed in intensity, with the clinician-facilitated intervention having a greater children's involvement and a greater linking of the educational material to the families' individual life experiences. The intervention had a strong cognitive orientation and a primary goal was to increase family members' understanding of the illness experience. It included individual sessions with the parents, an individual session with each child, and one or two family meetings. The lecture group discussion consisted of two 1-hour lectures, while the mean number of clinician-facilitated intervention sessions was 7.7. The most recent article (Beardslee *et al.* 1997a) reports on data gathered from the first 37 families who completed the initial assessment, and the immediate post-intervention assessment. Nineteen families had been randomly assigned to the clinician-facilitated intervention and 18 to the lecture intervention. Not unexpectedly, positive results were more marked in the clinician-facilitated group. They reported a significantly larger number of overall changes, with more parents and children reporting that they gained a better understanding of the parents' illness, and higher levels of change regarding communications about the illness. It should be pointed out that it will not be known for some period of time whether or not these interventions actually reduce the level of depressive disorder and other morbidities in these high-risk children.

Risk situations

There are many examples where children are at increased risk for psychiatric disorders and where attempts have been made to either reduce the risk itself or modify the effects of the risk. Some of the markers or indicators of increased risk are intrinsic variables (within the child), and others are extrinsic (outside the child) (Offord *et al.* 1998). Examples of the former include low

birth weight, developmental delay, brain damage, epilepsy, difficult temperament, mental retardation and chronic medical illness. Examples of the latter are parents with psychiatric disorder, violent and dysfunctional families, physical and sexual abuse, divorce, marked economic disadvantage and crowded inner-city neighbourhoods. Because of space limitations, this chapter covers only three risk situations: child abuse (see Emery & Laumann Billings, Chapter 20; Glaser, Chapter 21), parental divorce (see Friedman & Chase-Lansdale, Chapter 15) and environmental contaminants.

Child abuse

The prevention of child abuse is especially appealing for two reasons. First, there is limited success in the treatment of children and their families once abuse has occurred (Cohn 1979a,b). Secondly, the prevalence of child maltreatment in the general population is surprisingly high. The Mental Health Supplement to the Ontario Health Survey was a general population survey involving a random sample of almost 10 000 residents, aged 15 years and older (MacMillan *et al.* 1997). Based on a self-administered questionnaire, 31.2% of males and 21.0% of females reported a history of child physical abuse, while sexual abuse in childhood was reported by 12.8% of females and 4.3% of males.

Prevention studies can be classified into two main categories: those that focus on the prevention of physical abuse and/or neglect; and those that centre on the prevention of sexual abuse and/or abduction (MacMillan *et al.* 1994a). In the first category, there are both universal and targeted programmes (Leventhal 1996). Universal programmes include the provision of general services, such as satisfactory housing and financial support, quality childcare, and the availability of child development and parenting resource centres for children aged 0–5 years and their families. It is known that the availability of these resources for selected groups of impoverished preschool-age children results in improved health and well-being (McCain & Mustard 1999). Although it would be expected that providing the universal programmes outlined above, especially to vulnerable populations, would decrease rates of physical abuse and neglect, there are no clinical trials that have examined the efficacy of these types of services in decreasing maltreatment (Leventhal 1996).

The targeted interventions have focused on home visiting and there is evidence that extended home visitation can prevent physical abuse and neglect among disadvantaged families (MacMillan *et al.* 1994b; MacMillan 2000; MacMillan & Canadian Task Force on Preventive Health Care 2000). The Prenatal and Early Childhood Nurse Home Visitation Program is a model that has been tested in two randomized controlled trials in Elmira, New York and Memphis, Tennessee (Olds *et al.* 1993, 1997, 1998a,b, 1999; Kitzman *et al.* 1997; Karoly *et al.* 1998). The intervention consists of nurse home visitors working intensively with families to achieve three broad goals: improvement of pregnancy outcomes, improvement of the child's health and development, and improvement of the parental life-course. Positive results have been reported in each of these areas; for ex-

ample, in the intervention compared to the control groups, there were significant reductions in cigarette smoking during pregnancy among women who smoked cigarettes at registration (25% reduction); rates of child maltreatment from birth through the child's 15th year (79% reduction); and unmarried mothers' behavioural problems caused by alcohol and drug abuse over the 15 years following programme enrollment (44% reduction).

There are essential ingredients of home visiting programmes if they are to be successful (Leventhal 1996). Services should begin early, preferably during the prenatal period or right after birth, and extend through the first couple of years of a child's life. The visits must be frequent enough so that a trusting relationship is formed between the home visitor and the family. The home visitor should develop a therapeutic relationship with the parents, keep a watchful eye on the home, be able to model effective parenting, not lose sight of the child's needs, and be able to provide concrete services to the family.

Further work needs to be done to address the limitations of existing home visitation programmes (Leventhal 1996; Guterman 1997). They include developing effective strategies to deal with fathers and boyfriends as well as mothers, formulating and evaluating intervention approaches in cases involving parental substance and alcohol abuse, developing culture-specific interventions, and focusing on improving the parent's feelings of powerlessness. Two further points should be emphasized. It cannot be expected that leaner, cheaper, watered-down interventions will have the same beneficial effects as those effective interventions reported in the literature. A major challenge in the prevention of child abuse and neglect is to discover strategies to move from small demonstration studies to large-scale dissemination projects with proven effectiveness.

The literature on the prevention of child sexual abuse is not nearly as extensive as that on physical abuse and neglect. The central finding is that there is evidence that educational programmes, usually delivered in the school setting, can improve safety skills and knowledge about sexual abuse, but no study has produced results that education actually reduces the occurrence of sexual abuse (MacMillan *et al.* 1994a; MacMillan 2000; MacMillan & Canadian Task Force on Preventive Health Care 2000). The effect sizes attained in these programmes vary as a function of both programme and child characteristics (Rispen *et al.* 1997). Programmes of longer duration that focus on skill training, and permit a long enough time for children to integrate self-protection skills into their cognitive repertoire, are more likely to be effective. Younger children (less than 5.5 years) and economically disadvantaged children derive a greater benefit from these programmes, although these differential effects fade over time as do the overall programme effects. The implication here is that it makes sense to repeat the programmes at regular intervals.

Children of divorce

Divorce involves large numbers of children. The proportion of

children growing up in homes with two biological married parents has dropped from almost 90% in the 1960s to about 50% of children in the UK and 40% in the USA (Wadsworth 1986). Escalating rates of divorce, out-of-wedlock child-bearing and cohabitation are the major contributors to these changes. In the USA in 1996, divorces and annulments involved over 1 million children (National Center for Health Statistics 1997). In most instances the divorce is followed by remarriage or cohabitation, and thus many children are exposed to a sequence of change in their family members, relationships and roles (Cherlin & Furstenberg 1994; Bumpass & Raley 1995). The effects of divorce on the psychosocial adjustment of children have recently been reviewed (Hetherington & Stanley-Hagan 1999). Many children experience adjustment difficulties in the months immediately following parental divorce, especially in the externalizing behaviour domain, and to a lesser extent in the internalizing area. For many children, the problems lessen over time, but a meta-analysis of 95 studies confirmed that, on average, children of divorced parents are less well adjusted socially, emotionally and academically than children of non-divorced parents (Amato & Keith 1991). Even in those cases where children have shown no upset, or only short-term problems immediately following their parents' divorce, difficulties in adjustment can arise as a result of the divorce in adolescence and even in adult life. However, it should be emphasized that children's reactions to divorce vary widely, and the vast majority of children do not show severe and enduring behaviour problems (Hetherington *et al.* 1992; Hetherington 1993).

Interventions for divorced parents and their children have been reviewed (Grych & Fincham 1992; Emery *et al.* 1999; Hetherington & Stanley-Hagan 1999) and the interventions are of three types: child-focused, parent-focused and those centring on the legal system. Adequate research in this area is scarce. Interventions for children are usually school-based, involve groups of children of divorced parents, consist of both educational and therapeutic activities, and are of short duration.

The most extensively evaluated school-based programme is the Children of Divorce Intervention Project (Pedro-Carroll & Cowen 1985; Pedro-Carroll *et al.* 1986; Alpert-Gillis *et al.* 1989; Pedro-Carroll & Alpert-Gillis 1997). This intervention attempts to foster feelings of support, clarify divorce-related misconceptions (e.g. that the children are responsible for the divorce), and develop effective coping skills to deal with the stressors associated with divorce. In the initial evaluation (Pedro-Carroll & Cowen 1985), 75 grade 4–6 children from four suburban schools were randomly assigned to either an immediate 12-week intervention or a delayed intervention initial group. Positive findings were reported by teachers, parents, group leaders and the children themselves in anxiety behaviours and in school-related problems, but not in perceived self-competence. In subsequent studies of urban children with diverse ages, ethnicities and socioeconomic backgrounds (Pedro-Carroll & Cowen 1985; Pedro-Carroll *et al.* 1986) and of kindergarten and first-grade teachers (Pedro-Carroll & Alpert-Gillis 1997), gains were reported for the intervention

group compared to the comparison group in the emotional-behavioural area and in school-related competencies. One child-focused intervention programme that has been widely disseminated (Kalter *et al.* 1984, 1988) showed few positive results on ratings of children's adjustment before and after participation in the group, and, in addition, there was a lack of a comparison group.

Parent-focused interventions employ group therapy to enable parents to deal more effectively with the stresses of divorce, increase their coping skills and adjustment, and only secondarily are aimed at improving parenting and family relationships (Hetherington & Stanley-Hagan 1999). Although the average effect size of parent-focused programmes on the adjustment of parents is 0.80 SD, the interventions are associated with minor or no improvement in child adjustment (Emery *et al.* 1999). One of the more promising programmes grew out of the Oregon Divorce Study (Forgatch & DeGarmo 1999). Results of this randomized controlled trial, where the intervention programme consisted of 14 parent group sessions, showed that the mothers in the intervention group reported significant improvements in maternal discipline; in addition, significant improvements in teachers' ratings of children's behaviour were reported.

The third type of intervention focuses on legal issues: mediation and coparenting (Emery *et al.* 1999). Although there may be a number of advantages of mediation for divorcing couples compared to an adversarial settlement (Kelly 1989), there is no evidence that it improves the adjustment of the children. Further, there are no consistent findings of an association between type of custody and children's adjustment (Grych & Fincham 1992).

The intervention literature on the children of divorced parents has several important flaws. There are very few well-conducted randomized controlled trials, the informants providing the outcome measures were not blind to the intervention status of the children, and the follow-up periods were brief. Further, because only a proportion of the children of divorce will exhibit adjustment problems, many of the children receiving the intervention did not need it, and it may even have been harmful because of labelling and stigmatization. In addition, for any intervention to show significant differences between the experimental and control groups, it will have to have a marked beneficial effect on the subgroup of children exhibiting adjustment problems. It should be kept in mind that the most these interventions have been shown to do in the emotional and behavioural area is to reduce symptoms slightly, and certainly not decrease emotional and behavioural disorders *per se*.

Environmental contaminants

Because there is evidence that environmental pollutants can adversely affect children's health (Environment Leaders of the Eight 1998), lessening or eliminating them is an important universal prevention initiative. Children are especially vulnerable to these environmental agents because of their early reliance on breast milk which can become contaminated (Sonawane 1995),

and because of the short stature and early crawling activities of young children who spend approximately 90% of their time indoors (Chance & Harmsen 1998). Further, because of their disadvantaged housing arrangements and neighbourhoods, children of poverty experience a disproportionate impact from environmental health threats (Mott 1995; Chaudry 1998).

There are virtually no data on the effects of long-term low-level exposure to pesticides (which are designed to be neurotoxic), despite the fact that many are persistent in the environment and are routinely detected in human tissue. However, methylmercury has resulted in episodes of frank neurotoxic poisoning in humans (Rice 1998). Further, there is epidemiological and experimental evidence that exposure to phencyclidine hydrochlorides (PCPs) in the developmental years produces impairment in cognition functioning and attention (Ware *et al.* 1986; Stern *et al.* 1994). In addition, air pollution has been associated with increased rates of low birth weight in China (Wang *et al.* 1997) and reduced lung function in many countries (Brunekreef *et al.* 1997; Raizenne *et al.* 1998).

The most studied neurotoxicant is lead. It has been clearly established that exposure of fetuses and children to amounts of lead routinely observed as a consequence of environmental contamination produces deficits in IQ (Schwartz 1994; Needleman 1998). It has been reported that a 2.6 decrease in IQ score is associated with an increase in blood level from 10 to 20 µg/dL in a meta-analysis of eight studies (Schwartz 1994). It has been noted that lead has other detrimental effects on children in addition to IQ, including attentional problems, language function and, perhaps, social adjustment (Rice 1998). It is clear that the elimination of environmental contaminants would improve the health of children. In particular, the elimination of lead poisoning would reduce cognitive and attentional deficits in children (Needleman 1998). The beneficial effects of such a manoeuvre for individual children would be small, with the greatest impact occurring among the economically and socially disadvantaged populations of children. The removal of lead from gasoline in 1990 in the USA has been heralded as one of the public health triumphs of the twentieth century. Between 1976 and 1994, the mean blood lead concentration in US children was reduced by almost 80%, in direct proportion to the amount of tetraethyl lead produced (Needleman 1998).

Low-income countries

Although there have been substantial improvements in children's survival over the past several decades and in physical health and education, children's mental health has probably worsened (Desjarlais *et al.* 1995). Millions of children grow up in unbearable circumstances as refugees, displaced persons, street children, casualties of war or victims of child labour. The prevention of mental disorders in populations of these children requires major societal changes in these countries where the well-being of children, not just their survival, becomes a high priority. It cannot be assumed that effective interventions in

wealthy countries will necessarily be effective in poor ones (Dans *et al.* 1998; Rahman *et al.* 2000).

However, there are universal interventions that show promise of enriching the lives of children and decreasing mental health problems even in these severely economically disadvantaged circumstances. The first is to improve maternal education (Caldwell 1986; Hobcraft 1993). It has been reported that the status of women in most, but not all, low-income countries, as reflected by their literacy rate, is a more important predictor of the well-being of children than are economic indicators such as the gross national product (GNP; Caldwell 1986). Possible mechanisms by which more maternal education may translate into increased child well-being have been suggested (Hobcraft 1993). Women with more education marry later, have their first child later, have fewer children, are much less likely to die in childbirth, and are more responsive to modern hygienic practices.

The factors that appear to confer advantages to the offspring of better educated mothers lead to a second universal intervention: better family planning. The more numerous and closely spaced the pregnancies of a mother, the greater risks for not only maternal and infant mortality but for poor developmental and mental health outcomes (Desjarlais *et al.* 1995). A third universal intervention that is capturing the interest in the developing world is to enrich the lives of the first 5 years of children (Young 1997). The provision of adequate nutrition, and early child development and parenting programmes will have both short-term and long-term beneficial effects on the lives of these children (McCain & Mustard 1999). The last universal prevention programme to be mentioned is to increase the percentage of children enrolled in schools. In low-income countries this has increased from under 30% in 1960 to over 70% in the 1980s (Carnegie Commission 1992) but many of them drop out in the elementary school grades. Obviously, the topic of the prevention of emotional and behavioural problems in children in poor countries is an important and complex one, and only a brief summary of selected issues is presented here.

Barriers

There are obstacles to carrying out prevention studies but there are two that are particularly relevant to child psychiatrists. The first is that in many instances, particularly in North America, child psychiatrists are funded on a fee-for-service basis. Thus, there is no remuneration for activities related to planning and carrying out prevention projects that do not involve direct clinical contact. A second obstacle is that child psychiatrists are usually not trained to do prevention work (Group for the Advancement of Psychiatry 1999); their expertise lies in individual clinical work. At a minimum, one could argue that child psychiatrists should know the prevention literature thoroughly so that they can advise groups planning and launching prevention projects (Rae-Grant 1991; Harrington 1997; Group for the

Advancement of Psychiatry 1999; Offord *et al.* 1999). Further, child psychiatrists should be at home in making use of the epidemiological perspective in their clinical work, e.g. if a child psychiatrist is having to deal with a spate of similar referrals from one school, it should suggest to the child psychiatrist that intervening at the school level needs to be considered.

A second potential barrier to prevention initiatives is an uncivic community, one in which the community, or an entire country, is so disorganized that prevention initiatives would have little chance of success (Offord *et al.* 1999), e.g. launching a social skills training programme in a school has little chance of success if the school is disorganized and demoralized.

A third issue is that effective primary prevention programmes are not guaranteed widespread implementation. In the case of childhood lead poisoning, a strong national effort to eliminate the disease developed in the early 1990s in the USA (Needleman 1998). As mentioned earlier, the effort was successful in eliminating lead from gasoline, but not lead from paint. By 1998, 7 years after publication of the prevention plan, it had been abandoned because of the roles and attitudes of several powerful institutions.

Conclusions

Our knowledge about what works to prevent child psychiatric disorders has grown in important ways over the past two decades. However, a number of challenges remain to be dealt with. The first concerns efficacy vs. effectiveness (Tugwell *et al.* 1985). Most of the evaluations to date are efficacy evaluations: the programmes are designed and evaluated in the context of ideal conditions. These ideal conditions include highly skilled programme personnel, high levels of motivation on the part of the individuals and organizations involved, and high levels of resources. Whether or not the effects observed can be obtained when the same programmes are applied in a field setting, where conditions are less than ideal, is uncertain and probably unlikely in the absence of special supports. The expansion of an efficacious small demonstration to a large-scale effective programme disseminated to many settings has not been successfully accomplished.

A second issue concerns implementation and the fidelity with which an intervention is applied (Moncher & Prinz 1991). The impact of programmes to prevent emotional and behavioural disorder has been shown to be directly related to the fidelity of implementation (Botvin *et al.* 1995). Manualization of programme content and procedures, and regular inservicing of programme staff have been recommended as strategies to maximize implementation rigour and fidelity (Durlak 1995).

Thirdly, the impact of prevention programmes may be dependent on individual characteristics, such as gender, socioeconomic status, culture and/or the level of the symptomatology already present. As a result, effect sizes, which reflect the average benefit for the average person, may mask significant variation in benefit

that exists between individuals. Stoolmiller *et al.* (2000) have shown that the effect of a universal conduct disorder prevention programme was dependent on the level of aggressive symptoms present at the outset—the most aggressive children benefited most from the programme.

Fourthly, there are particular problems in demonstrating the effectiveness of universal programmes and they have been discussed in detail (Hundert *et al.* 1999). One of the difficulties is that by the time there is the will to evaluate universal programmes, they are already widespread in some form or another and, in addition, participation in a study may stimulate diffusion of programmes to the comparison group. In the Tri-Ministry Study, interventions similar to the ones being implemented in the experimental schools were present in the comparison schools. Further, during the course of the study, the percentage of teachers in comparison schools stating that social skills was taught as a special subject increased from 35.7% in the year prior to the study to over 50.0% in the fourth year of implementation. The social skills programme in the experimental schools was pitted against existing social skills programmes in the comparison schools, thus setting the bar high to show effectiveness of the programme in the experimental schools.

Fifthly, effective programmes tend not to be maintained, let alone disseminated (Offord 1996). Their cost, acceptability and requirement of a charismatic leader for their success are some of the barriers preventing sustainability of efficacious and effective programmes.

Finally, there is a disturbing trend that prevention programmes without proven effectiveness end up being widely disseminated (Kalter *et al.* 1984, 1988). Certainly, as suggested previously, one of the important functions of child psychiatrists in the prevention field is to inform policymakers and colleagues about the strength of scientific evidence supporting the effectiveness and ineffectiveness of various preventive initiatives.

Activity in the preventive field has grown enormously over the past two decades. In the second edition of this textbook, published in 1985 (Rutter & Hersov 1985), there was no chapter devoted to prevention nor were the terms ‘prevention’ or ‘primary prevention’ mentioned in the index. There are some promising leads now in the prevention field, but much work remains to be done. More precise knowledge is needed from small studies about what works in which populations, under what conditions, and what the mechanisms are by which the intervention has its effects, and how large these effects are. It is important to work out that if an intervention were shown to be efficacious in a demonstration project, what are the chances of it being successfully widely disseminated.

A final point. It makes no sense for the prevention and treatment enterprises to be seen as being antagonistic, competitive and separate from each other. There is much room for collaboration between prevention and treatment personnel in initiatives, such as discovering strategies to prevent comorbidity, the so-called primary prevention of secondary disorders (Kessler & Price 1993). The burden of suffering from child and adolescent psychiatric disorders is so high that both effective treatment and

prevention programmes are needed to reduce this burden substantially.

Introduction

The plural ‘behavioural therapies’ in the title of this chapter reflects the growing sophistication and range of applications that have come about in the half century since operant and classical conditioning principles of learning were first applied systematically to the clinical problems of children and adolescents. The names of the various therapies, which, to varying degrees, are rooted in behaviourism, represent milestones on a journey of ever-increasing conceptual elaboration and theoretical inclusiveness: applied behaviour analysis, behaviour modification, behaviour therapy, cognitive-behaviour therapy, behavioural family therapy, functional family therapy, behavioural case-work and cognitive-behavioural psychotherapy.

Theoretical background

Behaviour therapy starts from a clear objective of producing planned goal-directed change. It represents a theory—indeed, a philosophy—of treatment and behaviour modification, rooted in broad empirically based theories of learned human behaviour. The central assumption of behavioural work is that much abnormal behaviour and cognition in children is on a continuum with normal (non-problematic) behaviour and thought. These phenomena do not differ, by and large, from their normal counterparts in their development, their persistence and the way in which they can be altered. The laws of learning that apply to the acquisition and changing of normal functional (e.g. socially approved) behaviour and attitudes are assumed to be relevant to the understanding of dysfunctional actions and cognitions. Unfortunately, and it is the case with all forms of learning, the very processes that help the child adapt to life can, under certain circumstances, contribute to maladaptation. An immature child who learns by imitating an adult does not necessarily comprehend when it is undesirable (deviant) behaviour or distorted thinking that is being modelled. The youngster who learns adaptively on the basis of classical and instrumental conditioning processes to avoid or escape from dangerous situations can also learn in the same way (maladaptively) to avoid school or social gatherings. A caregiver may unwittingly reinforce antisocial coercive behaviour by attending, or giving in, to it.

Of course, there is much more to both adaptive and maladaptive learning than is conveyed by these examples. There may be

learned behavioural, cognitive or affective overlays to problems that have an organic basis (conditions such as epilepsy and the Lesch–Nyhan syndrome, or an adverse temperamental predisposition), which are therefore accessible to some alleviation by behavioural methods. In addition, the application of behavioural principles based on a model of normal learning may not always be clinically apposite. The process of learning for some children may be altered by anomalies of brain function, as may be the case with attention deficit hyperactivity disorder (ADHD), where it is hypothesized that the learning situation can be complicated by a rapid delay-of-reward gradient. Such an aberration might require a treatment plan that arranges for a sufficiently speedy delivery of reinforcers to produce, and maintain, change (for a discussion of these and similar issues see Taylor 1994).

Levels of intervention

Behaviour therapy based on the one-to-one (dyadic) or behavioural family therapy (systemic) model tends to take place in the clinic. Behavioural training based on the triadic or behavioural consultation model (using significant caregivers or teachers as mediators of change) often takes place in the home, or is located in a school. When it involves group work it may take place in a community centre. Although the distinction between treatment and training is at times blurred, the treatment model is most appropriate to the emotional disorders of childhood (e.g. fears and phobias), the training model to the longer term problems (e.g. antisocial behaviour and pervasive developmental disorders). At least four levels of intervention need to be implemented in concert in order to meet long-term goals (Evans 1989):

- 1 altering the immediate consequences of the undesirable behaviour and/or belief;
- 2 reducing the probability of the behaviour or belief occurring by rearranging the environment;
- 3 facilitating (teaching, reinforcing, shaping) the emergence of alternative skills and attitudes; and
- 4 designing long-term prevention through imparting new patterns of behaviour and/or attitudes.

At the simplest level (point 1, above) there are three basic learning tasks that are commonly encountered in child therapy:

- 1 the acquisition (learning) of a desired response in which the individual is deficient (e.g. compliance, self-esteem, self-control,

bladder and bowel control, fluent speech, social or academic skills);

2 the reduction or elimination (unlearning) of an unwanted response in the child's repertoire (e.g. self-deprecatory self-talk, aggression, temper tantrums, stealing, facial tics, phobic anxiety, compulsive eating); or

3 the exchange of one response for another (e.g. social approach behaviour in place of excessively shy withdrawal).

Each of these tasks (and potential ameliorative methods) may be served by either one or a combination of the major types of learning: operant and classical conditioning, observational, and cognitive learning.

Behaviour modification

Early behavioural theorists, in reaction to the subjectivism of psychoanalysis, sought a positivist approach to the therapeutic treatment and training of severely handicapped and disturbed children. It involved the systematic application of response-contingent (operant) principles of learning to the problems of autistic and mentally handicapped patients (Ferster & De Myer 1962). They attended to the functional relationship between precisely defined and observable actions (targets for modification) and clearly specified environmental contingencies, thereby achieving an overt, if restricted, conceptual formulation of behaviour change.

Operant conditioning

In essence, operant behaviour (mainly under voluntary control) is defined by the manner it changes the environment; it is behaviour that is maintained by its consequences. Actions are increased or strengthened—and thus shaped—by having consequences that are rewarding (positive reinforcement) or that lead to the avoidance of, or escape from, punishment (negative reinforcement). They are reduced or eliminated by punitive sanctions (fines, penalties, etc.) that follow, contingently, their unwanted performance. The term 'operant' refers also to behaviours that have an identical effect on the environment. A child may find that he or she can get his or her parent to delay or forgo an unwelcome command to go to bed (a rewarding outcome) by a variety of operants: screaming, crying or pleading. The parent, by giving in, escapes the aversive behaviour (also a rewarding outcome). The repeated consequence of such submissive and coercive behaviours reinforces them, in other words increases the probability of their occurrence by parent and child in future situations of a similar kind. This illustration of positive and negative reinforcement for child and parent, respectively, is familiar to clinicians treating oppositional-defiant problems.

Functional analysis

A careful observation-based analysis of the positive and negative reinforcing stimuli that produce or maintain fearful, antiso-

cial or other unwanted behaviours is referred to as a 'functional analysis'. The analysis leads to procedures that bring about the systematic manipulation of a behaviour's consequences so as to modify its subsequent performance. With their individual learning histories, their experience as they grow up, of attention, approval, disapproval or neglect, children have unique reinforcement profiles. An event that functions as a reinforcer for one child may not do so for another. Similarly, a reinforcer for an individual in one situation may not have the same effect in another (for detailed accounts of the theoretical and practical aspects of behavioural analysis see Gambrill 1977; Herbert 1987a; Sturmey 1996). The functional analysis is also referred to as an 'applied behaviour analysis'. It became the source of the formulation in the earliest single-case studies that were published in a newly founded *Journal of Applied Behavior Analysis* (Baer *et al.* 1968). The term 'behaviour modification' was applied to this form of behavioural work.

Although early practitioners reported successful interventions, their emphasis on short-term gains often neglected developmental, diagnostic and generalization issues, the need for follow-up, and the possibility of negative concurrent effects such as disruptions to family relationships.

Behaviour therapy

Classical conditioning

At about the same time as these advances in operant technology (the late 1950s and early 1960s), behavioural therapy began to come into its own in the treatment of clinical patients, notably those with anxiety disorders. The early theorists and practitioners in this development (Wolpe 1958; Eysenck 1960) were impressed by the therapeutic possibilities of stimulus-contingent reinforcement, and preferred to call their approach 'behaviour therapy' to emphasize the clinical application of this principle of learning. The essence of stimulus-contingent reinforcement, a model of learning called classical or respondent conditioning developed by Ivan Pavlov (1927), is that a stimulus (the unconditioned stimulus) is presented to the organism and reflexly elicits a response. A previously neutral stimulus repeatedly paired with the unconditioned stimulus gradually acquires its response-eliciting properties. The response of the organism is now conditioned to the second stimulus (the conditioned stimulus). Emotional reactions of phobic intensity can be evoked directly by classical conditioning, a fact demonstrated in a distasteful experiment on a young child (Little Albert) by Watson & Rayner (1920).

The most often quoted account of a prescient and more benign therapeutic use of classical conditioning, referred to as counter-conditioning, is Mary Cover Jones' successful treatment of Little Peter's fear of a rabbit (Jones 1924). She used guided re-exposure to the anxiety-eliciting rabbit in a systematic but gradual manner and in the presence of food (conceptualized as a stimulus that would produce an incompatible positive

response). Mowrer & Mowrer (1938) invented the urine alarm ('bell-and-pad') for the treatment of nocturnal enuresis. A pad, when moistened with urine during the night, closed a circuit and rang a bell. It was arranged that when that happened, someone would wake the child, take him or her to the toilet, and change the bed and night clothes. This conditioning technique was and, in updated versions, continues to be very effective.

Some 20 years later, a curious gap in the development of such promising therapeutic procedures, Wolpe (1958) was to make a major contribution to the rationale for using respondent conditioning in the establishment, maintenance and 'cure' of anxiety states: the development of systematic desensitization. He relied primarily on relaxation as the competing, and therefore, inhibitory response, calling the process 'reciprocal inhibition'. Researchers have sought, by a process of experimental deconstruction, the active and necessary therapeutic ingredients of systematic desensitization. Despite disagreements (some practitioners question the need for relaxation), it remains an effective procedure for a variety of anxiety disorders of childhood and adolescence. Mowrer (1947), in a further theoretical advance, described the interaction of stimulus-contingent and response-conditioned learning in the development of phobic anxiety. He suggested that the intense fear of stimuli associated with a distressing event was established by classical conditioning, while responses that remove the individual from the fear-eliciting stimuli (escape/avoidance) are reinforced by relief, the operant process of fear (drive) reduction.

Observational learning (vicarious conditioning)

Stimulus–response theories of learning and their various clinical applications continue to be acknowledged for their undoubted usefulness. However, learning theory moved on, influenced in large part by the innovative work of Bandura (1977). His concept of vicarious conditioning, or learning by observation, is central to the child's rapid acquisition of much complex and novel behaviour, and also its modification. Watching and imitating the behaviour of exemplary models is considered by social learning theorists to be the cornerstone of learning for socialization (an issue we return to).

Emotional responses can be conditioned observationally by witnessing the affective reactions of others undergoing painful or pleasurable experiences. Fearful and avoidance behaviour can similarly be extinguished. Modelling has been used to reduce 'normal' fears, such as the dark, animals and spiders, as well as more serious symptoms of anxiety disorder. Children are encouraged to observe other children (or adults) approaching and coping with (rather than mastering) the feared object, or engaging in anxiety-reducing strategies they have been taught.

Cognitive-behavioural therapy

The critical role of cognition in childhood learning (Bruner 1975) led to a sometimes reluctant reappraisal by many behaviour therapists of the significance of 'private events', and the cog-

nitive mediation of problematic behaviour. Thus, we arrive at an acceptance in the 1980s and 1990s, in what came to be known as cognitive-behavioural therapy (CBT), of the phenomenology of problems as primary data. It is proposed that cognitions (e.g. schemata, attributions, opinions) require investigation in order to understand children's emotional and behavioural difficulties (Kendall & Gosch 1994). These might include self-statements describing fears, such as those reported by Zatz & Chassin (1983) in test-anxious children. Their cognitions not only encompass many self-denigrating statements (e.g. 'I'm doing poorly; I don't do well on tests like this; everyone usually does better than me'), they also make use of few facilitative, coping statements (e.g. 'I am bright enough to do this; I am doing the best that I can; I do well on tests like this').

Cognitive-behavioural therapy focuses on goal-setting and self-directed behaviour by the child, also targeting divergent thinking as a way of encouraging inventive solutions to personal difficulties. The techniques used have their roots in cognitive therapy (e.g. Socratic questioning, persuasion, challenging, debate, hypothesizing, cognitive-restructuring, verbal self-instruction and internal dialogue). Others are drawn from behaviour therapy (e.g. operant procedures, desensitization, exposure training, social-skills training, role-play, behaviour rehearsal, modelling, relaxation exercises, redefinition, self-monitoring). The methods share a common assumption: that children can be taught to eliminate some of their maladaptive behaviours by challenging their irrational beliefs and faulty logic, by getting them to instruct themselves in certain ways, or to associate wanted behaviour with positive self-statements and unwanted ones with negative self-statements.

A recent development which is an adaptation of cognitive therapy as it was originally applied to adults is cognitive-behavioural play therapy (CBPT): a developmentally sensitive treatment for young children that relies on flexibility, decreased expectation of verbalization by the child, and increased reliance on experiential approaches (Knell 1998, p. 28). There is a need to reach preschool-age children whose conceptual language is still too immature to benefit from traditional cognitive strategies, but whose positive response to play and play therapy is well established (Axline 1947; Webb 1991).

Applied social learning theory

Social learning theory

Cognitive-behavioural therapy, which, as we have seen, goes well beyond the earlier epistemological position of radical behaviourists, finds much of its rationale in the development of social learning theory (SLT). There is an emphasis on the crucial fact that rewards and punishments, and other events, are mediated by human agents and within attachment and social systems, and are not simply the impersonal consequences of behaviour. Children do not simply respond to stimuli; they interpret them. They relate to, interact with, and learn from people

who have meaning and value for them. They feel antipathetic to some, attached by respect and/or affection to others, and thus may perceive an encouraging word from the latter as rewarding (positively reinforcing), but from the former as valueless, perhaps even aversive. Stimuli influence the likelihood of particular behaviours through their predictive function; contingent experiences create expectations rather than stimulus–response connections (Bandura 1977). The failure of children to comprehend such meanings, which is the case in semantic-pragmatic disorder or Asperger syndrome, is devastating in its effects.

Behavioural family therapy

Behavioural family therapy and parent management programmes draw on applications of social learning, cognitive, and family theory (Herbert 1998c; Patterson 1982; Herbert & Wookey 1998; Webster-Stratton 1991; Webster-Stratton & Herbert 1994; Sanders 1996). They typically address themselves to the fact that parents of children with behaviour problems tend to flounder because they issue so many commands, provide attention following deviant behaviour, and are unlikely to perceive deviant behaviour as deviant. There is a tendency to get embroiled frequently in extended coercive hostile interchanges. They give vague commands, and are generally ineffectual in bringing their children's deviant behaviour to a halt. A typical programme is described later in the chapter.

Functional family therapy

Alexander & Parsons (1982) have integrated aspects of structural and strategic family therapy with behavioural family therapy in a promising approach to delinquency and related problems. Patients are trained in communication and problem-solving skills, contingency contracting and self-regulation skills, such as relaxation.

Psychodynamic influences

The drift of behaviour therapy to a cognitive mode is paralleled by a noticeable, if modest, leaning of cognitive therapy towards psychodynamic thinking (Power 1991). The psychoanalysts' exegesis of the mysteries of intrapsychic life and their preoccupation with motivation are precisely where, in Wachtel's opinion, they have much to offer behaviour therapists as they investigate the 'what' and 'why' questions of clinical problems (Wachtel 1977, 1997). Hersen (1981), an eminent behaviour therapist, has acknowledged that his fellow professionals often rely, perhaps unwittingly, on techniques associated with traditional psychotherapy in overcoming resistance to therapy, by utilizing support, interpretation and reality confrontation.

It is generally recognized that the insights that arise from intrapsychic exploration and interpretation do not necessarily lead to changes in behaviour; behaviour change, in turn, does not necessarily lead to an insightful understanding of personal

difficulties. Nevertheless, there is a sense in which a functional analysis can achieve this. At its simplest, behaviour is a function of certain contingent stimuli, originating in the person's internal and external environment. Here, the important questions are: 'What triggers (elicits) the phobia?' or 'What is the pay-off (reinforcement) the child obtains when behaving in this antisocial way?' At a more interpretative level, the child's behaviours may have the function of solving (or attempting to solve) a developmental or life problem. They serve a purpose; they are functional (dysfunctional though they may appear to the parental or professional eye) for the individual. An example of this is the 'pay-off' of attention, guilt-reduction, nurturance, or some other reinforcement that maintains what otherwise appears to be incomprehensible self-injurious behaviour (Oliver & Head 1993).

It is suggested that psychodynamic ideas constitute a semantic theory about meanings, rather than a scientific model of practice, and as such may contribute to a broader, more integrated perspective for the psychological therapy of children. This contribution to therapy is not the scientific one of elucidating the causes of children's choices and actions, but the semantic one of making sense of them (Rycroft 1970, p. 328).

Transition and change: a developmental perspective

Learning, like growth and development in children, is essentially about change. Parents too—and indeed their family—are locked into a developmental life cycle, with its stage-related life-tasks. The nature, sources and consequences of parents' ideas about development (Goodnow & Collins 1990), and the ramifications of transition and change in family life, are important in the assessment of children's problems.

In the early stages of behaviour therapy's history there was little or no communication between clinical practitioners and developmental psychologists. There have been attempts to integrate findings between the two disciplines since the 1970s (Achenbach 1974; Herbert 1974). The evaluation of normality and abnormality within a developmental framework requires a familiarity with general principles of development (Herbert 1998a; 2001). For Cicchetti *et al.* (1983), to take one example, abnormal patterns of behavioural adaptation (as represented by clinical problems such as hyperactivity and failure to thrive) are most fruitfully construed and formulated in terms of a series of stage- and age-related tasks. The issue of competence is common to all of them and, as the child gets older, his or her self-esteem. If the child fails to develop skills and social competence, he or she is likely to suffer, among other problems, a sense of inadequacy. There is evidence not only of the power of parents to facilitate or hinder the child's mastery of developmental tasks, but to do this unwittingly (Cicchetti *et al.* 1983).

These matters become important themes in parenting skills programmes, most of which set themselves the task of increasing parents' sense of 'self-empowerment' (Herbert & Wookey

Table 53.1 Sources of increased self-empowerment.

	Content	Process
<i>Knowledge</i>		
Child development	Developmental norms and tasks	Discussion
Behaviour management	Behavioural (learning) principles	Books/pamphlets to read
Individual and temperamental differences	Child management (disciplinary strategies)	Modelling (videotape, live role play, role reversal, rehearsal)
	Relationships (feelings)	Metaphors/analogies
	Self-awareness (self-talk, schema, attributions)	Homework tasks
	Interactions (awareness of contingencies, communications)	Networking
	Resources (support, sources of assistance)	Developmental counselling
	Appropriate expectations	Videotape viewing and discussion
	Parent involvement with children	Self-observation/recording at home
		Discussing records of parents' own data
		Teaching, persuading
<i>Skills</i>		
Communication	Self-restraint/anger management	Self-reinforcement
Problem-solving (including problem analysis)	Self-talk (depressive thoughts)	Group and therapist reinforcement
Tactical thinking (use of techniques/methods)	Attend–ignore	Self-observations of interactions at home
Building social relationships	Play–praise–encourage	Rehearsal
Enhancing children's academic skills	Contracts	Participant modelling
	Consistent consequences	Homework tasks and practice
	Sanction effectively (time out, loss of privileges, natural consequences)	Video modelling and feedback
	Monitoring	Self-disclosure
	Social/relationship skills	Therapist use of humour/optimism
	Problem-solving skills	Relaxation training
	Fostering good learning habits	Stress management
	Self-assertion/confidence	Self-instruction
	Empathy for child's perspective	Visual cues at home
	Ways to give and get support	
<i>Values</i>		
Strategic thinking (working out goals, philosophy of child rearing, beliefs)	Treatment/life goals	Discussion/debate
	Objectives (targeted child behaviours)	Sharing
	Ideologies	Listening
	Rules	Respecting/accepting
	Roles	Negotiating
	Relationships	Demystifying
	Emotional barriers	Explaining/interpreting
	Attributions	Reframing
	Prejudices	Resolving conflict
	Past history	Clarifying
		Supporting
		Adapting

1998; Webster-Stratton & Herbert 1994). This rather vague concept can be operationalized in terms of knowledge, skills and values (see Table 53.1).

There are far-reaching benefits for the enhancement and timing of interventions to be had from an appreciation of the development of different pathways to adult antisocial behaviour (Frick 1998) and the relevance of attachment theory and parental responsiveness to family behaviour therapy (Rutter 1995; Wahler & Meginnis 1997). Also helpful is an understand-

ing of the causes and consequences of any 'mismatches' in the parents' and children's ideas and expectations that arise from differences in conceptual level, and which promote conflict (Goodnow & Collins 1990).

Behavioural assessment and formulation

Rigorous assessment is the sine qua non of effective behavioural

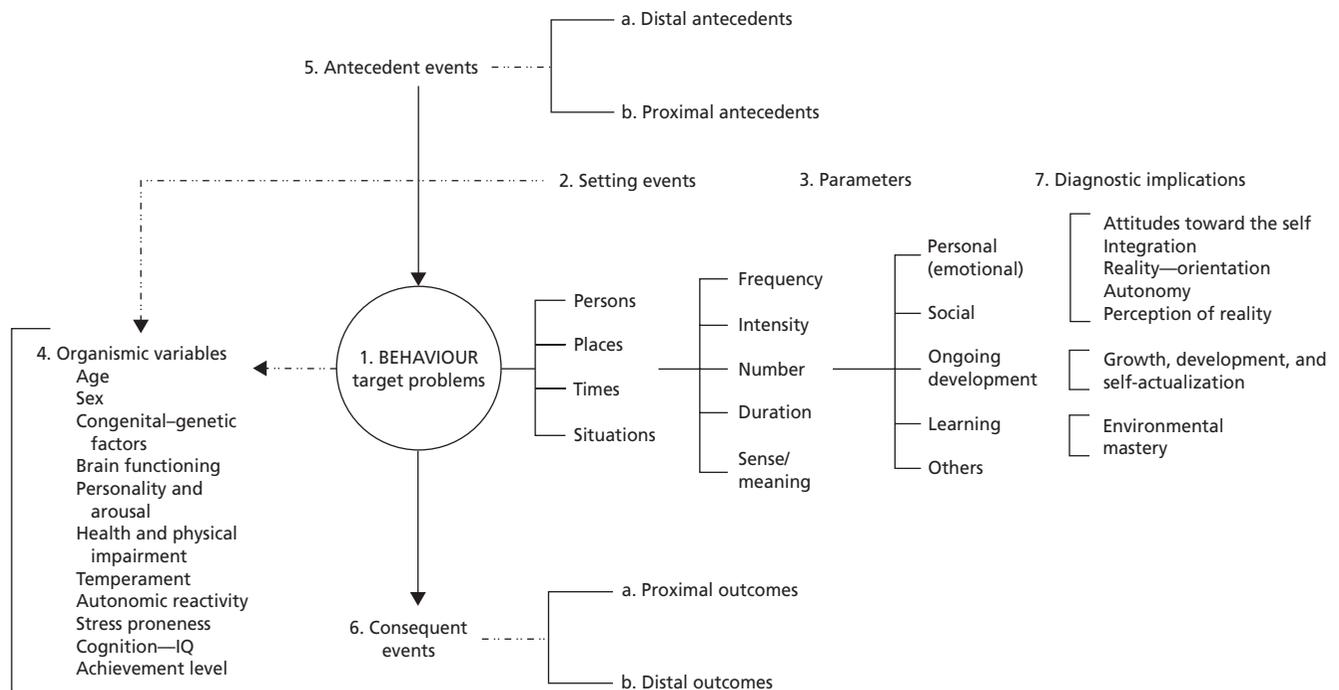

Fig. 53.1 A conceptual framework for an assessment of behaviour problems.

treatment. The strategy is to begin with a broad-based assessment of the child and his or her environment (e.g. family, school, peers) and then to obtain information regarding specific stimulus features, response modes, antecedents and consequences, severity, duration and pervasiveness of the particular problems. The assessment utilizes a multimethod problem-solving approach to obtain as complete a picture of the child and the family as is possible. When the collection of sufficient data allows, there is a behavioural formulation, a set of explanatory hypotheses describing the determinants, historical and current, of the problem. A conceptual framework for gathering data for assessment and a clinical formulation is provided in Fig. 53.1.

The formulation of the client's problem bridges the assessment, the treatment plan and implementation, and is arrived at in several stages summarized by the mnemonic ASPIRE (Sutton & Herbert 1992).

Stage 1: Assessment (AS)

The what and why questions are directed towards the precise identification of the antecedent (A), consequent (C), and symbolic conditions which control the targeted behaviours and/or beliefs (B) which are problematic. This linear analysis is elaborated into a recursive sequence such that Cs become As, which generate new Cs, and thus ramify to affect the actions of others in the vicinity of the main protagonists (say, parents and child). The main assessment tasks are twofold: to identify target problems and to identify controlling variables.

Identifying target problems

Point 1 in Fig. 53.1 underlines the importance of a developmental context for evaluating (say) a child's fearfulness or aggressiveness. The judgement arises from the essential normality of these emotions, universal responses and normal adaptations to a wide range of life events, and which are therefore functional in the sense of having survival and reward value. The parameters that separate behaviours defined as problematic from the anxieties, avoidance, aggression, indecision and obsessions shown by all children at one time or another are, *inter alia*, their rate and intensity (point 3 in Fig. 53.1). The persistence (duration) with which they are manifested, their pervasiveness, and the sheer number of problems with which they are associated are also important diagnostic criteria.

Their implications for the individual's well-being and effective functioning at home and in the wider world (e.g. school) provide further diagnostic guidelines for the therapist (point 7 in Fig. 53.1). The meaning of the problems, the sense made of them, the pay-off they provide for the child, and indeed for the family, constitute vital elements of the overall assessment.

Identifying controlling variables

Two categories are generally considered when identifying controlling variables: current environmental variables (antecedent and consequent events; points 5 and 6 in Fig. 53.1) and organismic variables (point 4 in Fig. 53.1). The contemporary causes of problem behaviour may exist in the client's environment or in

his or her own thoughts, feelings or bodily processes (organismic variables), and they may exert their influence in several ways: as eliciting or discriminative antecedent stimuli or as outcomes (consequences) of a reinforcing kind.

Proximal antecedents

Proximal (current) influences (point 5b in Fig. 53.1) are direct in their effects and close in time to the actions they influence. They are functionally related to behaviour and can thus be tested in therapy, as hypotheses about causation, using single-case experimental designs (see Barlow & Hersen 1984).

Organismic variables

These variables (point 4 in Fig. 53.1) include individual differences produced by, *inter alia*, age, cognitive structures, temperament and past learning (Chess & Thomas 1995). Behaviour therapists tend to adopt a transactional position, the view that behaviour results from interaction of the current situation and individual differences of a biological and psychosocial nature. The influence of children on their parents' behaviour and choices, past and present, is active and powerful.

Brown & Harris (1989) use the term 'life structure' for the interface of the internal and external worlds of the individual and to reflect the transitions and changes in the child's family life, his or her moods, regrets and attitudes. This moves the assessment on from a consideration of current antecedent influences to an inquiry into distal (historical) antecedents (point 5a in Fig. 53.1).

The analysis of the problems may be assisted by information about the patient's past (e.g. attachments, health, reinforcement history, attitudes, life-events) (point 5 in Fig. 53.1), but the information is gathered primarily as a source of clues to contemporary conditions that influence the elicitation and maintenance of symptoms rather than as primary treatment objectives in themselves. The behaviour therapist places most emphasis on providing the patient with new learning experiences. The past may haunt the present in the sense that it may influence current attitudes. An adolescent boy may try, by means of offensive behaviour, to sabotage his mother's relationship with his stepfather, because she has 'betrayed' a deceased father and husband. Some parents harbour guilty attributions about past child care 'mistakes' that, in turn, engender overprotective actions toward their children. It may be necessary, before programmatic work can begin, to lay such 'ghosts' to rest, by discussing past events and possibly changing attitudes to them, using techniques such as cognitive restructuring ('reframing').

Stage 2: Planning (P)

The strategic treatment plan and the tactical specification of methods/techniques for bringing about change, the 'how' questions, generally flow from the assessment of the determinants or causes of the problem(s). In an ideal world this formulation

would inform the choice of therapeutic strategy or some broader based community intervention. One of the strengths of behaviour therapy (the 'Rigorous Evaluation' in the ASPIRE process) is that the specificity of goal-setting and requirement that patient(s) and therapist monitor change allow both parties to judge fairly early in the intervention whether the programme is on the right track or not. It is also one of the advantages of behavioural work (and the reduction of phobic fear is an example) that therapy does not necessarily depend on the discovery and understanding of the historical causes of the problem.

Stage 3: Implementation of the intervention (I)

The overall principles governing the choice of treatment are those of alleviating distress and enhancing personal and social performance. Such benefits should endure beyond the immediacies of the treatment process, and treatment used within an overall planned programme of management. There are also several ethical imperatives to be taken into account. Children may be limited in their understanding of a treatment or its implications and consequently unable to give full consent (Royal College of Psychiatrists 1989; Francis 1999).

Non-specific conditions

Relationship and other therapeutic process variables cannot be overlooked in behaviour therapy any more than in other forms of psychotherapy. They are necessary but usually not sufficient conditions of change. Positive expectations about the outcome of treatment and attitudes towards the therapist are important elements in determining the success or failure of programmes, yet parents often complain that professionals simply do not understand, or attend to, their personal concerns. Prior to therapy, parents of conduct problem children, for example, often feel as if they are 'under siege'. The child's hyperactivity, distractibility, developmental problems and unpredictability drain the parents and lead to many ripple effects. Their relationships with other family members, friends and people in the community (notably at school) are quite likely to be adversely affected. Marital discord and depression are common (Webster-Stratton & Hammond 1999).

A collaborative approach to therapy designed to address these difficulties is described by Webster-Stratton & Herbert (1993, 1994). They suggest that the first role of the therapist in the collaborative process is to build a supportive relationship with the parents. This is often achieved through appropriate use of self-disclosure, humour and optimism, as well as actively advocating for parents (such as at the child's school). A second role is to empower parents, through reinforcing and validating parents' insights, helping them to modify powerless thoughts, promoting self-efficacy (knowledge, skills and values) and building family and group supports. A third role is to teach by persuading, explaining, suggesting, adapting, giving assignments, reviewing, summarizing, ensuring generalization, using videotape examples and role-playing. A fourth role is to interpret or 'translate'

the cognitive, behavioural and developmental concepts into words that the parents can understand and apply. This includes the use of analogies and metaphors, reframing, and making connections between the parents' own childhood or other life experiences and those of the child. A fifth role is to lead and challenge, including setting limits (especially in groups), pacing the sessions, and dealing with resistance.

Bandura (1977) is of the opinion that success depends on the degree to which the interventions create or strengthen the client's expectations of personal efficacy, hence the concentration on 'doing' (e.g. behaviour rehearsal, modelling, role-play, homework tasks) in behavioural parent training.

Clinical applications

It is an indication of the versatility of modern behaviour therapy that it is possible here to mention only a small sample of psychiatric, psychiatry/health liaison, and school-based problems to which behavioural methods have been applied. Behavioural methods have been evaluated in different ways. Some have compared behavioural interventions, at termination and follow-up, with other therapeutic approaches, and with no-treatment (e.g. waiting list) patient groups, as controls (Blagg & Yule 1984). Others have tested the ability of behavioural methods to reduce deviant, neurotic and other behaviours/symptoms to within normal limits (Bernal *et al.* 1980). Psychometric instruments are often used to measure change in symptomatology. The contribution of a behavioural component to a multisystemic or multimodal programme may be 'teased out' (unpublished data). The deconstruction of particular methods, experimentally 'stripping' out aspects that are therapeutically inert or redundant in relation to the desired outcome of therapy (a feature of early research on systematic desensitization), is an important validation procedure. Cost-effectiveness studies comparing group vs. individual interventions are also carried out (Christenson *et al.* 1980; Cunningham *et al.* 1995).

Emotional disorders

Anxiety disorders

Cognitive-behavioural therapy

The primary goals of CBT with anxious children, in the light of what has been established theoretically, are:

- 1 management of the anxiety;
- 2 reduction of the child's distress; and
- 3 increasing mastery and coping skills.

Children are helped to detect early signs and triggers of anxious arousal, and then to utilize these cues as signals for initiating active cognitive and behavioural coping strategies. Treatment gains have been maintained at 3-year follow-up assessments (Kendall & Southam-Gerow 1996). Probably the most fre-

quently used cognitive approach with anxious children is verbal self-instruction training (Kanfer *et al.* 1975).

Ronan & Deane (1998) have described in detail their FEAR plan in which children combine these individual skills within an integrated 'coping template'—a programme that outcome studies suggest is effective (Kendall 1994). The inclusion of parents in this and other approaches is recommended, the Family Anxiety Management (FAM) programme being an example of how to enhance the individual programme for children with anxiety disorder. Barrett *et al.* (1991) demonstrated, in a study of 79 children aged 7–14 years, the advantage of adding to a CBT approach a family management treatment condition (dealing with parents' interactions with their children during anxiety attacks, emotional upsets and family communication plus exercises in problem-solving), as compared with CBT on its own and a waiting list control group. At the end of treatment (individual) 57% of cases were clinically improved, rising to 70% a year later. However, the combined treatment resulted in an 84% improvement at termination, rising to 96% at 1-year follow-up.

Systematic desensitization

This tends to be the preferred intervention for children exhibiting simple and social phobias (Ollendick & King 1998). The method consists of three basic steps:

- 1 progressive relaxation training;
- 2 development of a fear-provoking stimuli hierarchy; and
- 3 the systematic graduated pairing of situations in the hierarchy with relaxation.

A vast array of controlled and uncontrolled single-case studies and a number of group studies have evaluated systematic desensitization applied to a variety of phobias. They have established its credibility as a 'probably efficacious' method. However, it is not the method of choice for those phobias, that occur because of a lack of skills, or inadvertent rejection by significant others (King *et al.* 1988). Younger children appear to have difficulty in acquiring muscular relaxation and in being able to image clearly the fear-producing stimuli (Rosentiel & Scott 1977). As a result, *in vivo* desensitization and emotive imagery have become increasingly popular, especially in working with young children. Methods used in children manifesting night-time fears include the use of engaging stories and images of heroic characters to build up positive affect with which fear-eliciting stimuli are gradually interwoven and 'defeated'.

Eye movement desensitization and reprocessing

It has been said that eye movement desensitization and reprocessing (EMDR) has greater rapidity of treatment effects relative to other exposure methods. However, Muris *et al.* (1998) found that EMDR in the treatment of phobic children was less effective than traditional exposure techniques.

Operant methods

The exposure-training described earlier for anxiety reduction has also been referred to as reinforced practice, as developed by Leitenberg & Callahan (1973). It combines a number of operant components. Children's avoidance behaviours are treated by reinforcing graduated approaches to the feared stimulus. The components of reinforced practice are:

- 1 repeated and graduated *in vivo* practice at approaching the phobic stimuli;
- 2 social reinforcement for small improvements;
- 3 trial-by-trial feedback on performance; and
- 4 the therapist's communication to the child of expectations of gradual success.

Panic disorder

Panic attacks and panic disorders are common in adolescence (Ollendick 1998). Little is known, relatively speaking, about these disorders or their treatment for children and young adults. However, adolescents have been successfully treated using CBT procedures (Ollendick 1995) with gains maintained at a 6-month follow-up. Further evaluations of CBT with adolescents, and studies of its application to children, are required.

School refusal

School refusal is a heterogeneous problem, notorious for its conceptual complexities. All of the methods described above have been recruited in the daunting challenge of returning an adamant school-refuser back to the classroom. Fortunately, as attested to by an extensive clinical literature, behavioural strategies, embedded in individually tailored programmes, are highly effective in this task. A functional analysis—both contingency analysis and assessment of the broader functions of school refusal—is central to whichever methods, ranging from operant to cognitive procedures, are used (Blagg 1987; Kearney & Silverman 1990; King *et al.* 1995; Elliott 1999).

Blagg & Yule (1984) compared the effectiveness of family-based behaviour therapy (FBT), a hospital-based multimodal inpatient programme (MIT), and home tuition/psychotherapy (HT/P). FBT (taking, on average, 3 weeks and about 6 sessions) led to a far more rapid resolution of school attendance difficulties associated with school phobia and separation anxiety than the MIT and HT/P conditions (both taking, on average, 1 year). The psychotherapy programme, involving daily tuition, fortnightly individual psychotherapy and concurrent parent counselling, did least well. At 1-year follow-up 93% of the FBT children were successful in returning to school, compared with 38 and 10% for the MIT and HT/P programmes, respectively.

Post-traumatic stress disorder

Almost all treatment strategies for post-traumatic stress disorder (PTSD) focus on re-exposing the individual to traumatic

cues under safe conditions, so as to encourage approach behaviour in addition to emotional processing of traumatic memories. Systematic desensitization, imaginal and *in vivo* exposure methods are vital components incorporating reparative and mastery elements. Methods for treating PTSD are described in detail by Smith *et al.* (1998) and Joseph *et al.* (1997); a CBT package incorporating prolonged therapeutic exposure, cognitive restructuring, and work with parents is, in their opinion, the treatment of choice for PTSD in childhood. King *et al.* (1999) evaluated the efficacy of child and caregiver participation in the CBT treatment of 36 sexually abused children aged 5–17 years who were suffering from PTSD. They reported significant improvements in PTSD symptoms and self-reports of fear and anxiety compared with controls. Maintenance of improvements was evident at a 12-week follow-up. In general, the involvement of parents did not enhance the efficacy of CBT. As is generally observed, there remains much research to be conducted on this disorder.

Obsessive-compulsive disorder

Studies of the results of using behaviour therapy for the once seemingly intractable symptoms of obsessive-compulsive disorder (OCD) have established its pre-eminence in work with adults (Foa & Meadows 1997). Despite less systematic evaluative research on children and (particularly) adolescents, it is probably fair to arrive at a similar, if guarded, verdict for them (Apter *et al.* 1984; Berg *et al.* 1989).

The essence of the method is that the patient voluntarily confronts the feared object or ideas, either directly or in imagination. At the same time he or she is strongly encouraged to refrain from ritualizing, with support provided by the therapist, and possibly by others (e.g. parents). A compulsive hand-washer may be encouraged to touch an object believed to be contaminated, and then urged to avoid washing for several hours until the anxiety provoked has decreased. Treatment then proceeds on a step-by-step basis, guided by the patient's ability to tolerate the anxiety and control the rituals. A more cognitively based therapeutic perspective emphasizes changing the patient's beliefs and thought patterns. The phenomenology of the disorder incorporates cognitive distortion involving risk appraisal and responsibility (Rachman 1993). It is suggested that obsessions persist as long as such misinterpretations continue. A review of the literature is available in Francis & Gragg (1996) and March & Mulle (1998).

Depression

The need for a broad-based intervention with depressive problems seems to be the conclusion of available studies (Kazdin 1990). Tricyclic medication, behaviour therapy, counselling, psychotherapy and cognitive therapy appear to be the main options, singly or in combination. Depressed patients tend to manifest a high rate of intrusive negative thoughts, including

selective ruminations about past events that were unhappy, thoughts about the hopelessness of the future, and their own helplessness. It would therefore seem plausible as a therapeutic strategy to combine cognitive-behavioural methods (which enhance their self-esteem and self-empowerment) with drugs, where indicated. The evidence certainly suggests that this is indeed the case (Butler *et al.* 1980; Stark *et al.* 1987; Kazdin 1990; Moore & Carr 2000a,b). However, many of the treatment outcome studies on depressed children involve non-referred children manifesting depressive symptoms. When compared with non-treatment controls, cognitive behavioural methods are beneficial in reducing these symptoms. Cognitive restructuring, role-playing, self-control training and problem-solving tend to predominate in these studies, but what the necessary and/or sufficient 'therapeutic ingredients' are in such multiple component programmes remains uncertain (Kazdin 1990). It is also unclear how these approaches would generalize to clinical populations.

When it comes to adolescence, changing life-tasks and levels of cognitive, emotional and social maturity call for age-appropriate developmental perspectives when confronting depression (Reynolds & Coats 1986; Lewinsohn *et al.* 1990). A multimethod approach (usually involving CBT and, not infrequently, medication), both chosen on the basis of a comprehensive clinical assessment, remains currently the most successful way of dealing with adolescent depression.

Disruptive behaviour disorders

Oppositional/non-compliance problems

Problems of disobedience are commonplace in children as they grow up. However, there is a typical developmental progression in which certain children start to show extreme oppositional and argumentative behaviour early in life, and then gradually progress up a figurative pyramid of increasingly more severe patterns of aggressive, nonconformist, disruptive behaviour (Frick 1998). There are prognostic and treatment implications arising from two developmental pathways to the fully fledged condition:

- 1 the children mentioned above (with childhood onset conduct disorders); and
- 2 a substantial number of young people who begin showing antisocial behaviour as they approach adolescence, with little or no history of oppositional behaviour during childhood.

The young people who begin showing conduct problems in adolescence are less likely to persist in their antisocial behaviour in adulthood (Farrington 1995).

Positive parenting practices, notably appropriate and timely transactions between mothers and their young children, are the key to a child's willingness to comply with the demands of the socialization process (Dix 1991). Failure is costly to parents and a blight, in the long run, on the lives of seriously uncontrolled children who suffer from oppositional-defiant disorder (Loeber &

Hay 1997; Herbert 2000). Here then is a powerful incentive to intervene early with effective remedial or preventive programmes.

Oppositional-defiant disorder

Positive parenting is commonly assessed by behaviour therapists within the framework of reinforcement theory: the provision of information, attention or approval presented following the child's prosocial actions, but withheld following inappropriate actions (Herbert 1987b). Those with reasonably obedient children give more so-called alpha commands that are characterized by being specific and direct, given one at a time and followed by a wait of 5 s. Parents of children with oppositional-defiant disorder (ODD), who give more negative commands than parents of 'normal' youngsters, can be taught to use these alpha commands rather than their ineffectual beta variety which include chain commands, vague commands and question commands (Forehand & McMahon 1981).

Developmental theorists emphasize a more general influence on socialization drawn from social attachment theory, namely the concept of 'responsiveness'. Behavioural theorists have interpreted this construct within an expanded reinforcement framework (Wahler & Megginis 1997). There is experimental evidence indicating the weakness of maternal praise as a positive reinforcer for compliance from children with conduct problems. Wahler & Megginis (1997) are of the opinion that the potential impact of maternal feedback is inherently governed by the mother's general responsiveness, and that praise and mirroring are simply components of this attribute. It is suggested that the dual operation of specific positive reinforcement (praise) and responsive feedback are required in reducing non-compliance in children, with or without more serious conduct problems. As yet no proven method for encouraging responsiveness is available. However, programmes attending to the needs of parents alongside discussion of the needs of their children show some promise (Herbert & Wookey 1998).

Mealtime and bedtime difficulties

Oppositional mealtime activities that cause concern are refusing food, fiddling with it, leaving the table, producing a tantrum, crying and complaining. The effectiveness of a range of behavioural treatment procedures has been demonstrated for reducing such disruptive activity and the duration of meals, while increasing food intake (Ireton & Guthrie 1972). Serketich & Dumas (1996) conducted a meta-analysis of over 100 studies of behavioural parent training and found it a highly effective intervention for childhood oppositional behaviour problems.

Behavioural management techniques applied to settling and waking difficulties have been found to be successful in 90% of children between 1 and 5 years old (Richman *et al.* 1985). Douglas & Richman (1984) produced a manual for bedtime problems that has been successfully used by health visitors and in community clinics. Individual or group behavioural pro-

grammes attending to both antecedents (commands) and consequences (reinforcement) in the ABC equation illustrated in Fig. 53.1, produce better generalization of effects. Attention to each side of the equation provides the parent with constructive skills (Forehand & McMahon 1981).

Guidelines for setting up behavioural programmes for the oppositional/non-compliance problems associated with mealtimes and bedtime difficulties, respectively, have been prepared for practitioners and parents by Herbert (1996a).

Conduct disorders

Children with conduct disorders, with their extremes of aggressive antisocial behaviour, are capable of wreaking havoc in their own and other people's lives, and their prevalencies are probably on the increase, creating a need for a therapeutic service that outstrips the resources available (Herbert 1995). A large percentage of the 'early starter' children with conduct problems are likely to remain circulating through the revolving door of the social services, mental health agencies and criminal justice systems (Loeber & Hay 1997). Many different types of intervention have been applied to children and adolescent youths with conduct disorders. But, as Kazdin (1998) observed, little outcome evidence exists for most of the techniques. Four treatments, in his opinion, with the most promising evidence to date are problem-solving skills training, functional family therapy, multisystemic therapy, and parent management training (also known as behavioural parent training).

Behavioural parent training

With regard to behavioural parent training (BPT), the developmental literature provides some useful guidelines to supplement behavioural theory in parent consultation work. Factors that facilitate prosocial behaviour include a rich supply of positive reinforcement for positive behaviour, 'fuelled' by a strong attachment to a caregiver with whom a child can therefore identify; firm moral demands made by parents upon their offspring; the consistent use of sanctions; techniques of punishment that are psychological rather than physical (methods which signify or threaten withdrawal of approval); and an intensive use of inductive methods, such as reasoning and explanations.

Today there is less emphasis in BPT on the contingency management of specific target behaviours, and more on broad principles of child management. Attention is also paid to enhancement work on the interpersonal interactions of members of the family, the perceived efficacy of parents and the marital relations which are often fraught. Parents, individually or in groups, are encouraged and guided to increase their positive interactions with their children through the use of play and other special/quality time activities, and by looking for the positives in their actions. They are encouraged to reinforce their children's appropriate behaviour with praise, encouragement and other

rewards; also to introduce the child to behaviours that are either intrinsically reinforcing, or which make previously unattainable reinforcements available. Homework practice tasks help parents to limit unnecessary commands, to increase the clarity of their house rules and the consistency with which they follow them through. Parents are guided to implement brief mild non-aggressive sanctions, such as judicious ignoring, time-out, loss of privileges and logical consequences. They are provided with the means of understanding and analysing problematic behaviour; in addition, they role-play negotiation and problem-solving strategies in order to avoid what were previously corrosive confrontational situations. The techniques studied and rehearsed in groups include planned ignoring, time-out, alpha commands, praise, differential attention, response-cost, logical consequences, and use of tokens and recording charts. Parents are encouraged to monitor their children's activities effectively (Dishion & McMahon 1998).

Behavioural parent training programmes have been put under the microscope of many validation studies (for reviews of highly successful applications see Webster-Stratton 1991; Kazdin 1998; Brestan & Eyberg 1998). Brestan & Eyberg (1998), applying rigorous evaluative criteria, identified two particularly 'well-established' treatments: Patterson & Gullion's (1968) *Living With Children* programme, and Webster-Stratton's (1988) Group Discussion Video Modelling Programme, the latter providing videotapes with examples of multiethnic American parents with their 'problematic' children 'doing it right' and 'getting it wrong', the vignettes leading to group discussions and homework exercises.

Other behaviourally based approaches include behavioural marital therapy (Jacobson & Margolin 1979; Baucom *et al.* 1998); behavioural casework (Herbert 1993), and treatment foster care (Chamberlain 1994). Cognitive marital therapy focuses on helping couples challenge negative beliefs and attributions in their relationships. There is evidence that low general marital satisfaction is correlated with a variety of child outcomes, in particular for conduct problems of childhood (Sanders 1996; Browne & Herbert 1997; Webster-Stratton & Hammond 1999). Dadds *et al.* (1987) demonstrated that although couples who were high or low in marital discord showed similar levels of improvements with child management training, couples high in marital discord had greater difficulty maintaining the gains made unless they received partner support training as well. This is where behavioural marital therapy or couple therapy may be useful. Meta-analyses of behavioural and cognitive marital therapy indicate that the average treated case fares better than between 79 and 83% of untreated controls (Hahlweg & Markman 1988; Dunn & Schwebel 1995).

Operant methods

Behavioural approaches using reinforcement of desired behaviour in the classroom and home have been repeatedly demonstrated to lead to beneficial changes, albeit usually short-term and situation-specific, in disruptive behaviour, aggression, poor

co-operation with peers and poor school attendance (Patterson 1982). Academic performance also responds to classroom reinforcement programmes (O'Leary & O'Leary 1977; Goldstein 1995).

Direct work with adolescents

The issue of parent training gives rise to a conceptual boundary problem. At what stage in childhood-onset conduct disorders does the practitioner shift the therapy paradigm from the so-called triadic model that involves caregivers as primary mediators of change to one that more appropriately deals with an individual in his or her own right (as in dyadic or group-based cognitive behaviour therapy)? A growing number of theorists acknowledge the significance of the cognitive representation of events and experiences in the development of conduct and delinquent disorders (Hollin 1990; Kendall & Hollon 1994).

Children and adolescents with these disorders tend to have difficulty anticipating consequences of their behaviour, attribute other's behaviour in ambiguous situations to their hostile intentions and underperceive their responsibility for early stages of dyadic conflict. These distortions are addressed in individual or group work with cognitive behavioural strategies (Herbert 1998b). For example, there are anger-management programmes designed specifically for adolescents (Feindler & Ecton 1986). Most of them consist of three stages, cognitive preparation, skill acquisition and application training, the intention being to lower the likelihood of aggressive behaviour by increasing awareness of the signs of incipient hostile arousal and by encouraging self-control.

Attention deficit hyperactivity disorder

There are several commonly used approaches in dealing with ADHD, a problem often associated (comorbid) with conduct disorders in childhood:

- 1 creating and maintaining a well-structured ('prosthetic') environment to compensate for poor stimulus control;
- 2 behaviour therapy (notably operant techniques to shape up prosocial behaviour);
- 3 CBT to enhance poor information processing and self-control; and
- 4 stimulant medication, which can be combined with each of the above.

Multiple problems are the rule, and demand the sort of multimodal assessment and treatment that, in turn, requires co-operation between child psychiatry, psychology, paediatrics and education (Richters *et al.* 1995). The heterogeneity of ADHD makes it imperative to assess a variety of underlying causes, such as family conditions (physical, social, psychological), attachment difficulties, emotional problems, learning disabilities and physical impairments.

Behavioural parent and teacher training programmes, and structured programmes of contingency management, are the main and most successful psychosocial interventions, especially

when combined with medication (methylphenidate). Nolan & Carr (2000) have reported a review of 20 multimodal programmes. A CBT component usually entails a stop-think-do training programme conducted by the therapist or parents. There have been many favourable reports promoting this method (Braswell & Bloomquist 1991; Kendall 1994; Kendall & Gosch 1994). See Barkley (1995) and Taylor (1997) for parent-friendly guides to the management of this daunting problem.

Ecological approaches

Structural causes that undermine parenting and family life, such as poor housing, inner-city deprivation and alienation, contribute to the development of conduct disorders. An example of a broadband ecological approach is the Early Alliance Programme conducted by Dumas *et al.* (1999). They describe an integrated set of four preventive interventions which are delivered across multiple domains of functioning and across multiple social settings, designed to promote competence and reduce risk of early-onset conduct disorder, substance abuse, and school failure (see also Borduin *et al.* 1995 on the multisystemic treatment of juvenile offenders).

Delinquency

Although not all young persons adjudicated as delinquent suffer from conduct disorders, nor the reverse, there is a substantial overlap and the antisocial groups treated by behavioural methods tend often to merge. Major reviews of behavioural interventions suggest that individual behaviour therapy is not a popular option for practitioners dealing with offender populations. However, there have been reports of limited successes (Herbert 1987b; Kazdin *et al.* 1992).

Therapists have drawn on communication skills as one of their treatment targets within multimodal interventions. The package might involve communication training, feedback, positive interruptions, problem-solving and decision-making skills, providing rationales, happy talk, positive requests, non-blaming communication, negotiation skill-training, didactic dialogue and family games. The behavioural methods are likely to include self-correction, overcorrection, positive practice, observation and recording behaviour, self-management, cognitive restructuring, positive reinforcement, differential attention, response-cost, time-out, and the use of symbolic rewards (tokens and points). Contracts are drawn up defining goals and mutual obligations (Alexander & Parsons 1982). Among the best known multimodal cognitive-behavioural programmes is Aggression Replacement Training (ART; Glick & Goldstein 1987), which includes three main approaches to changing behaviour: structured life-skills learning (social skills and social problem-solving), anger control training and moral education. Outcome studies indicate that the programmes have led to improved skills, improved self-control and more acceptable institutional

behaviour. A programme based on ART by Leeman *et al.* (1993) was successful in improving conduct problems and reducing recidivism.

There are encouraging demonstrations on a variety of quantitative and qualitative outcome measures (notably behavioural indices, cognitive functioning, family relationships, and different academic and social skills) that short-term changes can be achieved by using techniques like these. However, there is less room for optimism about the longer term benefits and, in the case of delinquent youngsters, about any significant generalization from general disruptive behaviour to specifically offending activities.

Developmental problems

Enuresis

Butler (1998) comments on one of the reasons why enuresis provides such an interesting challenge: the fact that with its clearly defined dependent variable (a 'cure' rather than the usual 'improvement' criterion of success) it offers an ideal opportunity to test out particular theories and models. The evidence for the superiority of the urine alarm method (with rates of remission between 80 and 90%) over no treatment and other treatment control procedures is well documented for nocturnal enuresis (Doleys 1977, 1978). Doleys' (1977) review of data, based on over 600 subjects, revealed an average relapse rate of 40%; but nearly 60% of these returned to continence after booster sessions. Less specific psychotherapeutic interventions, such as individual or family therapy, have proved to be no more effective than no-treatment control conditions or other forms of treatment (Ondersma & Walker 1998). However, a meta-analysis by Houts *et al.* (1994), in reporting that the highest success rates for psychological programmes were those using urine alarms, found them no more effective than the medical treatments (e.g. tricyclics) at post-treatment, although they were significantly superior at follow-up.

Butler (1998) provides a helpful review of the advantages of the enuresis alarm, and some of the practical difficulties that hinder the realistic expectation of success. Many clinicians prefer to begin treatment with the use of incentive sticker charts, adding components such as the urine alarm if the child does not respond. A detailed description of behavioural and combined methods of treating nocturnal and diurnal enuresis has been prepared for practitioners and parents by Herbert (1996b).

Encopresis (soiling)

Encopresis has been treated by a variety of methods, but not with comparable success. Family therapy has not proved useful without the addition of behavioural, dietary and/or a medical intervention (Walker 1995). Individual psychotherapy has not

been demonstrated to be more effective than no therapy (Doleys 1977). Doleys (1978), in his review of treatment studies, reported that 93% of cases were successfully treated by the use of behavioural methods. Researchers have recommended the combination of behavioural techniques and laxatives in the common 'retention with overflow' cases of encopresis (Firestone & Koplewicz 1992; Herbert 1996b). This short-term treatment protocol involves an assessment of possible fear elements (constipation may make toileting painful), an initial clean-out phase (usually with laxatives), psychoeducational input, scheduled toilet sittings, cleanliness training, mild penalties for inappropriate behaviour, and positive reinforcement of appropriate toileting behaviour (e.g. for 'effort') and for not soiling. Fibre intake and other dietary issues are aspects of treatment (for reports of successful programmes see also Stark *et al.* 1990; Nolan *et al.* 1991).

Psychophysiological disorders

Anorexia and bulimia nervosa

The operant paradigm generally applied to this potentially life-threatening disorder includes, *inter alia*, restricting the anorexic patient to his or her room and making activities and privileges contingent on weight gain. Those who advocate operant methods claim that they produce faster and larger weight gains during hospitalization than do other medically or psychiatrically orientated techniques. Some of the most painstaking outcome studies have investigated operant procedures aimed at rapid weight restoration. What emerges (see review by Harris & Phelps 1987) is that behavioural interventions focusing solely on this goal are not sufficient to accommodate the many-sided subtlety and complexity of this puzzling condition, and are not particularly effective in the longer term. Short-term gains may be made more durable by interventions that address issues such as interpersonal problem-solving and the dynamics of low self-esteem (e.g. cognitive-restructuring, conversational therapy). Systematic desensitization has been used to mitigate the anorexic individual's extreme fear of obesity (Ollendick 1979). Ollendick combines systematic desensitization with cognitive restructuring (see also Garner & Bemis 1985).

Treatment approaches to bulimia have involved group therapy (Boskind-Lodahl & White 1978), interpersonal therapy (Fairburn 1995) and behaviour therapy interventions (Fairburn 1980, 1981; Linden 1980; Mizes 1995). Results indicated that bulimic individuals exhibiting the most severe symptoms over the longest periods of time were (unsurprisingly) the least responsive to treatment. Cognitive-behavioural treatments appear to be the most effective, with little relapse after improvement (see review by Mizes 1995). In general, patients reduce their frequency of bingeing and purging by 75–80%, with 30–40% ceasing altogether to binge and purge.

Child abuse

Azar & Wolfe (1989) have described several factors that make the treatment of children with abusing families difficult. One is the tendency to focus on eliminating a circumscribed problem when, in fact, the abusive events are highly complex (Wolfe & Birt 1995; Babiker & Herbert 1998). Interventions with parents usually involve elements of self-control training (e.g. anger management), problem-solving, and the encouragement of proximity-seeking and attachment behaviour (Iwaniec *et al.* 1988). Of necessity, they usually need to tackle wider systemic (family) issues. The treatment targets might include the following.

- 1 *Characteristics of the parents:* alcohol abuse; deficits in bonding and child-rearing skills, faulty expectations of the child; low self-esteem; ineffective communication; poor reinforcement skills; punitive attitudes, and failure to supervise the child.
- 2 *Characteristics of the child:* problems involving hyperactivity, non-compliance and aggression; incontinence; inappropriately inflexible responses to different situations; disability.
- 3 *Unique interactions of the child and his or her parents:* coercive/aversive communications; mutual avoidance; inappropriate, inconsistent or non-contingent reinforcement/punishment.
- 4 *Significant others in the family:* interference, subversion of maternal authority by grandparent; sexual/physical abuse by relative/lodger, etc.
- 5 *Environmental factors:* poverty, overcrowding, social isolation.

Specific techniques to implement these goals are detailed in Herbert (1987a, 1993) and Deblinger & Heflin (1996). The findings from several studies of BPT in child-protection work have indicated improved child care and management, and/or a reduction in the reoccurrence of child abuse. Wolfe & Wekerle (1993) concluded on the basis of a review that cognitive-behavioural approaches enjoyed a consistent success rate at helping maltreating parents improve several of the conditions that predispose them to abusive and neglectful treatment of their children. All such programmes produced improvements in parenting skills; for example, in their ability to interact positively with their children and control behaviour without over-reliance on negative physically coercive child management techniques. Reassessment after treatment and at follow-up (generally 3 months–1 year) tended to support the maintenance and generalization of these changes. Abuse or neglect did not recur among treatment families in those studies reporting significant outcome data.

King *et al.* (1999) made the point that among the plethora of psychological symptoms that appear in the wake of child sexual abuse, several are characteristic of PTSD. Their review of the cognitive-behavioural treatment of sexually abused children, drawing on case studies, open clinical trials, multiple baseline investigations and randomized clinical trials, suggests that the efficacy findings are ‘encouraging’.

The characteristics of the dysfunctional thoughts of abused children that lead to anxiety are that they repetitively construe

events as harmful or dangerous, that they cannot be ‘reasoned away’, and that they become readily attached to a wide range of stimuli that can elicit them. Jehu (1992) has demonstrated clearly how important negative schemas are in the long-term sequelae of sexual abuse, explaining why some young females develop severe anxiety disorders that persist into adulthood, while others remain relatively unscathed. Here would seem to be the opportunity to do remedial and/or preventive cognitive-behavioural work with maltreated children and adolescents.

Stevenson’s (1999) review of meta-analytic studies of controlled trials for mental health treatments in child abuse cases indicated that the mean effect sizes have a range from 0.45 for the impact of family therapy on family interaction to 0.96 for the efficacy of behavioural treatments (Stevenson 1999, p. 96). He states that ‘. . . the same treatments that are most efficacious (behavioural and cognitive methods) and least efficacious (non-behavioural methods) with adults (Shapiro & Shapiro 1982) are also, respectively, the most and least efficacious for children’ (Stevenson 1999, p. 97).

Can we simply treat the problems of abused children as complex disorders regardless of their particular causal path? Holmes’ (1995) finding that, within a group of adults being treated for anxiety and depression, the various psychological therapies being applied were very effective for patients without a history of abuse but ineffective for those with such a history makes such an assumption somewhat questionable.

Discussion

Unanswered questions

There are many content and process issues in behavioural work that require clarification by future researchers. The questions are not only concerned with the effective strategies in behavioural therapy, but also the impact of treatment style of working. Does a collaborative style of working achieve better and longer lasting results than the expert model? And, if so, under what circumstances and by utilizing what particular strategies? What are the sufficient and necessary therapeutic elements that make a particular method effective? What can be done to mitigate the learned helplessness of some patients or overcome resistance to therapy? What is required to reduce high attrition rates or modify intractable attributions that effectively exculpate parents from accepting that they have any influence on, or responsibility for, their offspring’s actions? These are but a few of the issues that await answers.

Status of behavioural therapy

We have seen examples of the wide range of methods, and the diversity of child and family problems, to which contemporary behavioural therapies are applied. They incorporate, in addition to the original aetiologically simplistic conditioning theories,

procedures and principles derived from more complex conceptual models, such as social and developmental psychology and cognitive science (Kazdin 1978).

Nevertheless, behavioural therapy has maintained a surprising degree of cohesiveness, perhaps because of its steadfast commitment to the importance of empirical validation. The behavioural therapies have been investigated and evaluated more intensively than any other psychological interventions, but it is a moot point as to which ones meet all the requirements set out in Paul's (1967) criteria. As he describes them: 'What treatment, by whom, is most effective for this individual with that specific problem, and under which set of circumstances' (Paul 1967, p. 111). Yet Taylor & Biglan (1998) considered that behavioural family therapy methods are, along with other behavioural interventions, highly compatible with the emerging trends towards time-limited treatments which are empirically supported and which painstakingly document programme gains (Taylor & Biglan 1998, p. 49; see also Carr 2000 and Target & Fonagy 1996). Comparisons with client-centred methods, psychodynamic therapy, systemic and structural family therapy, Adlerian methods, and Parental Effectiveness Training indicate the advantage of giving priority to behavioural parent training and behavioural family therapy (Webster-Stratton 1991; Brestan & Eyberg 1998). The consideration paid to a child's social and interpersonal context (vital features in parent management training and behavioural family therapy, when dealing with externalizing disorders) appears to be equally significant in the treatment of internalizing (e.g. anxiety) conditions. Here there is also an encouragingly high success rate (Kendall 1998; Ollendick *et al.* 1998).

Future directions

Kazdin (1997) acknowledged that among the important questions yet to be addressed (his remarks apply to the conduct disorders but they have wider clinical relevance) are the magnitude of change and durability of treatment effects. These give rise to issues about how to evaluate treatment and about the status of any particular intervention. As he put it:

We cannot yet say that one intervention can ameliorate conduct disorder and overcome the poor long-term prognosis. On the other hand, much can be said. Much of what is practised in clinical settings is based on psychodynamically orientated treatment, general relationship counselling, family therapy and group therapy (with antisocial youths as members). These and other procedures, alone and in various combinations in which they are often used, have not been evaluated carefully in controlled trials. Of course, absence of evidence is not tantamount to ineffectiveness. At the same time, promising treatments have advanced considerably and a very special argument might be needed to administer treatments that have neither basic research on their conceptual underpinnings in relation to conduct disorder nor outcome evidence from controlled clinical trials on their behalf. (Kazdin 1997, p. 175).

One might add that there is an ethical imperative that patients should not be exposed to invalid or unvalidated therapies.

Kazdin (1988) stated that to ensure progress, those processes that are considered to be responsible for therapeutic change ought to be assessed directly and to a high level of specificity, and codified ideally in treatment manual format. Replication in research and clinical practice requires knowing precisely the details of a treatment programme. There has to be a balance of clear manual guidelines, possibilities for improvisation, and space for individual therapist differences: a challenging task. Kazdin (1998) is of the opinion that difficult though it may be, it would be a mistake to think that facets of treatment and their implementation ought not (or cannot) be made explicit and codified. In today's health and other services, with their growing demand for empirically supported treatment procedures, simultaneous efforts are needed in order to educate practitioners and policymakers about what constitutes proper empirical validation (Taylor & Biglan 1998).

Most outcome research involves demonstrations of efficacy rather than demonstrations of effectiveness or clinical utility. Efficacy studies are directed at establishing whether a particular intervention works (e.g. reduces symptoms, increases adaptive functioning) and they are usually conducted under tightly controlled conditions. Effectiveness, or clinical utility studies, are directed at establishing how well a particular intervention works in the environments, and under the conditions, in which treatment is typically offered (Lonigan *et al.* 1998). Such studies, unfortunately, are in short supply.

Search for integrative concepts

The search for theoretical coherence for contemporary behaviour therapy, with its wide conceptual base, remains unresolved (Power 1991). Kendall & Lochman (1994) claimed that CBTs present a broader convergence of concepts in their rationale than is achieved in most other approaches. They state that: '... they integrate cognitive, behavioural, affective, social and contextual strategies for change... the cognitive-behavioural model includes the relationships of cognition and behaviour to the affective state of the organism and the functioning of the organism in the larger social context' (Kendall & Lockman 1994, p. 844). Where, however, do we find a theoretical framework to integrate the models drawn from various branches of experimental psychology referred to above, or to accommodate ideas from the growing alliance of family therapy, cognitive therapy, psychotherapy, and behaviour therapy? It is not enough simply to link up, without definition, the names (e.g. 'behavioural cognitive psychotherapy') of somewhat disparate approaches. There is a risk that practice degenerates into an atheoretical rag-bag of ad hoc techniques.

A rationale for many practitioners, at its broadest level, derives from the fact that all therapy is about change, and change implies learning. In that sense all therapies contain an element of learning in the form of workable applications. Goldstein *et al.* (1966, p. 63) propose that, whatever else it is, psychotherapy

must be considered a learning enterprise involving specific behaviours, attitudes or even, possibly, a whole new outlook on life. Such an overinclusive definition can be made to explain everything, but predict (as is the case with psychoanalytic theory) nothing. Nor, unfortunately, does it serve to bind together into a theoretically coherent system, the many elements that make up contemporary behavioural practice.

Role of psychotherapy

Because of the remit of this chapter I have not been able to do justice to any of the interventions that come under the rubric of psychotherapy. Reviews of psychotherapy suggest that many of its concepts have been validated, and that it is better than no treatment for a large number of childhood problems (Lee & Herbert 1970; Kazdin 1988; Tuma 1989; Fonagy & Moran 1990; Weisz & Weiss 1993). Traditional psychotherapy is not a natural science, whereas behavioural work differs from psychotherapeutic traditions in finding its origins in controlled laboratory experiments on learning processes (Pavlov 1927; Skinner 1953; Ferster & De Myer 1962) rather than clinical casework (Freud 1916). It is an article of faith for behaviourally orientated psychologists who call themselves ‘applied scientists’ that explanations dealing with complex aspects of human functioning which tend to be more intuitive, literary or semantic than ‘scientific’ hinder the discovery of valid treatment methods.

This argument fails to impress those who are antipathetic to behaviour therapy. A scientific approach to treatment is rejected by some critics as impersonal, political and mechanistic. The putative ethical relativism of behaviour therapists is thought to imply an undue influence on the client towards received societal values. They are also regarded as disingenuous to claim an unswerving commitment to an epistemological model confined exclusively to learning theory (Erwin 1978; Power 1991). Wilson & Evans (1983) found that 22% of a sample ($n=118$) of members of the American Association for the Advancement of Behaviour Therapy formulated three written case-descriptions introducing psychodynamic and intrapsychic terminology.

Systemic thinking

A further objection arises from an obsolete view that behaviour therapy is very much a method of treatment aimed at the individual child, and therefore out of step with current systemic thinking. In fact, the systemic philosophy of family theory has had a significant influence on the development of behavioural practice. It was important for therapists to be more aware of the dynamics of family life, their contribution to the causation of childhood psychopathology, the role of children as family scapegoats (‘symptom-carriers’) and, when formulating the reasons for a member’s behaviour, the fact that a family is more than the sum of its parts. Where non-behavioural family therapy has had modest results in dealing with children’s psychological problems, the addition of a behavioural perspective has enhanced the success rate significantly, notably in dealing with externalizing

(disruptive) disorders (Gurman *et al.* 1986; Webster-Stratton 1991; Herbert 1998c).

What does not work?

Because the frontiers of behavioural therapy are still expanding it is difficult to answer the question: ‘Which problems are not amenable to a behavioural approach?’ The range of problems now tackled has been, and continues to be, broadened by its enlarged theoretical base. In terms of therapeutic process the more directive and performance-orientated style of the behavioural approach may simply not provide an appropriate universe of discourse for those who wish to discuss, in depth and in conversational mode, some personal problem. Given such a case, can judgements about what constitutes a ‘successful’ outcome be defined by conventional clinical criteria? According to humanistic ideologies, which feature often in counselling and psychotherapeutic work, the concerns on which the counsellor and client focus are precisely those excluded from scientific method.

Despite behavioural therapists’ predilection for explicit and objective methods, Sloane *et al.* (1975) found that patients rated them at least as highly on interpersonal factors, such as warmth and empathy, as non-behavioural therapists. Bandura (1969) insists that the emphasis of behavioural therapy on explicit negotiated objectives and self-direction as therapeutic goals gives patients access to self-empowering knowledge and skills, which also represent a liberating therapeutic philosophy. A collaborative therapeutic process, as described by Webster-Stratton & Herbert (1994), underpins such a viewpoint.

Conclusions

This chapter has described contemporary behavioural therapies, bringing them (with their developmental, cognitive and systemic elaborations) up to date from their early behaviourist origins. It is now possible to claim with some confidence that in relation to child and adolescent mental health problems, such as anxiety, depression, ODD, conduct disorders, ADHD, OCD, and developmental problems such as enuresis and encopresis, behavioural programmes are among the favoured interventions. For these and other conditions (notably learning disability, anorexia and autism) there are circumstances, following a comprehensive assessment, where a multimodal or multisystemic programme is likely to be enhanced by a behavioural component. There is, inevitably, a continuing need for good programme designs based, because so many clinical child disorders are heterogeneous in nature, on multimodal assessment procedures and appropriate (quantitative and qualitative) outcome measures. Other requirements are built-in strategies to facilitate temporal and other forms of generalization.

Behavioural therapy research and service delivery programmes are conducted too often by inappropriately trained or minimally experienced individuals. Such a question mark over programme and professional ‘integrity’ reflects the need for

agreed standards of competence in behavioural work, which means, in turn, the establishment of accredited multidisciplinary training courses. Some do exist, but they are few in number and do not meet the need for nationally organized training programmes.

The nature of systemic family work involves a partnership with family members, much discussion and debate. The inner life and subjective experiences of caregivers and children (beliefs, attributions, attitudes) are acknowledged to be important in the assessment and treatment of problems. In a very real, in informal sense, parents use behavioural methods in order to teach, influence and change the children in their care. Although parents are unfamiliar with the 'small print' and terminology of learning theory, behavioural methods, when explained carefully, do tend to have face validity for them. For those who believe in the advantages of a partnership model in work with families, this demystification of the therapeutic process is welcome.

For the author, behavioural therapy is a 'craft', an amalgam of applied science and art. There is, in fact, an impressive empirical knowledge base. However, the application of science is only part of the story. Because of the exigencies of clinical work it requires the 'spirit' of scientific method, rather than the restrictive 'letter' of what might be called 'scientism'. There should be room for creativity and divergent thinking. There is the art of teaching children, the skill of devising and using imaginative materials to capture their interest, and by means of a shared therapeutic alliance, the intuition to unravel complex problems with parents and their offspring, and the empathy to boost their confidence and self-esteem.

Cognitive-behavioural Approaches to the Treatment of Depression and Anxiety

David A. Brent, Scott T. Gaynor and V. Robin Weersing

Introduction

In this chapter, we review the efficacy of cognitive-behavioural therapy (CBT) for the treatment and prevention of child and adolescent depression, anxiety, post-traumatic stress disorder (PTSD), and obsessive-compulsive disorder (OCD). In general, our review is restricted to randomized controlled trials, but when treatment development is at a relatively early stage, as is the case in the treatment of PTSD and OCD, open trials are also included. Prior to reviewing the extant literature, we provide some background on the development of CBT, the common elements to cognitive-behavioural treatments, some general principles in the administration of CBT, and developmental considerations in the use of this approach for children and adolescents.

General description

Cognitive-behavioural therapy includes a wide range of therapeutic techniques predicated upon the principle that there is a close interrelationship among thoughts, feelings and behaviour. Modification of distressing feeling states and problematic behaviours can therefore be accomplished by alteration in patterns of thinking that are associated with vulnerability to disorder. These pathogenic forms of thinking are often termed ‘cognitive distortions’ or ‘automatic thoughts’. Most cognitive therapies identify cognitive distortions through some type of mapping procedure, by which one identifies the association of cognitions with certain affects and expectations, and then attempts to determine if those cognitions are grounded in reality or, rather, represent distortions. By understanding expectable patterns of distortions, anxious or depressed individuals can learn to anticipate typical responses to a given situation, and be prepared to counter those distortions with more rational and adaptive self-talk, coping and countervailing ideas.

Cognitive-behavioural therapy model of depression

Beck, one of the founders of cognitive therapy, proposed that depression was manifested by a negative cognitive triad: distorted thinking about oneself, about the future, and the world (Beck *et al.* 1979). Certainly, in adults, prospective studies have demonstrated the power of hopelessness about the future to predict sui-

cide (Beck *et al.* 1985) and, in children, hopelessness predicts drop-out from therapy (Brent *et al.* 1998). Moreover, there are studies indicating that cognitive distortions, more broadly, are a risk factor for the development of depressive symptomatology in children and adolescents (Garber & Hilsman 1992; Garber *et al.* 1993; Lewinsohn *et al.* 1994). On the other hand, it has been argued that cognitive distortions, while useful to track clinically, are simply epiphenomenal to psychopathology. Murphy *et al.* (1984) compared the change in hopelessness in depressed adults treated with a tricyclic antidepressant to those treated with CBT. Pharmacotherapy was just as effective as CBT in relieving hopelessness, a cognitive ‘cause’ of depression. A recent study assessing the specificity of depressotypic cognitions to depression in adolescents concluded that pessimistic thinking and helpless attributional style were ‘weakly’ specific to depression; depressotypic cognitions were most strongly associated with the depressed group, but were also significantly associated with the non-mood disordered (clinical) control group. No significant associations were noted with the non-disorder control group (Lewinsohn *et al.* 1997).

The behavioural component of CBT has several origins. For the treatment of depression, this component is based on the recognition that a psychomotor-retarded patient lying in bed ruminating is not going to recover unless his or her level of activity is restored, the sleep cycle is normalized and the person begins to interact with his or her surroundings in an enjoyable way. In fact, increase in pleasurable activities is correlated with decrease in depression symptomatology (Lewinsohn *et al.* 1996). Subsequently, the ‘behavioural’ component has broadened to include a range of structured interventions that impact skills in child contracting, negotiation and problem-solving, social skills and assertiveness training, and in emotional regulation and distress tolerance.

Cognitive-behavioural therapy model of anxiety

In anxiety disorders, cognitive distortions appear to focus more on overestimation of the probability of unlikely but dangerous events, general perceptions of the world as risky and unsafe, and the inability to cope with these threats. It is hypothesized that individuals experience anxiety when certain situations trigger overly fearful thoughts, accompanied by defeatist self-statements and further automatic danger-focused cognitions. This cycle spirals pathogenically because such individuals lack skills to cope with anxious thoughts and feelings, and because

significant others in the environments (e.g. parents) may actually model poor coping behaviour and encourage avoidance.

With regard to anxiety disorders, PTSD and OCD, the behavioural component is coequal to cognitive restructuring, and involves exposure to feared thoughts, situations and sensations, and prevention of avoidance or compulsive responses. In general, the initial phases of treatment for the anxiety disorders include generating a graded hierarchy of anxiety-provoking experiences and learning techniques to manage and contain anxiety. This is followed by gradual exposure to the hierarchy of increasingly anxiogenic situations while harnessing cognitive techniques for anxiety management. In addition, parents can be trained in behaviour management in order to help facilitate courageous behaviour and extinguish anxious behaviour.

Cognitive-behavioural therapy structure and therapeutic stance

What are the elements of CBT that distinguish it from other therapeutic approaches? First, the treatment is goal-orientated, focused and time-limited. One of the most critical tasks for a cognitive-behavioural therapist is to help the patient and family operationalize their goals. The therapist then works with the patient to achieve these agreed goals. The beginning of every session in CBT starts with the generation of an agenda. This agenda helps to guide the patient and therapist as to the topics and priorities for a particular treatment session.

Secondly, the therapist is active and directive. Passivity will lead to certain defeat with depressed individuals who, without prodding and structure, have difficulty setting or pursuing therapeutic goals. Similarly, directiveness is required for the child with school refusal, or the individual with social phobia who avoids every novel social situation. Given the central role of avoidance in the genesis of anxiety disorders, it is critical for the therapist to gently insist that exposure take place.

The third characteristic of CBT is that of collaborative empiricism, meaning that the therapist and patient examine issues and the evidence supporting a particular viewpoint or strategy, collaboratively. In many CBT models with children, the therapist is introduced as a ‘coach’. The therapist is actively didactic and socializes the patient to the model so that the patient understands exactly what is expected to happen and the rationale for each particular intervention. Collaborative empiricism also means that concepts are operationalized in a concrete manner, by asking questions like, ‘How will we know when you’re better and we’ve reached our goal?’

Adaptation of cognitive-behavioural therapy to younger populations

There are several elements of cognitive therapy that require adaptation for its use in younger populations. Children’s experiences are embedded in a family context, and they rarely seek treatment on their own (Weisz *et al.* 1998). Therefore, involvement of the family is critical in socialization, education and goal-

setting, all of which have the potential to reduce the drop-out rate dramatically (Brent *et al.* 1993). For younger children, involvement of the family members may be helpful to reinforce, or actually deliver, CBT (Barrett *et al.* 1996; Cohen & Mannarino 1996a). There is evidence that a family anxiety management component greatly enhances CBT outcome for younger anxious children (Barrett *et al.* 1996). Moreover, relief of parental distress is important, in so far as parental emotional difficulties may interfere with otherwise credible treatments and result in poor outcome (Cohen & Mannarino 1996a,b, 1998a; Brent *et al.* 1998; Southam-Gerow *et al.* 2001). In addition, related familial constructs, such as discord, lack of support and lack of cohesion, may interfere with the outcome of otherwise efficacious treatments (Cohen & Mannarino 1996b; Kolko 1996; Brent *et al.* 1998; Birmaher *et al.* 2000).

Younger populations show a wide variability of developmental maturity. This makes it incumbent upon the therapist to assess cognitive development, and to explain the principles and concepts of treatment in language that the child can grasp. Children may also lack the ability to decentre, and take the perspective of others—a key element of CBT and a challenge in adapting CBT for very young patients (Weisz & Weersing 1999). A related issue is the importance of differentiating between a cognitive distortion and a cognitive deficit. A child may complain about having difficulty in school because of depression, but alternatively, he or she may have a learning disability. Another patient may complain about lacking friends because of the cognitive distortions accompanying depression, because of actual loss of friends as a result of social withdrawal and irritability, or because of a deficit in the social skills essential to the development and maintenance of intimate friendships.

Children and adolescents often show attendant difficulties with decision-making, problem-solving, emotional regulation and impulsivity, in addition to mood and anxiety disorders. In fact, poor decision-making and problem-solving often get these patients into difficulties that lead to increased anxiety, depression and self-destructive behaviour such as self-cutting or suicide attempts. Therefore, it is important to assess and remediate these difficulties, because otherwise these patients will continue getting into interpersonal difficulties with painful and often self-destructive consequences.

It is rare for a child or adolescent to initiate a request for treatment. Instead, treatment is usually requested by the parent, the school or a referring health professional. It is vital to try to educate and socialize the young patient as to the nature of his or her illness, the nature of psychotherapy in general, and CBT specifically, and to address any concerns and distortions that might sabotage engagement in a successful working alliance. It is important to recognize the adolescent’s need for autonomy, which can be reflected by telling the patient that the goal of treatment is to teach him or her how to become his/her own therapist. The collaborative empirical approach is usually quite well received by most adolescent patients, as it requires that the patient take a major role in setting the agenda and determining the goals of treatment. At the same time, parents must be involved and in-

formed; the therapist must avoid getting trapped into promises of confidentiality that not only cannot be kept, but do not constitute good care.

Cognitive-behavioural therapy of youth depression

In this section, we review controlled clinical trials to treat child and adolescent depressive disorders. As previously discussed, the defining features of cognitive-behavioural approaches toward youth depression have focused on the identification and modification of negativistic thought patterns, and improvements in disturbed behavioural self- and social-regulation skills thought to underlie the aetiology of depression. In youth depression treatment, these foci have been addressed through the application of cognitive and behavioural techniques such as:

- 1 mood monitoring;
- 2 cognitive restructuring;
- 3 behavioural activation, pleasant activity scheduling, and goal-setting strategies;
- 4 relaxation and stress management;
- 5 social skills and conflict resolution training; and
- 6 training in general problem-solving skills (for discussion, see Kaslow & Thompson 1998; Kazdin & Weisz 1998).

Although the total number of youth depression studies is small, and different investigations have used different combinations of these CBT techniques, preliminary evidence suggests that, overall, CBT packages have beneficial effects on youth depression symptoms. In two recent meta-analyses of treatment of adolescent depression, mean effects of CBT were estimated to be quite large, 1.02 and 1.27 post-treatment, respectively (Reinecke *et al.* 1998; Lewinsohn & Clarke 1999).

To date, there have been 13 randomized studies of CBT with depressed youth, four with depressed children and nine with depressed adolescents. In addition to differences in developmental level, youth in these studies have differed with respect to referral source (clinical vs. school or advertisement) and presence of a diagnosable depressive disorder (vs. presence of subclinical symptoms). These two domains are, obviously, not unrelated. Most studies rely on samples of depressed youth recruited from school or community settings who have mild to moderate symptoms of depression, as assessed by dimensional screening instruments, and they are discussed only briefly herein. However, within the past 5 years, several investigative teams have published controlled trials in youth who met diagnostic criteria for depression, and often were clinically referred. We will begin our discussion with these more recent and well-developed treatment programmes, and then more briefly review historical work with subclinical samples of community youth. For all studies, basic study characteristics (sample size, measures) and clinical response are summarized in Table 54.1.

Studies on clinical samples

Wood *et al.* (1996) compared the impact of five to eight sessions of CBT intervention with a comparable period of relaxation training in the treatment of early to middle adolescent outpatients with depressive disorders, with 54% of the CBT group and 26% of the relaxation group remitting by the end of treatment. Similar results were obtained on self-report measures of depressive symptoms, self-esteem and general psychosocial adjustment. Upon 6-month follow-up, the groups had converged, as a result of continued improvement in the relaxation group and symptomatic relapse in the CBT group. Younger age of diagnosis and higher level of functioning at intake were associated with better outcome (Jayson *et al.* 1998). The addition of a median of 6-monthly booster CBT sessions after acute treatment resulted in a much lower relapse rate than acute treatment alone (20 vs. 50%; Kroll *et al.* 1996).

Using a similar CBT treatment package to Wood *et al.* (1996), Vostanis *et al.* (1996a,b) randomized depressed outpatients to either individual CBT or an attention-placebo condition—non-focused intervention (NFI). CBT and NFI were equivalent with regard to the proportion *not* meeting depressive criteria at the end of treatment (87 vs. 75%) and at 9-month follow-up (71 vs. 75%). However, 46% of patients across conditions reported experiencing a ‘depressive episode’ at some point during the follow-up period (Vostanis *et al.* 1996b). On average, patients in both the CBT and NFI conditions attended six sessions with a therapist, but the range of sessions was from two to nine, occurring over a 1–5-month period.

Brent *et al.* (1997) tested CBT, derived from Beck *et al.* (1979), against systemic behaviour family therapy (SBFT) and a non-directive supportive therapy (NST), using a primarily clinically referred sample (two-thirds vs. one-third from newspaper advertisements) of depressed adolescents. In comparison to Wood *et al.* and Vostanis *et al.* these treatments were much longer and more regular (12–16 weekly sessions). At post-treatment assessment, significantly fewer of those subjects receiving CBT (17%) than NST (42%) continued to have diagnosable major depressive disorder (MDD). Remission, as defined by the absence of MDD and at least three consecutive Beck Depression Inventory (BDI) scores < 9, was more common in the CBT cell (60%) than in either SBFT (38%) or NST (39%). Reductions in suicidality and improvements in general psychosocial adjustment were not different across groups. CBT resulted in greater change in cognitive distortions than did either SBFT or NST, although changes in depressive symptoms were *not* mediated by changes in cognitive style (Kolko *et al.* 2000). Across treatment cells, poorer response was predicted by greater cognitive distortion, more severe depression at intake, and referral via an advertisement rather than by clinical referral. The latter finding was mediated in part by lower hopelessness in those who were referred to the study via advertisement (Brent *et al.* 1998). Removal from the study and drop-out were predicted by double depression (depression comorbid with dysthymia) and greater hopelessness, respectively (Brent *et al.* 1998).

Table 54.1 Cognitive-behavioural therapy (CBT) treatment of youth depression.

Abbreviations: BDI, Beck Depression Inventory; CDI, Children's Depression Inventory; IPT, interpersonal therapy.

Comorbid anxiety was associated with more robust response to CBT, and maternal depressive symptoms were associated with a poorer response to CBT. At post-treatment, CBT continued to be superior to NST and SBFT, even in the presence of multiple adverse predictors, suggesting that CBT may be the most efficacious intervention for use in real world service settings with clinically complex cases. At 2-year follow-up, differences between treatment groups on the presence of current MDD were not significant (Birmaher *et al.* 2000), although the descriptive data again favour CBT (6%) over SBFT (23%) and NST (26%). Recurrence of depression over the 2-year follow-up period was predicted by greater severity of depression symptoms at intake, and by higher levels of parent-child conflict (Birmaher *et al.* 2000).

Diagnosed community samples

The following set of studies used community samples of youth with diagnostic depression recruited either from schools or via advertisements.

Lewinsohn *et al.* (1990) randomized 59 participants to either, Coping with Depression-Adolescent Version (CWD-A) alone, CWD-A plus the parent group (consisting of seven weekly sessions), or a waiting list control (WLC). CWD-A consists of 14 2-h psychoeducationally orientated group sessions delivered over 7 weeks. The focus of CWD-A is on increasing social skills, pleasant events/activities, and problem-solving and conflict resolution skills, while reducing anxious and depressive cognitions. At the conclusion of treatment, 43% of the adolescent-only group and 48% of the adolescent-plus-parent group no longer met diagnostic criteria compared to only 5% of the WLC subjects. Significantly decreased scores on abbreviated self-report depression measures were also obtained for both treatment groups relative to the WLC group. In addition, treatment gains persisted at 1-, 6-, 12- and 24-month follow-up. The adolescent-plus-parent group did not result in better outcomes than the adolescent-only condition. Poor outcome was associated with greater depressive symptomatology, comorbid anxiety symptoms and greater cognitive distortions at intake (Clarke *et al.* 1992).

Clarke *et al.* (1999) replicated these results, with 65, 69 and 48% of subjects in the adolescent-only, adolescent-plus-parent and WLC conditions, respectively, no longer meeting diagnostic criteria for MDD or dysthymia post-treatment. In this trial, there was a rerandomization to a one to two session booster condition that did not reduce the rate of depression recurrence for those who had remitted by the end of treatment. However, for patients who had not yet recovered from depression at the end of the acute treatment phase, booster sessions did accelerate their rate of recovery. Across both studies assessing the effects of CWD-A with diagnosed samples, a positive treatment response was predicted by a less severe initial depression, higher initial engagement in and enjoyment of pleasant activities, and fewer irrational thoughts (Clarke *et al.* 1992; Lewinsohn *et al.* 1996).

Rosselló & Bernal (1999) compared the efficacy of a 12-week, individually administered CBT programme to a similar dose of interpersonal therapy (IPT) and WLC in adolescents with diagnosed MDD and/or dysthymia referred by school personnel. Both active interventions were adapted to be culturally appropriate for use with Puerto Rican youth (Rosselló & Bernal 1999). Attendance problems occurred in both treatments as only 68% of IPT cases and 52% of CBT cases completed over seven treatment sessions. To assess outcome, a clinical cut-off was selected on the Children's Depression Inventory (CDI) that was approximately three points lower than the mean intake CDI score for the sample. Using this criteria for clinically significant change (Jacobson & Truax 1991), 59% of adolescents in the CBT condition and 82% of IPT cases achieved clinically significant improvement in depression symptoms by post-treatment; data were not provided for the WLC condition. Using an unspecified normative cut-off point for the CDI, the authors indicated that 56% of the IPT cases, 48% of the CBT cases, and 61% of the WLC were 'severely depressed' at intake. At post-treatment, these percentages were 11, 24 and 34%, respectively, and 17 and 18% at 3-month follow-up for IPT and CBT, respectively. While this investigation has several methodological difficulties (e.g. substantial attrition and no intent-to-treat analyses conducted), these results provide some of the first information on the efficacy of CBT for depressed Latino youth and the only extant comparison of CBT and IPT in adolescent depression.

Symptomatic community samples

There are several community-based studies of symptomatic children and adolescents in which CBT is compared to other active treatments (e.g. relaxation treatment, self-control, modelling) as well as a WLC (Butler *et al.* 1980; Reynolds & Coats 1986; Stark *et al.* 1987; Kahn *et al.* 1990; Liddle & Spence 1990; Weisz *et al.* 1997). In general, all active interventions are superior to WLC and the impact is sustained on follow-up but, with few exceptions, CBT showed no differential impact compared to the other active interventions. These studies are important because they are some of the only CBT studies of depressive symptoms in children, are usually delivered in a group format, and therefore may guide future efforts to prevent early-onset depression.

Prevention

Clarke *et al.* (1995) tested the efficacy of an adaptation of CWD-A in preventing diagnosable depression in adolescents with sub-syndromal depressive symptoms, but without a diagnosable depressive disorder. One hundred and fifty high school students, who scored highly on the Center for Epidemiological Studies-Depression scale (CES-D) but failed to meet diagnostic criteria for a current depressive disorder, were randomly assigned to the 15-session CWD or 'usual care'. At 12 months post-intervention, fewer cases of depressive disorder (15%) had developed in the CWD group than in the control group (26%).

Summary of cognitive-behavioural therapy for youth depression

Taken together, results from these three tiers of studies suggest that CBT for youth depression appears to be more efficacious than no treatment, WLC, or attention placebo controls, and some studies, especially in clinically referred samples, indicate that CBT can produce better results than alternative active treatments (Wood *et al.* 1996; Brent *et al.* 1997). Data from Brent *et al.* (1998) suggest that CBT may also be 'robust' to many of the adverse clinical indicators in depression treatment. Efficacy also appears to be robust to format (group vs. individual), emphasis (behavioural vs. cognitive), and dose (5–16 sessions).

While these results are promising, many patients continue to have clinically significant levels of depression at post-treatment, and near majorities of patients experience at least one recurrence of depression within 2 years of treatment termination. It is perhaps not surprising that many patients (estimates range from 29 to 48%) seek additional services following acute CBT (Brent *et al.* 1999).

These studies provide some clues with regard to the improvement of depression using CBT. CBT did more poorly in the face of maternal depressive symptoms, greater severity, and double depression; family discord also retarded recovery and predicted recurrence. Therefore, additional interventions that target maternal depression and family discord may well augment outcome. Moreover, particularly refractory and chronic conditions, such as double depression, may respond better to combinations of medication and CBT than to either monotherapy alone, as is suggested by comparable data in adults with chronic depression (Keller *et al.* 2000). We currently have very little information on the treatment of serious depression in pre-adolescents, and it is unclear how CBT may need to be adapted to take into account the more concrete cognitive style and greater dependence on parents seen in most pre-adolescent as compared to adolescent patients (Weisz & Weersing 1999).

Cognitive-behavioural therapy of anxiety disorders

In this section, we review controlled clinical trials to treat childhood anxiety disorders: separation anxiety, generalized anxiety disorder, and simple and social phobia. No studies have specifically focused on panic disorder. Studies of the treatment of PTSD and OCD are reviewed in separate sections. Table 54.2 outlines key features and outcomes of these clinical trials, which are described in further detail below.

Coping Cat studies and variants

Kendall (1994) reported the first controlled trial of a manualized CBT, the Coping Cat programme, for anxiety disorders in children. Forty-seven youths were randomized to either 16–20 sessions of individual CBT or an 8-week WLC, after which

youths were offered CBT. Four essential components were included:

- 1 recognition of cognitive, emotional, and somatic manifestations of anxiety;
- 2 recognition of cognitive distortions that are anxiogenic;
- 3 development of a plan to cope with anxiety-provoking situations; and
- 4 learning how to evaluate one's performance in potentially anxiety-provoking situations, and to reward desirable performance.

Children were liberally reinforced by therapists for participating in the therapeutic activities, and especially for successful coping, with the goal to transform from a 'scaredy cat' to a 'coping cat'. A summary of a session-by-session treatment from Kendall (1994) is noted in Table 54.3.

The proportion of youths who no longer met diagnostic criteria for an anxiety disorder was much higher in CBT than WLC (64 vs. 5%). Furthermore, a significant strength of this study was the multimodal measurement of anxiety through parent and self-report, and behaviour observation, with remarkably consistent treatment-by-time interactions greatly favouring CBT. Given the high rate of comorbid depression (32%), it is salient to note that CBT, although it did not specifically target depression, resulted in a significant reduction in self-reported depression.

Follow-up at 1 and 3.4 years later showed preservation of the gains that occurred during treatment (Kendall 1994; Kendall & Southam-Gerow 1996). When, as part of the long-term follow-up, participants were asked to recall which aspects of treatment were most relevant and helpful, subjects stressed the therapeutic relationship, games and activities, and the discussion of problems. However, recall of specific skills in coping with anxiety, *in vivo* exposure, and relaxation exercises were all related to positive outcomes in anxiety, ability to cope, and reduction in anxiogenic cognitions (Kendall & Southam-Gerow 1996).

Kendall *et al.* (1997) replicated and extended these results in a larger clinical trial of Coping Cat vs. WLC for 94 youths with anxiety disorder. Again, CBT was overwhelmingly superior to WLC with regard to proportion no longer meeting criteria for anxiety disorder at post-treatment (46–53 vs. 4%). Group differences were also detected for self-reported coping statements, anxiogenic cognitions, and self-reported, parent-reported and behaviourally observed anxiety symptoms.

As in the first trial, the WLC group received CBT after 8 weeks of treatment, allowing for a comparison of the differential efficacy of 8 vs. 16 weeks of CBT. The effects of the full 16 weeks of CBT were vastly superior, suggesting that the initial skill-building component alone is not efficacious without the addition of the exposure component. Gains in the treatment programme may occur through decreases in subjects' anxious self-talk (Treadwell & Kendall 1996). In a 1-year follow-up, there was strong evidence for the maintenance of initial therapeutic effects across measures of anxiety.

Barrett *et al.* (1996) adapted and extended Kendall's treatment model (termed 'Coping Koala') and tested the additive

Table 54.2 CBT treatment of anxiety disorders.

Author	n	Age (years)	Diagnosis	Interventions	Number of sessions	Proportion without anxiety disorder at follow-up (%)	Proportion without anxiety disorder at 1 year (%)	Remarks

Table 54.3 Outline of Kendall’s Coping Cat CBT treatment by session (Kendall 1994).

Session	
1	Build rapport, gather information about anxiety-provoking situations and how child responds
2	Learn to identify two types of feelings
3	Develop a hierarchy of anxiety-provoking situations and responses
4	Relaxation training with personalized cassette
5	Recognize self-talk, reduce anxiogenic self-talk
6	Recognition and development of coping strategies (e.g. self-talk)
7	Learn how to self-evaluate and self-reward coping behaviour
8	Review of concepts and skills
9	Practice of new skills (e.g. coping self-talk, relaxing imagery) in low-anxiety situations
10–13	Exposure to imagined and real situations with increasing levels of anxiety, test recognition of anxiety, self-coping, and evaluation of performance
14–15	Practice in very stressful situations Development of ‘infomercial’ aimed at informing other children how to cope with anxiety
16	Review of therapy experience, skills, and consideration about application in future anxiogenic situations
17–20	Generalization, biweekly sessions (optional)

Table 54.4 Family anxiety management (FAM) for parents (Barrett *et al.* 1996).

Sessions	
1–4	<i>Contingency management</i> Rewarding coping and courageous behaviour Ignoring excessive anxiety and initial empathetic response
5–8	<i>Management of own anxiety</i> Awareness of anxiety in stressful situations Learn problem-solving and coping behaviour to mitigate anxiety Model positive coping for children
9–12	<i>Communication and problem-solving</i> Responding to conflict, especially around dealing with child’s anxious behaviour Encouragement of daily discussion and improved communication between parents Training in problem-solving skills

efficacy of a family anxiety management (FAM) component. FAM consisted of three components:

- 1 education of the parents in contingency management to reinforce courageous and to ignore anxious behaviour;
- 2 teaching the parents to manage their own anxiety and model positive coping; and
- 3 training in communication and problem-solving (detailed in Table 54.4).

In this study, anxious youth were randomized to one of three cells: CBT alone, CBT+FAM, and WLC. Those selected for CBT alone received 12 60–80-min sessions, whereas those se-

lected for CBT+FAM received approximately 30 min on CBT and 40 min on FAM.

Overall, both CBT+FAM and CBT alone were markedly superior to WLC in the proportion of children without a diagnosable anxiety disorder post-treatment (89, 51 and 26%, respectively). The combination of CBT+FAM appeared to be particularly helpful for younger girls, for whom the rate of no longer having an anxiety disorder diagnosis was much lower than in those who received CBT alone (100 vs. 55%; 84 vs. 37%). In contrast, among older participants (aged 11–14), both active treatments resulted in a 60% remission rate with respect to the proportion no longer meeting diagnostic criteria for an anxiety disorder. Similarly, in males the results were closely comparable in the CBT+FAM (84%) and CBT alone (65%) groups. The authors speculated that the age effect might be a natural consequence of the greater dependence of younger children on their parents, whereas the sex difference is less easy to explain.

This same research group randomized 128 youths (three-quarters of whom had significant anxiety, the remainder at risk for the development of an anxiety disorder) to either a modified version of the Coping Koala (10-week group CBT with three FAM sessions) or WLC (Dadds *et al.* 1997). There were significant treatment effects, both at the end of treatment and 6 months later on parent and clinician rating of child adjustment, anxiety, avoidance and functioning. Diagnostically, no differences in the rates of disorder were noted at the end of treatment, but a significant difference emerged by 6 months after the intervention (see Table 54.2; 56 vs. 27% rate of anxiety in WLC vs. intervention), both in the at-risk and fully symptomatic subgroups. This might have been caused by a ‘sleeper’ effect or the timing of the follow-up assessment, which coincided with the beginning of next school year, when symptoms might have

re-emerged. Therefore, group CBT+FAM was more efficacious than WLC for both treating anxiety disorder and decreasing the incidence of anxiety disorder in those with subclinical symptoms.

Programmes for school refusal and social anxiety in children and adolescents

Last *et al.* (1998) examined the relative efficacy of 12 weekly sessions of CBT vs. supportive-expressive therapy (SET) for children and adolescents with 'school phobia', who most commonly met diagnostic criteria for simple or social phobia (58%) or separation anxiety disorder (32%). Both treatments resulted in a significant improvement in school attendance with no major between-group differences. Specifically, the proportion of children who had reached 95% school attendance by the end of treatment was 65% in the CBT cell vs. 48% in the comparison cell, a non-significant difference. There was evidence of differential attrition, with all nine subjects who dropped out having been randomized to the CBT cell. On re-entry to school the next academic year, both groups demonstrated similar rates of having mild or no difficulty returning to school (70 vs. 71%). Level of school attendance at the end of treatment was inversely related to difficulty returning to school on follow-up. Both treatments were more efficacious for younger participants and for those who showed better school attendance at baseline.

In another study of CBT for school refusal, King *et al.* (1998) randomized school-refusing children and adolescents aged 5–15 to either six sessions of CBT plus five parent sessions in contingency-setting and child management delivered over 4 weeks, or a WLC group. Approximately two-thirds of subjects had at least one diagnosable anxiety disorder. CBT resulted in dramatically improved school attendance compared to the WLC condition (proportion attending >90% of school days, 88 vs. 29%), with this improved attendance maintained at 12-week follow-up (82%).

Bernstein *et al.* (2000) reported on the efficacy of CBT+imipramine vs. CBT+placebo for the treatment of school refusal in adolescents. Therefore, this study was designed to test the efficacy of imipramine added to CBT, but not CBT *per se*. In contrast to all of the above-noted studies, all of the subjects were adolescents and had both depression and anxiety. The CBT intervention was an adaptation of the model of treatment used by Last *et al.* (1998), with a reduced number of sessions (eight rather than 13). The imipramine+CBT was superior to the placebo+CBT with regard to school attendance (70 vs. 28% attendance), the proportion attending at least 75% of classes (54 vs. 17%) and rate of decrement in depressive symptoms. The poor outcome in the CBT+placebo cell, relative to a previous application of this CBT intervention (Last *et al.* 1998), could be brought about by the older age of the subjects, their greater clinical complexity (depression and anxiety) or lower dose of treatment received.

Hayward *et al.* (2000) reported on a clinical trial of group CBT vs. WLC condition in 35 female adolescents with social

phobia. Those 12 subjects randomized to group CBT received 16 sessions, consisting of education about anxiety (sessions 1 and 2), development of coping strategies, assertiveness, and cognitive restructuring skills (sessions 3–8), and simulated and *in vivo* exposure (sessions 9–16). At the end of treatment, a lower proportion of those randomized to CBT met full diagnostic criteria for social phobia (55 vs. 96%). While these gains were sustained upon 1-year follow-up, the WLC group also improved spontaneously, so that the two groups were no longer different with respect to rates of social phobia (40 vs. 56%). There was also some limited support that the intervention might be helpful in preventing the recurrence of depression in those who had a prior depressive episode, as only 17% of the CBT-treated subjects with a previous depressive episode had another depressive episode over follow-up, whereas 64% of the previously depressed WLC group experienced a recurrent depressive episode.

Summary of anxiety disorder studies

There is strong and consistent evidence that a structured CBT intervention, either individual or group, is more helpful than WLC in reduction of anxiety symptoms and restoration of functionality, and that these improvements are sustained over follow-up. At the same time, a high proportion of those treated still reported continued anxiety symptomatology, which suggests either the need for longer or more intensive treatment, or the combination of pharmacotherapy with CBT in those with residual symptomatology. The addition of a family anxiety management component appears to boost the response rate of CBT, especially for female and for younger patients. CBT also appears to be helpful in the prevention of anxiety in those with subdiagnostic manifestations of anxiety; also, treatment of anxiety may relieve or even prevent further depression. However, almost all the above-cited studies compare CBT to WLC; in the one study that compares CBT to another credible treatment, the two treatments were equivalent. While decrements in anxious self-talk are related to improvement in CBT, it is unclear whether CBT is truly a specific treatment for anxiety disorder. Also, this series of studies did not use intent-to-treat analyses, although attrition was generally low. Finally, an additional caveat is that the majority of the subjects for these studies came via advertisements, which may attract more treatment-responsive subjects (Brent *et al.* 1998).

Cognitive-behavioural therapy of maltreatment and post-traumatic stress disorder

Sexual abuse

With regard to the treatment of sexually abused youth, Finkelhor (1990) noted four contributors to anxious symptomatology, inappropriate behaviours and impairment following sexual abuse: traumatic sexualization, stigmatization, power-

lessness and betrayal. Cohen & Mannarino (1996a,b) subsequently demonstrated that these four factors are related to symptom formation, and therefore are particularly important to address in psychotherapy. Inappropriate sexual behaviour following abuse may result from modelling the behaviour of the abuser, cognitive distortions about what is appropriate sexual behaviour, and reinforcement from seductive and coercive adults. Thus, therapy would need to focus on relearning appropriate behaviour and restructuring cognitive distortions. Stigma can be examined by trying to understand the victim's cognitions about the abuse, such as thinking of oneself as 'damaged' or dirty. Powerlessness and betrayal can be addressed by helping the child to understand what are the limits to which these inferences should be generalized, and what steps to take should a similar situation arise again. The preceding description serves as a backdrop for evaluating the five randomized treatment trials for sexually abused youngsters and the one dealing with physically abused youth.

Cohen & Mannarino (1996a) randomized sexually abused preschool-age children to 12 sessions of either CBT or NST. Both treatments targeted both the parent and child. Parental issues addressed in the CBT model were ambivalence about belief in the abuse, attributions about the abuse, concerns that the child was now 'damaged', provision of appropriate support to the child, issues dealing with a personal history of abuse (if applicable), and legal issues. Topics focused on with the child included safety education and assertiveness, identification of appropriate and inappropriate touching, attributions about the abuse and the abuser, and attendant anxiety symptoms. NST provided support through active listening, clarification of affect, and affirmation, but without a focus on specific skills or problem-solving, thereby controlling for attention and treatment credibility. CBT was more efficacious than NST in reducing symptomatology from the clinical to non-clinical range for parent-reported total and for internalizing problems (56 vs. 22%, 60 vs. 11%). In addition, six of those in NST vs. none in the CBT group had to be removed from treatment because of sexually inappropriate behaviour. Parental negative reaction to disclosure and parental depression predicted behavioural and emotional difficulties of the child at the end of treatment, independent of treatment assessment (Cohen & Mannarino 1996b). The CBT group showed sustained improvement upon 1-year follow-up (Cohen & Mannarino 1998a) with continued problems with inappropriate sexual and externalizing behaviour predicted by the degree of parental support.

Cohen & Mannarino (1998b) compared 12 sessions each of CBT to NST for sexually abused children and adolescents and their parents. A much greater proportion of youth in CBT vs. NST moved from the clinical to non-clinical range for self-reported depression, inappropriate sexual behaviour, parent reported social competence, and total behaviour problems. A higher proportion of youth in NST ($n=7$, 27%) were removed for inappropriate sexual behaviour, or dropped out, relative to those assigned to CBT ($n=2$, 6%). Child cognitions about the abuse were related to post-treatment anxiety, anger, depression,

PTSD and dissociation (Cohen & Mannarino, 2000). Family support and adaptability were related to post-treatment anxiety, depression and PTSD.

Deblinger *et al.* (1996) randomized 100 sexually abused school-aged children to one of four conditions: community care, child CBT, a non-offending parental intervention, or child CBT + parental intervention, in a 2×2 factorial design. The child CBT intervention consisted of 12 45-min sessions delivered weekly, as did the parental intervention; the combined intervention lasted 80–90 min per week. The child intervention included gradual exposure, modelling, education, coping and body safety skills training. The gradual exposure was designed to help the child unlink associations made between the triggers for PTSD and abuse-related cognitive and external reminders. The parental intervention involved teaching the parent therapeutic ways to respond to their children's fears and avoidance through modelling, gradual exposure, coping and child management skills (e.g. contingency management, negotiation, communication and problem-solving skills). There was a treatment-by-time effect favouring the child CBT intervention for its impact on PTSD. There was also a treatment-by-time effect favouring the parental intervention for child-reported depressive symptoms, improvement in parental skills, and parent-reported externalizing symptoms. Among children whose parents reported them as above the clinical cut-off for externalizing problems, only 26% of those assigned to a parental intervention were still at or above the cut-off post-treatment, as compared to 80% of the child and community treatment groups. Although there were no parent-by-child intervention interactions detected, the complementary effects of the two treatment components suggest that the combined treatment may be the most efficacious, especially in children who present with both internalizing and externalizing difficulties.

Berliner & Saunders (1996) randomly assigned sexually abused children to one of two 10-week group treatments: 'conventional abuse treatment' vs. conventional abuse treatment + stress-inoculation training and gradual exposure. Treatment analyses were restricted to the subjects who completed treatment and a 2-year follow-up, whereas nearly twice that number were initially recruited into the study. Groups were stratified by age, and the two older age groups were homogeneous for gender. The conventional treatment was highly structured and didactic, focusing on different aspects of the abuse experience, including self-esteem, body awareness and sexuality, impact of exposure, and reaction of family and friends. The experimental intervention also taught children about identification of anxiety, relaxation and thought-stopping coping exercises, and gradual exposure (*in vivo*). There were significant decreases in self-reported anxiety, sexual abuse-related anxiety, depression, inappropriate sexual behaviour, and parent-related internalizing and externalizing scores across the course of both treatments but, contrary to hypotheses, there were no differences between the two treatments. At 2-year follow-up, 20–40% of the group remained improved; however, 20% had deteriorated. The lack of a differential intervention effect was attributed to the

relatively low levels of PTSD and anxiety symptomatology at intake, lack of substantive difference between the two treatments, and insufficient dosage of important cognitive elements.

Celano *et al.* (1996) compared the efficacy of 8 weeks of CBT vs. treatment as usual for African-American sexually abused girls aged 8–13. Each child in the CBT intervention received two individual 30-min sessions dedicated to each of the four domains from the model of Finkelhor (designed to decrease stigmatization and blame, feelings of betrayal, traumatic sexualization, and powerlessness/anxiety); safety education was also provided. A parental component followed the same topics in parallel. The treatment as usual was less structured, but involved discussion with both parent and child about abuse-related feelings and symptomatology, self-esteem, peer and family issues, parent–child communication, feelings about the perpetrator, and reaction to disclosure.

Thirty-two subjects completed treatment; the higher drop-out rate in the experimental treatment (10 vs. 5 drop-outs from treatment as usual) makes the findings difficult to interpret. For the most part, both treatments resulted in significant decrements in symptomatology, similar to the findings of Berliner & Saunders (1996). Differential effects were found favouring the experimental intervention with regard to increasing parental support, and decreasing parent self-blame; treatment as usual had greater impact than the experimental treatment on depression.

Physical abuse

Kolko (1996) compared the treatment outcome of physically abused children randomly assigned to individual child and parent CBT, family therapy, or routine community services. Each intervention consisted of around 18 h of treatment delivered over a 16-week period. The CBT programme was delivered to parents and children by separate therapists. The parental CBT programme focused on teaching intrapersonal and interpersonal skills, including anger control and cognitive coping skills, and appropriate punishment and contingency management. CBT for children focused on their views of family stressors and violence, coping, self-control, safety skills, and social skills training (e.g. enhancing social support, assertion, negotiation). Family therapy consisted of three phases:

- 1 gaining an understanding of family roles and interactions and developing a no-violence contract with each family member;
- 2 teaching problem-solving and communication skills; and
- 3 establishment of problem-solving as routine family alternatives to coercion and physical violence.

The community service component was more heterogeneous, but consisted of case management, risk assessment, teaching of family skills, provision of parenting information, and referral to support groups.

Family therapy was associated with a greater reduction in child-reported parent-to-child violence, and both CBT and family interventions were associated with greater reduction in child-reported child-to-parent violence. Both interventions were also associated with greater impact on child abuse potential, indi-

vidual child externalizing symptoms and parental general distress and depression, and family cohesion and conflict. The rates of reabuse were higher in community care (30%) than in CBT (10%) and family therapy (12%), although these results escaped statistical significance. This study demonstrates the relative advantage of both CBT and family therapy over routine community care for physically maltreated youth and their families, and supports the importance of including the parents, either in a structured CBT or a family therapy intervention.

In summary, studies of maltreated (mostly sexually abused) children support the efficacy of CBT interventions over non-directive supportive treatment, and over standard community treatment. Modification in abuse-related cognitions appears to be related to relief of internalizing symptomatology. Perhaps because of the difficulties inherent in working with these populations, the drop-out rate in several of these studies was substantial and, unfortunately, none of the studies appeared to have utilized an intent-to-treat data analytic approach. The importance of involving the parent in the cognitive treatment was demonstrated in several of the above-noted studies, and the role of parental distress and support in predicting child outcome is consistent with these findings.

Natural disasters

Several research groups have studied CBT approaches to the treatment of trauma caused by unpredictable catastrophic environmental events. Galante & Foa (1986), in the aftermath of a disastrous Italian earthquake, provided a seven-session group treatment programme to children in some affected villages and not others. The group treatment involved expression of fears about the earthquake, discussion of erroneous beliefs about earthquakes, focus on grief and rebuilding for the future, and role-playing about taking an active role in one's survival. A greater reduction in the proportion of children at risk on the Rutter Teacher Children's Questionnaire was found in those villages where the children received the treatment programme.

Goenjian *et al.* (1997) treated early adolescent students in two schools 18 months after a devastating earthquake in Armenia. Subjects were randomized to trauma/grief-focused psychotherapy or no treatment. The intervention consisted of four 30-min classroom-based group psychotherapy sessions, and an average of 2–4 1-h individual sessions. Five content areas were addressed:

- 1 cognitive distortions and avoidance related to trauma;
- 2 identification of traumatic reminders, and enhancing toleration for these reminders by exposure, seeking external support, and cognitive restructuring;
- 3 mastering interpersonal problem-solving skills to deal with losses and other adversities and promote adaptation to the post-disaster environment;
- 4 helping the bereaved person attain a non-traumatic representation of the deceased person (when applicable); and
- 5 promotion of normal development, in the light of missed

developmental opportunities because of loss, and collapse, of family and community infrastructure.

Therefore, this intervention contains a mixture of cognitive, supportive-expressive, and interpersonal dynamic elements.

Eighteen months after the conclusion of treatment, a reduction in PTSD symptomatology was noted for the active intervention, and an increase in PTSD symptomatology was observed in the non-intervention group, with parallel findings for depression. Three years after the earthquake, and 18 months after the intervention, 28% of the intervention group and 69% of the non-intervention group still exceeded the clinical cut-off for PTSD, and 46% of the intervention group and 75% of the non-intervention group were over the clinical cut-off for depression. Of particular significance in this study is the worsening of the course of the untreated group over time, both with regard to PTSD and depression. These results provide support for the utility of a brief intervention directed at those who have been exposed to natural disasters, as exposees are at high risk for PTSD and depressive disorders that become increasingly prevalent over time without intervention.

March *et al.* (1998a) reported on a group CBT intervention for PTSD after a single-incident stressor, termed multi-modality trauma treatment (MMTT). In MMTT, PTSD is conceptualized as an aversive emotional response to a traumatic stressor, resulting from a severe traumatizing stressor interacting with pre-existing personal vulnerability to the effects of trauma (e.g. anxiety disorder or anxious temperament). Subsequently, cues reminiscent of the traumatic event can elicit the alterations in arousal, memory and affect that comprise PTSD. Over time, it is hypothesized that persons with PTSD develop 'fear structures', which are sequences of trauma-related cues, thoughts, affects and memories. To evaluate the efficacy of MMTT, March *et al.* (1998a) treated 17 subjects screened for PTSD whose precipitant was a 'single incident'. Four groups received MMTT, with two of the four groups lagged 4 weeks behind the other two groups, allowing for experimental control for time effects.

Of the 17 subjects, 14 completed the treatment and three were lost to follow-up. At the end of treatment, 57% no longer met criteria for PTSD, and by 6 months after the completion of treatment, 86% no longer met criteria for PTSD. There were also significant effects with respect to self-rated anxiety, depression, trait anger, and a change from external to internal locus of control; the latter noted only at the 6-month follow-up. MMTT appears to have promise and should be evaluated in larger clinical trials that control for the attention and support of psychotherapy.

Obsessive-compulsive disorder

The initial treatment studies for paediatric OCD involved the serotonergic antidepressant clomipramine and, more recently, the selective serotonin reuptake inhibitor (SSRI) sertraline (Flament *et al.* 1985; DeVaugh-Geiss *et al.* 1992; Riddle *et al.* 1992; March *et al.* 1998b). However, in both sets of studies,

while it was recognized that there was significant improvement relative to placebo, subjects at the end of these medication trials often remained significantly symptomatic. Therefore, psychosocial interventions, either alone or in combination with medication, hold promise for resulting in more complete restoration of functionality in this serious and potentially debilitating disease.

March *et al.* (1994) reported on a structured CBT protocol for the treatment of OCD. The essence of this treatment approach is the encouragement of the child to externalize the disease, OCD, into a 'nasty name' that is to be run off the child's land. In this way, the child is to become the 'boss' of OCD. The child is to make a 'map' of OCD on the basis of situational triggers and subsequent OCD symptoms (obsessions and compulsions). This map identifies triggers that the child can manage easily, those that are still under the control of the 'OCD' and those in-between. The in-between, or 'transition zone', represents the substrate for constructing a hierarchy of tasks for exposure and response prevention, with the ultimate aim to expand the amount of 'land' (self) that the child is now the 'boss' of, relative to OCD. CBT techniques for achieving this goal include management of the anxiety associated with obsessions and compulsions, and graduated exposure to more and more 'compelling' triggers which, in turn, will allow the child to gain back more 'land'. March *et al.* (1994) reported on the CBT treatment of 15 subjects ranging in age from 8 to 18, with all but one receiving concurrent medication. Of the 15 subjects, 10 (67%) showed >50% decline in the Yale-Brown Obsessive Compulsive Scale (Y-BOCS), and three were considered non-responders. According to the Clinical Global Improvement (CGI), 9/15 (60%) were judged to be asymptomatic at follow-up.

Franklin *et al.* (1998) treated 14 children and adolescents with OCD with a similar CBT protocol to that described by March *et al.* (1994), with the exception that the latter treatment omitted anxiety management training and focused exclusively on exposure and response prevention, with half receiving all their sessions in 1 month and half receiving them as weekly treatments. The vast majority (12/14, 86%) were at least 50% improved on the Y-BOCS, with treatment improvement sustained over the 9-month follow-up. Both fear and engagement in rituals declined significantly over time. The intensive and weekly treatment groups were compared, and the effect sizes were somewhat larger in the weekly group, although not statistically so. CBT appeared to be as effective and durable in those who were treated with concomitant medication as in those who were not.

De Haan *et al.* (1998) have reported on the only randomized controlled trial of 12 weekly sessions of CBT (similar to the Franklin *et al.* 1998 model) vs. medication (clomipramine) in paediatric OCD. The average dosage of clomipramine was 2.5 mg/kg, slightly lower than the planned target of 3 mg/kg, because of the emergence of side-effects. Behavioural treatment produced a greater decrease in OCD symptoms than did clomipramine. Non-responders who accepted a combination of medication and behaviour therapy achieved further symptomatic improvement.

These data indicate that CBT has a role in the management of paediatric OCD. The simpler exposure and response prevention may be as efficacious as the more elaborate protocol articulated by March *et al.* (1994), and has been shown in one randomized trial to be as, or even more, efficacious than medication. Further research is indicated to examine the individual and combined effects of CBT and pharmacotherapy for paediatric OCD.

Conclusions

The CBT approaches reviewed in this chapter cover a wide range of techniques, from cognitive restructuring, to social skills programmes, to exposure and response prevention. While these specific techniques may vary in their points of emphasis and placement along the cognitive-behavioural continuum, they emerge from a common tradition emphasizing the interrelatedness of thoughts, feelings and actions.

Overall, the research literature suggests that CBT for youth depression and anxiety is more efficacious than a WLC condition. For both youth depression and for treatment of sexually traumatized youth, there is a growing body of evidence suggesting that CBT may also be more efficacious than attention placebo controls or alternative active treatments. CBT may also be a robust intervention for depression even in the face of adverse clinical indicators. CBT treatment of anxiety may also ameliorate or even prevent depression.

Although these results are promising, many young patients with either depression or anxiety remain symptomatic or, worse, do not improve after an acute course of CBT. While the effects of CBT on anxiety appear enduring (Kendall 1994; Kendall & Southam-Gerow 1996), the recurrence of depression does not seem to be differentially affected by participation in CBT in the absence of additional booster sessions (Kroll *et al.* 1996; Wood *et al.* 1996; Clarke *et al.* 1999; Birmaher *et al.* 2000). A substantial portion of anxious youths also remain clinically impaired at post-treatment, and little information is available on the long-term recurrence of diagnosable levels of anxiety after acute CBT treatment (for a notable exception see Kendall 1994; Kendall & Southam-Gerow 1996).

Examining predictors of success in CBT may provide clues for how to boost response for treatment-resistant youths. In both depression and anxiety treatment, younger patients appear to respond better than older adolescents, arguing for an emphasis on early identification and CBT intervention for internalizing symptomatology among youths. It may also be useful to augment traditional child-focused CBT packages with family focused interventions in younger children, as this combination of family anxiety management with CBT has been demonstrated to be particularly efficacious in the treatment of anxiety in pre-adolescent children (Barrett *et al.* 1996). Maternal depression had a deleterious effect on CBT for youth depressive disorders. Therefore, identification and treatment of parental depression may boost the efficacy of CBT for the treatment of adolescent depression.

There have been a paucity of studies comparing medication treatment to CBT or evaluating the combination. SSRIs are now the second most prescribed class of psychotropic agents in youth (Weisz & Jensen, 1999), and there is growing evidence of their utility for youthful depression, anxiety and OCD (Emslie *et al.* 1997; March *et al.* 1998b). Because there appears to be significant symptomatic residual after either CBT or pharmacological interventions (Brent *et al.* 1997; Emslie *et al.* 1997; Pine 2000), combination treatment may be indicated, particularly for those with more chronic and severe conditions. Studies of chronic depression in adults confirm the clinical impression that the combination of CBT and pharmacotherapy is superior to either monotherapy (Keller *et al.* 2000). Even though the overall efficacy of the two types of interventions appears comparable, SSRIs may have the advantage of cost and time savings, whereas CBT may have an impact on functional status more broadly defined than just by symptoms (e.g. improved social skills and self-esteem).

Relatively little is known about the mechanism of action of CBT. Kolko *et al.* (2000) showed specificity of CBT vs. other psychosocial treatments with regard to change in cognitive distortions, but failed to demonstrate that changes in cognitions mediate change in depression. Southam-Gerow *et al.* (2000) showed a relationship between negative self-talk and levels of anxiety symptomatology. Cohen & Mannarino (1996b, 1998a, 2000) found a relationship between child cognitions about abuse and outcome in sexually abused youth. Therefore, the extant data, scant as they are, do support a key role for alteration of cognitions in ameliorating internalizing symptomatology. However, the assessment of cognitive distortion has usually derived from a paper-and-pencil measure that is highly correlated with depression or anxiety. Other related domains, such as measures of mood regulation (Flett *et al.* 1996; Catanzaro 1997), tendency to ruminate or distract in the face of negative emotion (Nolen-Hoeksema & Morrow 1993), ability to acknowledge negative affect (McFarland & Buehler 1997), and ability to access positive memories to regulate negative mood (Rusting & DeHart 2000). Laboratory measures of cognitive and emotional regulation may also be helpful in understanding the relationship between information processing, working memory, attention and emotional regulation (Gotlib & McCann 1984; Power *et al.* 1996). More precisely targeted studies, using laboratory-based tasks, may help to inform us of the mechanisms of action of CBT and at the same time may allow more precise treatment development and treatment prescription. It may not be far-fetched to imagine that a treatment plan will be developed that combines neuroimaging and emotional regulation paradigms to pinpoint critical issues to target in treatment.

It would also be desirable to have additional information about the effectiveness of CBT in conditions more representative of typical clinical practice (Weisz *et al.* 1998). The findings on the robustness of CBT for the treatment of depression in the face of clinically complicating conditions may bode well for the effectiveness of the techniques in practice. Efforts to transport standard CBT protocols to anxious and depressed youth in com-

munity settings are now ongoing. It is quite likely that effects of CBT will be more modest in real-world samples of youth that may be characterized by parental histories of depression and substance abuse, high life stress and current chaos, single-parent or step-parent living situations, and multiple comorbid conditions (Hammen *et al.* 1999). However, such empirical transportability studies are needed because they will help us to understand overall efficacy in community settings, identify predictors of treatment response, and help provide guidance as to what aspects of CBT will need to be adapted to maximize effectiveness in real-world settings.

A related research agenda is the role of CBT in large-scale prevention. There is evidence that CBT can prevent the onset of depression and anxiety, but such findings need to be replicated. In addition, it is critical to evaluate the cost-efficiency of such an effort.

Overall, CBT has a strong track record as an intervention for youth with depression, anxiety and exposure to trauma. Future work on its use in combination with medication in complex and refractory cases, in extending its efficacy to efforts in the prevention of anxiety and depression, and in understanding its mechanisms of action should all enhance the utility of this intervention for paediatric anxiety and depression in the future.

Acknowledgements

This work was supported by NIMH grants MH18269, MH46500 and MH55123. It should be noted that the second and third authors contributed equally to this manuscript. The assistance of Beverly Sughrue in preparation of the manuscript is appreciated.

Problem-solving and Problem-solving Therapies

*Bruce E. Compas, Molly Benson, Margaret Boyer,
Thomas V. Hicks and Brian Konik*

Introduction

The capacity to solve social and interpersonal problems is an integral feature of adaptive development. Conversely, deficits in problem-solving are related to both internalizing and externalizing disorders in childhood and adolescence. Problem-solving skills and deficits are implicated in social information processing models of aggression and disruptive behaviour disorders (Crick & Dodge 1996), cognitive models of depression (Lewinsohn & Gotlib 1995), the development of social competence (Rudolph & Heller 1997), self-regulatory processes (Eisenberg *et al.* 1997) and coping with stress and adversity (Compas *et al.*, 2001). The apparent significance of problem-solving skills is further evident in its prominence in many forms of cognitive-behavioural interventions for children and adolescents, including the treatment of anxiety, depression, conduct disorder and family conflict. The centrality of problem-solving skills in psychological treatment is reflected in a subset of therapies that are explicitly labelled 'problem-solving therapy' (Dujovne *et al.* 1995; Mynors-Wallis *et al.* 1997; Nezu *et al.* 1998).

In spite of the pervasive role of problem-solving skills in child/adolescent psychopathology and treatment, much of the research on, and application of, these skills has dealt with them in isolation from other forms of self-regulation. Problem-solving skills can be best understood as a component of a larger set of adaptive self-regulatory skills that are involved in successfully managing stressful and adverse situations, circumstances and events. In this chapter we examine problem-solving skills in the context of the more general processes of self-regulation and coping, the current role of problem-solving in the treatment of child/adolescent psychopathology, and consider future directions for increasing our understanding of the importance of problem-solving in child/adolescent psychopathology.

Conceptual models of problem-solving

Definitions of problem-solving

Problem-solving is broadly defined as a cognitive and behavioural process involved in managing and mastering the challenges and difficulties encountered in everyday living (D'Zurilla & Goldfried 1971; D'Zurilla & Sheedy 1991). Problem-solving encompasses both a cognitive-motivational orientation and a

set of cognitive and behavioural skills used in responding to and overcoming daily problems. The primary components of problem-solving skills as outlined by D'Zurilla & Nezu (1990) include:

- 1 problem definition and formulation;
- 2 generation of alternative solutions;
- 3 decision-making and selection of a solution; and
- 4 implementation and evaluation of a solution.

Problem definition and formulation involves obtaining relevant, factual information about the problem, clarifying the nature of the problem and delineating a set of realistic problem-solving goals. Generation of alternative solutions includes the identification, discovery or creation of as many alternative solutions as possible in order to maximize the likelihood that the best possible solution or solutions will be among them. Decision-making involves the evaluation and comparison of the different alternatives and the selection of the best overall solution for the particular problematic situation. Finally, implementation and evaluation of a solution includes self-monitoring and assessment of the outcome of the solution that has been implemented.

Shure & Spivack (1971), in their conceptualization of interpersonal cognitive problem-solving, highlighted the following three related skills.

- 1 *Alternative thinking*: the generation of alternative solutions to a given problem.
- 2 *Consequential thinking*: the ability to imagine the short- and long-range outcomes of particular solutions.
- 3 *Means-ends thinking*: the ability to plan a sequence of specific goal-directed actions in order to avoid obstacles and solve problems in a desirable timely manner.

Problem-solving skills are often described as synonymous with problem-focused coping strategies: strategies for coping with stress that are orientated toward managing or dealing with the problem that is the source of stress (D'Zurilla & Chang 1995). As such, problem-solving skills are orientated toward resolving a problem in the social environment or a problematic situation and are distinct from the skills that are used in managing emotional distress and arousal (typically referred to as emotion-focused coping). Problem-solving responses are instrumental and involve engagement with the problem at hand, as opposed to disengagement or avoidance of the problem.

Problem-solving skills are related to higher social competence and adaptive functioning in children and adults, and deficits in problem-solving skills have been documented in children and adolescents with disruptive behaviour disorders, anxiety dis-

orders, depression and interpersonal conflict. Both well-adjusted and poorly adjusted children generate socially undesirable solutions to problems, such as aggressive retaliation, but only well-adjusted children also identify positive solutions and probable outcomes to various alternative solutions (Spivack *et al.* 1976). Problem-solving skills are also related to other psychological variables among children and adolescents, including family conflict and communication skills (Robin *et al.* 1990), externalizing disorders (Kazdin 1997) and internalizing disorders (Sacco & Graves 1984).

Problem-solving, self-regulation and coping

In spite of the well-established relationships between problem-solving skills and both social competence and psychopathology, it is important to place problem-solving in a broader context. Specifically, problem-solving skills are one component of broader processes of self-regulation and coping with stress. Self-regulation refers to the capacity of the individual to initiate, terminate, delay, modify the form or content, or modulate the amount or intensity of a thought, emotion, behaviour or physiological reaction; or redirect thought or behaviour toward a new target (Compas *et al.*, 2001). Coping further refers to a subset of self-regulatory processes that are volitionally and intentionally enacted specifically in response to stress (Compas *et al.* 1999). Specifically, coping involves conscious volitional efforts to regulate emotion, cognition, behaviour, physiology and the environment in response to stressful events or circumstances (Compas *et al.* 2001).

Coping processes, including problem-solving skills, are controlled and volitional in nature, as contrasted with other responses to stress that are automatic and involuntary. The basis for the distinction between controlled voluntary and automatic involuntary responses is based on extensive research from cognitive, social, developmental and clinical psychology. This includes research on associative conditioning and learning (Shiffrin 1997); research on strategic/controlled and automatic cognitive processes in emotions and emotional disorders (Mathews & MacLeod 1994; McNally 1995); research distinguishing some involuntary aspects of temperamental characteristics from intentional behaviour and cognitive processes (Rothbart 1991); and research on automaticity in social cognition (Bargh 1997; Mischel 1997). Both voluntary and involuntary stress responses can be further distinguished as engaging with a stressor or one's responses to the stressor, or disengaging from the stressor and one's responses. The origins of the engagement–disengagement dimension can be found in the concept of the fight (engagement) or flight (disengagement) response (Cannon 1933, 1934; Gray 1991), and in the contrast between approach and avoidance responses (Krohne 1996). Problem-solving skills are an important aspect of engagement orientated coping responses.

Problem-solving skills have frequently been described as an example of the broader category of problem-focused coping strategies within a framework that contrasts problem-focused with emotion-focused coping (D'Zurilla & Chang 1995). How-

ever, recent research with children and adolescents has shown that the problem- and emotion-focused model does not adequately reflect the characteristics of the ways that children and adolescents cope with stress. Specifically, using confirmatory factor analyses to contrast different conceptual models of child and adolescent coping, both Ayers *et al.* (1996) and Connor-Smith *et al.* (2000) found that a problem- and emotion-focused model of coping did not achieve an adequate fit with self-reports of coping from large samples of children and youth. In contrast, results of confirmatory factor analyses suggest that three categories of coping may warrant further analysis (Ayers *et al.* 1996; Walker *et al.* 1997; Connor-Smith *et al.* 2000). The first involves active coping efforts that are intended to achieve some degree of personal control over the stressful aspects of the environment and one's emotions. This factor has been labelled 'active coping' by Ayers *et al.* (1996) and Walker *et al.* (1997), and we have used the label of 'primary control coping' (Connor-Smith *et al.* 2000). In our recent factor analytic studies, problem-solving coping loads on the primary control factor along with coping responses representing emotion regulation and emotional expression (Connor-Smith *et al.* 2000). This provides some evidence that problem-solving skills are closely related to other important aspects of self-regulation, including the regulation of emotion and arousal. Active or primary control coping is distinguished from accommodative or secondary control coping (e.g. acceptance, distraction, cognitive restructuring), and from disengagement coping (e.g. avoidance, denial, wishful thinking), the second and third coping categories.

Because coping involves conscious volitional regulatory efforts, it is a subset of executive functions or processes governed by the frontal cortex. Executive functions include the cognitive processes for future goal-directed behaviour that involve achieving and maintaining a problem-solving set, and include processes such as planning, organizational skills, selective attention and inhibitory control (Morgan & Lilienfeld 2000). The executive functions of the frontal cortex have been hypothesized to have a central role in response control or inhibition, and other aspects of self-regulation (Dempster 1992; Fox 1994; Barkley 1998). Furthermore, coping processes, including problem-solving, are strongly influenced by linguistic function, and some of the more complex aspects of coping include cognitive processes, such as generating plans or solutions to a problem, cognitively reframing a stressful situation, distracting oneself with pleasant thoughts, and accepting circumstances as they are. Thus, problem-solving skills are likely to emerge over the course of development in early and middle childhood. Tapert *et al.* (1999) found that neurocognitive abilities (as reflected in a measure of general intelligence) interacted with coping skills in predicting relapse to alcohol and drug use. These processes can be contrasted with involuntary responses to stress that are hypothesized to be controlled by more primitive aspects of the brain and central nervous system, including the amygdala and aspects of the limbic system (Kagan *et al.* 1992). These include the sympathetic and parasympathetic arms of the autonomic nervous system that control stress reactivity and recovery (Grossman

1992; Porges *et al.* 1994; Berntson *et al.* 1997). Although autonomic nervous system processes can be brought under conscious control to some degree (e.g. through biofeedback), they are triggered by automatic or involuntary responses to threat or challenge.

Problem-solving therapy

We now turn our attention to the role of problem-solving in the treatment of child and adolescent psychopathology. Early reviews of problem-solving interventions presented support for these programmes in effecting positive behavioural changes in children (Urbain & Kendall 1980; Pellegrini & Urbain 1985). The reported effects of problem-solving interventions included decreases in aggression and impulsivity, as well as increases in prosocial behavior and cognitive abilities. These early reviews also found several shortcomings in intervention programmes, such as small effect sizes, small sample sizes and the lack of control groups (Urbain & Kendall 1980; Pellegrini & Urbain 1985). Although these prior reviews represented an important contribution to the field, they were limited in several ways. First, the initial reviews were conducted over 15 years ago, limiting the conclusions that can be drawn about the current status of problem-solving interventions. Second, previous reviews have highlighted only certain aspects of problem-solving, such as focusing primarily on interventions based on Spivack & Shure's model (Pellegrini & Urbain 1985).

The present review is designed to provide a contemporary look at the effects of child/adolescent therapies that involve problem-solving, and to consider the development of problem-solving skills as contrasted with other components of these interventions. We approach the literature by examining therapies for four different problems: anxiety disorders, depression, disruptive behaviour disorders, and parent-adolescent conflict. The present review is not intended to be comprehensive, but rather to highlight certain interventions in which the teaching of problem-solving skills plays a central part. Although there are other models for the treatment of these disorders, comparative studies of problem-solving therapies with other approaches have been rare, an issue to which we return in the final section of this chapter.

Anxiety disorders

Problem-solving in the treatment of child/adolescent anxiety is best exemplified by the work of Kendall *et al.* (1990) in the development of a cognitive-behavioural therapy. This manualized treatment, the 'Coping Cat', was identified as a 'probably efficacious' treatment by Kazdin & Weisz (1998) in their review of empirically supported child and adolescent treatments.

Primary components

The Coping Cat is a 16-session treatment that involves several

behavioural methods for the treatment of anxiety including exposure exercises, relaxation training, modelling, role-plays, and positive reinforcement contingencies. These behavioural methods are combined with several cognitive techniques aimed at addressing the information-processing factors believed to underlie excessive anxious arousal. Cognitive techniques incorporated into Kendall's approach include the identification and modification of maladaptive self-talk, and the development of cognitive strategies for reducing unwanted physiological arousal. The Coping Cat treatment programme is divided into two sections. The first eight sessions are aimed at skill development and training, and the final eight sessions focus on skill implementation and practising the acquired coping strategies in anxiety-provoking situations.

Problem-solving components

Although the Coping Cat programme is not explicitly defined as a problem-solving approach to childhood anxiety, there are a number of problem-solving features incorporated into the programme. Through a series of lessons and exercises, children are taught to use a four-step plan for coping with unwanted anxiety. In order to help them remember these steps in challenging situations, children in Kendall's programme refer to this four-step plan using the acronym FEAR. The first step in the FEAR plan ('Feeling frightened?') helps children to identify the somatic signs and symptoms of their anxiety. The second step ('Expecting bad things to happen?') focuses on identifying negative cognitions that may be contributing to unwanted anxious arousal. This second step also serves to assist children in identifying an important aetiological component of their problem by examining 'anxious self-talk'. The third step in the FEAR plan ('Attitudes and actions that will help?') encourages children to generate alternative solutions to their problem and then consider which of those alternatives would be the most effective given the situation. This third step therefore involves not only the generation of possible solutions to the problem, but also a consideration of the consequences of each of the choices available. The final step of the FEAR plan ('Results and rewards?') asks children to evaluate the results of the methods they used to cope with the anxiety-provoking situation. After evaluating the results of their actions, children in the Coping Cat programme are encouraged to reward themselves for success or partial success in dealing with their anxiety.

The four-step FEAR plan central to Kendall's treatment package has a great deal in common with conceptualizations of the problem-solving process. The problem-solving strategies conveyed through the FEAR plan in Kendall's programme are consistent with the essential problem-solving skills identified by D'Zurilla & Goldfried (1971) and D'Zurilla (1988): problem definition and formulation; generation of alternative solutions; decision-making; and solution implementation and verification. Furthermore, this programme incorporates all three of the fundamental skills outlined in Spivack & Shure's (1976) model: alternative thinking; means-end thinking; and consequential

thinking. Thus, the Coping Cat treatment can be viewed as an attempt to teach effective problem-solving strategies to children in order to cope with unwanted anxious arousal.

Treatment outcome research

The effectiveness of this cognitive-behavioural treatment for child anxiety has been demonstrated in a series of empirical studies. Kendall (1994) conducted a randomized clinical trial of 47 children (aged 9–13 years) with a primary anxiety disorder diagnosis to compare his cognitive-behavioural intervention to a waiting list control condition. Based on child and parent reports, as well as behavioural observations, it was found that children in the treatment condition showed significantly more improvement at post-treatment as compared to children in the waiting list condition. Furthermore, these differences represented clinically significant improvement and treatment effects were maintained at both 1- and 3-year follow-ups (Kendall & Southam-Gerow 1996). A second randomized clinical trial of 94 children with a primary diagnosis of an anxiety disorder replicated and confirmed these results (Kendall *et al.* 1997). This second study again showed that treatment gains were maintained at 1-year follow-up.

Additional support for Kendall's cognitive-behavioural treatment can be found in research conducted in Australia by Barrett *et al.* (1996). By shortening the initial skill development and training section of the programme, these investigators modified Kendall's 16-session Coping Cat treatment to create a very similar 12-session cognitive-behavioural programme (the Coping Koala). In a study of 79 children with a primary anxiety disorder diagnosis, Barrett *et al.* (1996) found that their modified version of Kendall's programme produced both statistically and clinically significant change relative to a waiting list control. Treatment gains were maintained at 6- and 12-month follow-ups. In addition to the support provided by this Australian adaptation of Kendall's therapy, it is worth noting that other authors have provided evidence that Kendall's approach can be modified to create an effective group cognitive-behavioural treatment for anxiety disorders in children (Barrett 1998; Silverman *et al.* 1999).

Given the impressive empirical data supporting Kendall's approach, the next logical question involves the identification of the essential active ingredients within the Coping Cat programme. Specifically, is the acquisition of problem-solving skills essential to the effectiveness of Kendall's method? Addressing this question requires components analysis, and unfortunately only a single preliminary examination of treatment segments has been conducted to explore active ingredients within Kendall's Coping Cat therapy (Kendall *et al.* 1997). Mid-treatment assessment data were obtained in the second randomized clinical trial of the treatment in order to compare the effects of the first half of the programme, which focuses on education, to the second half of the programme, which focuses on exposure and skill implementation. Kendall *et al.* found that changes generated by the first half of treatment were not significantly different from the waiting list control condition. In contrast, changes

that occurred during the second half of treatment were significantly different from the waiting list control.

This preliminary examination suggests that an intervention limited to education regarding the nature of anxious arousal combined with learning a systematic approach to problem-solving in anxiety-provoking situations does not produce significant behavioural change. This suggests that not only learning but also practising problem-solving skills is important for behaviour change. However, as Kendall *et al.* (1997) noted, because the order of the treatment segments was not counterbalanced, an analysis of the effects of the second half of treatment is actually an analysis of the effects of both treatment segments combined. In other words, the effectiveness of this second half of the treatment may not simply be brought about by effects of imaginal and *in vivo* exposure, but rather by exposure that occurs while the child uses the systematic FEAR problem-solving strategy acquired during the first half of the programme.

Both Kendall *et al.* (1997) and Kazdin & Weisz (1998) have emphasized the need to 'unpack' cognitive-behavioural treatments for child anxiety disorders in order to identify treatment components that are essential to creating lasting behavioural change. This type of components analysis will also be necessary in order to clarify the importance of acquiring effective problem-solving skills for dealing with fear and anxiety. Although Kendall *et al.*'s preliminary examination of treatment segments seems to imply that simply educating children in effective problem-solving is not enough to effect significant change, it is not yet clear how essential problem-solving skills are when combined with exposure. Future studies are necessary to compare the effectiveness of an intervention that is limited to imaginal and *in vivo* exposure with a programme combining these exposure elements with education in effective problem-solving strategies.

Depression

Cognitive-behavioural treatment programmes targeting depressed children and adolescents have extensively utilized components of problem-solving training. One treatment protocol for depressed youth, the Adolescent Coping with Depression course for adolescents (Clarke *et al.* 1990), includes sessions that specifically focus on problem-solving. Research on this treatment programme indicates that the intervention effectively reduces symptoms of depression in adolescents diagnosed with dysthymia or major depressive disorder (Lewinsohn *et al.* 1985, 1990; Clarke *et al.* 1999).

Primary components

The Adolescent Coping with Depression programme (Clarke *et al.* 1990) is a 16-session cognitive-behavioural and psychoeducational treatment designed for adolescents aged 14–18 years. Sessions focus on relaxation training, pleasant events scheduling, cognitive restructuring, and building social skills, communication skills and problem-solving skills. The treatment

protocol is designed for a group format, although it can be adapted for individual treatment. Therapist-led groups include didactic presentations, group discussions, role-playing and in-group practice of specific skills. Adolescents complete weekly homework assignments focused on monitoring and practice of skills learned in group sessions. The programme includes optional parent groups that can be run simultaneously with the adolescent groups for nine sessions. Although these groups are run separately, two sessions of problem-solving included in the adolescent treatment manual are designed for joint parent-child group interactions.

Problem-solving components

The 16-session treatment includes four sessions that specifically focus on problem-solving and communication skills. Clarke *et al.* (1990) included problem-solving in the treatment protocol based on the hypothesis that the inability to resolve family conflicts may contribute to and maintain adolescent depression. Clarke *et al.* (1990) based their model of problem-solving and negotiation techniques on those developed by Gottman *et al.* (1976), Robin (1979) and Forgatch & Patterson (1989). The sessions draw on Robin's (1979) model of a four-step problem-solving process: problem definition; brainstorming alternative solutions; selection of a solution through negotiation; and specification of details for implementation of solution. Problem-solving and negotiation are the final skills taught and practised as part of the overall treatment programme.

The first session dedicated to problem-solving introduces rules for defining a problem and involves in-session practice of problem-solving and active listening through role-playing techniques. Adolescents are asked to practice these skills as homework before the next session. In the subsequent session, youths are introduced to brainstorming techniques. This includes structured guidelines for evaluating solutions and writing detailed contracts for implementation of the chosen solution. Adolescents then practice role-playing the process of problem definition, solution generation, evaluation and implementation. Participants are assigned homework involving the completion of the Issues Checklist (Robin & Weiss 1980) and practice of the skills learned in-session. The final two sessions dedicated to problem-solving address in-session interactions between youths and their parents. In the absence of parents, adolescents role-play with other group members in dyads that are closely supervised by therapists. These final two sessions address actual problems defined by the adolescents and their caregivers on the Issues Checklist. In-session, adolescents utilize the skills they have learned to practise problem-solving these issues. In addition, time is spent reviewing how to explain this process to parents and how to explore more distressing issues in the future.

Treatment outcome research

Outcome studies of the Adolescent Coping with Depression course have demonstrated statistically and clinically significant

changes in symptoms of depression at post-treatment and follow-up (Lewinsohn *et al.* 1990; Clarke *et al.* 1999). Patients in Lewinsohn *et al.*'s (1990) study were assigned to an adolescent only, adolescent-parent, or waiting list control group. Compared to participants in the waiting list group, adolescents in both treatment groups reported significantly fewer symptoms of depression on the Beck Depression Inventory (BDI) and the Center for Epidemiological Studies-Depression Scale (CES-D) post-treatment. Similarly, they reported a significant decrease in the number of participants meeting diagnostic criteria for depression, as determined by the Schedule for Affective Disorders and Schizophrenia for School-Age Children (Kiddie-SADS) interview in the treatment groups following the intervention. Differences between the two treatment groups were not significant, indicating that the parent group did not have a differential effect on the youth's self-report of depressive symptoms. Scores reflecting internalizing and externalizing symptoms on the Child Behaviour Checklist (CBCL; Achenbach 1991) completed by parents, on the other hand, were significantly lower for adolescents in the adolescent-parent group as compared with the adolescent only group at post-treatment. However, behaviours reported by parents of participants in the adolescent only group continued to decrease so that CBCL scores were equivalent by 6-month follow-up. Participants in both treatment conditions maintained treatment gains over a 2-year follow-up period.

These clinically and statistically significant reductions in depressive symptoms were replicated by the Clarke *et al.* (1999) study. This second study expanded the intervention by providing booster sessions and follow-up assessments. The results indicated that booster sessions did not reduce unipolar depression recurrence rates in the follow-up period, but did accelerate recovery in adolescents who were still depressed at the end of the intervention trial (Clarke *et al.* 1999).

Components analysis

Although no studies to date have looked at a components analysis of the problem-solving element of this intervention, Lewinsohn *et al.*'s (1990) study did investigate outcomes related to specific issues addressed by the treatment components. Measures were used to assess depressive cognitions, pleasant events, social skills and conflict resolution. The Issues Checklist (Robin & Weiss 1980), which contains 44 issues that are typically problematic for adolescents and their parents, was used to assess conflict resolution. Although this is not a precise measure of problem-solving skills, the components of the intervention that addressed problem-solving and negotiation also utilized this checklist. Therefore, outcome data on this measure are likely to reflect specific skills gained during treatment. However, the results indicated no significant differences post-treatment between the treatment and waiting list conditions on scores on the Issues Checklist (Lewinsohn *et al.* 1990). Nevertheless, scores on the Issues Checklist did improve over time, resulting in a significant difference between post-treatment and 6-month follow-up scores (Lewinsohn *et al.* 1990).

Disruptive behaviour disorders

Problem-solving therapies for disruptive behaviour disorders have been developed to train children and adolescents to identify effectively potential problem situations, to create alternative solutions to the problem, to evaluate the different possible results of each alternative and choose the most effective one. Early studies showed that non-clinical samples of oppositional and defiant children could improve their abilities to create alternative solutions to problems as well as display some limited improvement in overall problem-solving abilities (Gresham 1985). Building on this early work, Kazdin *et al.* (1987a,b, 1989, 1992) have demonstrated that these same problem-solving strategies can result in reductions in problem behaviours with clinical samples.

Kazdin *et al.* have developed a specific variation of problem-solving therapy, Problem-solving Skills Training (PSST), which incorporates aspects of self-instructional procedures similar to those in early problem-solving interventions (Camp & Bash 1981). Based on the work of Luria (1961), Vygotsky (1962) and Meichenbaum & Goodman (1971), it has been hypothesized that problem-solving skills training could lead to the reduction of impulsive behaviours (Spence 1994). In PSST the primary goal is to bolster the interpersonal problem-solving skills that are considered to be deficient in children with conduct disorder.

Primary components

Kazdin (1996) describes five essential features of PSST. First, the emphasis in PSST is on the process that the child uses in choosing behaviours, rather than on the behaviours themselves. The second essential feature of PSST involves teaching the strategy of a step-by-step analysis of interpersonal situations. In this phase, self-instructional features are used to direct the child's attention to critical elements of the process that can lead to a successful and appropriate resolution of a conflict. Third, although problem-solving skills are eventually applied to real world situations, PSST begins with the application of problem-solving skills to simulated situations presented in the form of games, academic tasks and stories. When efficacy is established in these simulations, the skills are progressively applied to real-world situations. The fourth component of PSST is the active role that the therapist takes in the treatment. The therapist not only teaches the skills, but also models the use of self-instruction and provides feedback and rewards for effective use of the skills. The use of a wide array of methods to teach problem-solving skills, such as modelling, role-play and positive reinforcement, is the final distinguishing component of PSST.

Problem-solving components

PSST was designed as a manualized treatment conducted over a minimum of 16 sessions over 4–5 months. The process of problem-solving has been broken down into five different steps.

Each of the following five problem-solving steps is linked to a self-instruction statement.

- 1 Step 1 requires a child to identify a problem.
- 2 Step 2 involves the child arriving at solutions to the problem.
- 3 Step 3 asks the child to evaluate the generated solutions.
- 4 Step 4 asks the child to choose the answer thought to be the most correct.
- 5 Step 5 requires the child to verify whether or not the answer was correct or appropriate, and the child is asked to determine whether the choice was self-reinforcing.

A central component in problem-solving skills therapy is the use of contingencies. Social reinforcement in the form of verbal, non-verbal and affectionate attention is used to facilitate skill development. A token system is used in PSST for two purposes: first to reduce the frequency of errors in problem-solving tasks and strategies; and secondly to reduce impulsive behaviour. Following a basic response–cost model, the child is given a specific number of tokens at the beginning of each session. When the child acts impulsively by moving too quickly through a task, or makes a mistake by improperly using a problem-solving skill, the child is fined a token. The child is able to earn additional tokens by accurately self-evaluating his or her performance at the end of a session. At the end of each therapy session the child is able to use these tokens to purchase a prize from a reward menu.

Treatment outcome research

Kazdin has conducted the majority of outcome studies on the effects of PSST in children with conduct disorder. In a series of studies, PSST has been compared against a non-directive relationship therapy (RT) and a waiting list control in the treatment of children exhibiting severe antisocial childhood behaviour. Kazdin *et al.* (1987a) examined the effects of PSST on children in the study who met diagnostic criteria for conduct disorder (69% of the sample), and children with scores in the clinical range on the Aggression or Delinquency scales of the CBCL. PSST was shown to reduce externalizing and aggressive behaviours significantly more than RT or no intervention. There were also significant reductions, as compared to RT and controls, in overall problem behaviours at school and home for the PSST group (Kazdin *et al.* 1987a).

In a subsequent study in which 75% of the participants met criteria for conduct disorder, PSST alone was compared to PSST with *in vivo* practice (PSST-P) that extended therapy and training to situations outside of treatment (Kazdin *et al.* 1989). Children in the PSST-P group were given tasks that involved applying skills learned to treatment in real-life situations where their problem behaviours often occurred. PSST and PSST-P groups were compared to RT groups and controls. Children in the PSST and PSST-P groups showed significantly greater reductions in antisocial behaviour and overall behaviour problems, and an increase in prosocial behaviour as compared to the RT and control groups. All differences between PSST and PSST-P groups were absent at follow-up (Kazdin *et al.* 1989).

More recent outcome studies have focused on comparing the benefits of combining PSST and other cognitive therapies such as parent management training (PMT; Kazdin *et al.* 1987b, 1992). The combined effects of PSST and PMT have been shown to be more effective at reducing externalizing and aggressive behaviours than either PSST or PMT alone (Kazdin *et al.* 1987b, 1992).

Clinical significance

Even though the children in these outcome studies showed a decrease in antisocial behaviour, the PSST intervention has not yet demonstrated high levels of clinically significant change. For example, in Kazdin's study investigating the effects of PSST in conjunction with PMT for children with conduct disorder, the total behaviour score on the CBCL was 10 points lower at follow-up but still had an average T score of 68.4, a level higher than 95% of the normative sample on this measure (Kazdin *et al.* 1987a). Kazdin's study comparing PSST to RT found similar results, with 1-year follow-up scores of total behaviour problems at a mean T score of 68.5 (Kazdin *et al.* 1987b). Kazdin *et al.* (1992) found reportedly stronger effects in a 1992 study combining PSST and PMT in which the mean total behaviour problem scores for children with conduct disorder was a T score of 63.9, but this still falls at a level greater than 90% of the normative sample on the CBCL. More research is needed to parcel out how PSST affects children with conduct disorder differently from other cognitive therapies, and to determine what other steps are needed to reach the ultimate goal of these children achieving normative levels of problem behaviours.

Parent–adolescent conflict

Problem-solving training has been used in interventions with parents and adolescents experiencing high levels of conflict and relationship difficulties (Patterson & Forgatch 1987; Foster & Robin 1989). From a skills-deficit viewpoint, parent–adolescent conflict results from a family's inability to solve difficult issues productively, and that directly teaching these skills will lead to less conflict and greater accord in families (Foster & Robin 1998). The most extensive research on problem-solving with this population has been conducted by Foster & Robin (1989), who designed an intervention called Problem-solving Communication Training (PSCT) for conflicting families.

Problem-solving components

PSCT involves 8–12 sessions usually conducted with the entire family present, in which therapists teach specific problem-solving methods as well as guide families in using these skills to solve actual problems they experience. Therapists use modelling, direct instruction and feedback, role-play, taped models of other families and written outlines to convey the problem-solving information.

In general, the conceptualization of problem-solving in this

intervention reflects the four- or five-step cognitive-behavioural process originally outlined by D'Zurilla & Goldfried (1971) and D'Zurilla (1988). First, parents and adolescents are taught to define problems in a concise and non-defensive manner. Secondly, they learn to generate solutions for particular problems, using specific brainstorming methods that emphasize the inclusion and non-evaluation of several possible solutions. In the next stage, solutions are evaluated for their potential effectiveness, following which a particular solution is chosen and implemented. The final step involves the evaluation of the chosen solution, and the possible choice of another solution if the original one is found to be ineffective.

In addition to teaching basic problem-solving skills, the PSCT treatment and similar interventions for parent–adolescent conflict incorporate training in communication skills, including active listening, non-verbal attention, expressing praise, and asking questions of the speaker (Patterson & Forgatch 1987; Foster & Robin 1989). The inclusion of communication skills in the intervention reflects the hypothesis that adolescents, when compared to younger children, have developed some of the higher order linguistic and interpersonal skills important for mastering these techniques.

Treatment outcome research

The effectiveness of PSCT has been examined in a series of studies. In one study, researchers trained 24 pairs of teenagers and their mothers in communication and problem-solving, using both hypothetical and real problems (Robin *et al.* 1977). Inclusion criteria included no psychiatric history, as well as a history of 'excessive disagreement'. After the five-session training, observed communication between parents and teenagers improved significantly, but reports of conflict at home remained unchanged.

In another study with a slightly different version of PSCT, 33 families experiencing disagreements were assigned to one of three groups: a waiting list control group, a best-alternative treatment group, or PSCT with a cognitive restructuring component (Robin 1981). Results indicated that both treatment groups showed decreases in anger intensity and improved relationship functioning, whereas only the PSCT group showed improvements in specific problem-solving and communication skills. A 3-month follow-up showed that both treatment groups maintained improved communication, despite increases in anger intensity.

Investigators have compared different versions of PSCT to assess which form of the intervention renders it most effective. In one study, evaluators compared traditional PSCT, PSCT with generalization training including homework, and a waiting list control group (Foster *et al.* 1983). The treatment consisted of seven sessions, and the training for the 28 participant families included both mothers and fathers. Results showed no change in observed communication in any of the groups, but the two treatment groups demonstrated improvements in questionnaire reports of familial relationship functioning, including decreases in

maternal anger. In addition, the generalization group appeared to show no enhanced performance of problem-solving skills outside of the therapy office and, in fact, appeared at 2-month follow-up to show relative declines in skills compared to the non-generalization group.

Stern (1984) evaluated whether the addition of anger management techniques increased the effectiveness of PSCT, by comparing basic PSCT to PSCT with anger and stress control instruction with a group of conflicting families. Results indicated that both groups showed enhanced communication and decreased insults in mothers and teenagers, as well as less anger intensity and fewer issues of conflict rated by mothers. Only teenagers in the anger management group showed decreases in anger intensity and fewer conflict-producing issues. Both groups showed improved communication and problem-solving skills, with anger management adding slight benefits.

Nayar (1985) compared PSCT with and without cognitive restructuring to a waiting list control group, using a small group of conflicting families who were trained in groups over seven sessions. Results indicated that both groups were more effective than the control group, and that the additional cognitive restructuring yielded decreases in maternal self-blame and distortion.

Clinical significance

A preliminary study of the clinical significance of problem-solving interventions revealed that this training produces some important changes for parents and teenagers in conflict (Robin & Foster 1989). Examining changes in communication, anger and number of conflict-producing issues, the investigators compared 45 families receiving PSCT with 29 control group families. On a measure of communication, 68% of treated parents and 39% of treated teenagers showed gains after treatment, compared to 24% of teenagers and 24% of parents in the control groups. On a measure of anger intensity and conflict, 54% of treated parents and 27% of treated teenagers showed improvements, compared to 24% of parents and 31% of teenagers in the control groups.

It should be noted that most studies of PSCT have generally involved families in which overall psychological functioning is fairly high, and changes in diagnosed psychopathology because of the intervention are usually not tracked. In preliminary studies of children with specific psychological disorders, PSCT has shown mixed and even negative results. One recent study, for instance, has shown that PSCT is not effective and may even decrease functioning in families in conflict where adolescents have attention deficit hyperactivity disorder (Barkley *et al.* 1992). In order to determine the clinical significance of PSCT, additional research is needed to assess the effectiveness of PSCT in conflicting families in which adolescents manifest psychological disorders, such as conduct disorder or depression.

Drawing clear conclusions about the effectiveness of PSCT is somewhat limited by methodological and measurement inconsistencies across studies, as well as by small sample sizes. Nevertheless, in several studies PSCT has yielded significant im-

provements in the functioning of conflicting families. The addition of anger management training appears to increase the effectiveness of PSCT, whereas some evidence indicates that generalization of the skills through homework assignments produces no additional change. In terms of component analyses, it may be difficult to parcel out whether or not problem-solving skills are the effective component of the PSCT intervention, because these skills make up the majority of the treatment. Nevertheless, future research could measure whether the communication training adds significantly to the intervention, or if any of the specific steps of problem-solving (e.g. identifying the problem or generating solutions) are more important than others.

Summary and future directions

Deficiencies in problem-solving skills have been implicated in internalizing disorders (anxiety, depression), externalizing disorders (oppositional-defiant disorder, conduct disorder), and family conflict in childhood and adolescence. Furthermore, treatments designed to increase problem-solving skills have been shown to be associated with both statistically and clinically significant improvement in all of these problem areas.

In several instances, cognitive-behavioural treatments that teach problem-solving skills meet the stringent criteria for empirically supported treatments outlined by Chambless & Hollon (1998). The effects of the treatments have been evaluated in controlled clinical trials in comparison to either a no treatment control condition or an alternative intervention, and the effects have been replicated by independent groups of investigators (Kazdin & Weisz 1998). For example, cognitive-behavioural interventions for the treatment of childhood anxiety disorders, which include elements of problem-solving training, have been shown to be effective in controlled outcome studies by Kendall *et al.* (1997) and effects of a similar intervention have been reported by Dadds *et al.* (1999). These studies provide relatively strong evidence for the efficacy of this treatment package that is superior to no treatment and is independent of effects of a single investigator. Other interventions that include problem-solving components can be classified as probably efficacious at this time, as they have been shown to be superior to either no treatment or to an alternative treatment, but these effects have not been replicated across more than one investigative team (Lewinsohn *et al.* 1990; Kazdin 1996; Clarke *et al.* 1999).

In spite of the significant progress that has been made in the development, implementation and evaluation of therapies involving problem-solving skills, four significant problems remain. First, there is little or no evidence that the teaching of problem-solving skills *per se* is an essential and active ingredient in these therapies. We did not find any research that included components analysis of cognitive-behavioural therapy supporting the role of problem-solving skills as essential to producing behaviour change in the treatment of either internalizing or externalizing problems. In the absence of studies that break treatments into their component parts, the effects of problem-solving

cannot be clearly delineated. A high priority for future research will involve the use of research designs that allow for specificity in determining the contribution of problem-solving skills as compared to other elements in comprehensive cognitive-behavioural treatments.

A second limitation of this research is the failure to consider problem-solving skills as a component of a broader range of skills of coping and self-regulation. Problem-solving skills are only one important aspect of the skills that are needed for the regulation of cognition, emotion, behaviour and physiological arousal. The usefulness of problem-solving skills may depend on the ability to first soothe and regulate emotional arousal, including the management of fear, anxiety, anger and dysphoria. Furthermore, problem-solving skills may be augmented by other regulatory skills, including those involved in adapting to problem situations (secondary control coping responses). Adaptational skills include the ability to distract or shift attention away from threatening stimuli, accept problems that may be uncontrollable, and cognitively reframe problems to view them in a more positive light.

Third, there has been little comparison or integration of problem-solving methods with other models of treatment. For example, behavioural treatments for disruptive behaviour disorders that emphasize working with parents to change parenting skills and the use of contingencies to manage children's externalizing behaviour problems have been shown to be effective (Webster-Stratton & Hammond 1997; Webster-Stratton & Hancock 1998). The integration of problem-solving therapies with these other treatment methods remains relatively unexplored.

Finally, there is little evidence of individual differences that may be associated with positive or negative response to problem-solving therapy. Child characteristics that may influence treatment response to problem-solving therapy may include general cognitive or intellectual skills, temperamental characteristics and comorbid conditions. Similarly, characteristics of children's social environments, especially the quality of parent-child relationships, may influence the efficacy of interventions that enhance children's problem-solving skills.

In spite of these limitations, significant progress has been made in the development and evaluation of problem-solving therapies for a number of disorders of childhood and adolescence. These interventions offer relatively powerful empirically based methods to professionals to use in the treatment of anxiety, depression, disruptive behaviour disorders and parent-adolescent conflict. Future research will be important in refining these interventions to enhance their efficacy and increase specificity in their application to problems of childhood and adolescence.

Introduction

Parent training programmes teach behavioural principles of child management by following a specific curriculum over several weeks. Parent training delivered in this structured way is the most widely researched psychological intervention in child and adolescent mental health. It is the single most effective intervention for the treatment of conduct problems in children, and is solidly based on extensively researched models of parent–child interaction. From early beginnings that focused on techniques for managing child misbehaviour at home, it has spread to include the promotion of child problem-solving skills, improvement of peer relationships, and the enhancement of literacy and school relationships. The content of programmes now goes beyond behaviour to address beliefs, emotions and the wider social context, and addresses issues that can impair parents' effectiveness, such as poor self-confidence, depression, an unsupportive partner and social isolation. Yet despite being highly effective and well received by parents, parent training is not routinely available as a treatment in any country in the world. This chapter will examine developments in parent training mainly in connection with child conduct problems, for which there is most evidence.

Distinction from other approaches

Some characteristics of parent training programmes are given in Table 56.1. They differ from other psychological interventions in important ways. A *psychoeducational* approach is used by many clinicians, where parents are informed about the nature of their child's difficulties and advised on management but are not expected to practise specific skills. *Individual behavioural work* is used by many clinicians for a wide range of presenting conditions (Herbert 1987). It has the advantage of flexibility, so that content, pace and duration can be tailored to the specific needs of a family. However, it may not match the range and depth of coverage of techniques found in a systematic programme. *Counselling* of a Rogerian type (Rogers 1961) is widely used in non-medical settings, with an emphasis on non-judgemental positive regard and respect for the parent. Listening well to parents helps engagement and is popular, but unless there are other elements such as helping them to find new solutions to their difficulties, as for example in the Parent Adviser Model (Davis & Spurr 1998), the gain for child mental health may be little.

Family therapy shares with parent training an interactional view of the maintenance of child behaviour problems. Exploration of families' beliefs and interrelationships may lead them to greater understanding of their predicament. Skills are not as a rule imparted, the theoretical model is not usually made explicit to the family and has less research backing, and there are fewer evaluations (Chamberlain & Rosicky 1995). *Humanistic parenting programmes* often focus on the improvement of parent–child relationships, particularly how to talk and communicate with a child (see review by Smith 1996). A strength of these programmes is that they are often delivered by voluntary sector organizations in community settings which can make them more accessible and acceptable than clinic services (Cunningham *et al.* 1995). A disadvantage is that sometimes staff are less well trained, and the programmes have seldom been rigorously evaluated using child outcomes.

Theoretical considerations

History

Parent training originated in the USA in the 1960s and drew on two traditions. The first was behavioural learning theory. This was developed by Skinner (1953) and others in the 1950s and led to its use in much adult clinical work, including the running of whole hospitals on token economies to increase desired behaviours. In the 1960s the learning theory framework was elaborated to include social learning. A logical application was to teach parents to manage the contingencies around child social behaviour. This was developed by, amongst others, Wahler *et al.* (1965) in Tennessee, and Patterson *et al.*, who founded the Oregon Social Learning Centre (Patterson 1969). The second tradition, less often acknowledged, was play therapy. Constance Hanf in Portland, Oregon developed an unpublished parent programme based on non-directive play (Hanf 1969) that greatly influenced the parent training programmes of Forehand (Forehand & McMahon 1981), Eyberg (Eyberg 1988; Hembree-Kigin & McNeil 1995), and Webster-Stratton (1981a, 1984). Since these foundations, parent training has incorporated a range of other concepts from child development and psychological treatment research, while paying less attention to others that are also relevant, as discussed below.

Table 56.1 Characteristics of effective parent training programmes.

<i>Content</i>
Structured sequence of topics, introduced in set order over 8–12 weeks
Subjects include play, praise, incentives, setting limits and discipline
Emphasis on promoting sociable self-reliant child behaviour and calm parenting
Constant reference to parent's own experience and predicament
Theoretical basis informed by extensive empirical research and made explicit
Detailed manual available to enable replicability
<i>Delivery</i>
Collaborative approach acknowledging parents' feelings and beliefs
Difficulties normalized, humour and fun encouraged
Parents supported to practise new approaches during session and through homework
Parent and child seen together in individual family work; just parents in some group programmes
Crèche, good quality refreshments, and transport provided if necessary
Therapists supervised regularly to ensure adherence and to develop skills

Parenting styles and child behaviour

A note of caution before examining the association between child-rearing styles and child behaviour! Some pundits confidently assert the 'right' and 'wrong' ways to bring up children. However, judging by the changes in the last 100 years, what we assert today may be dramatically overturned in future. For example, in Victorian Britain it was stated that children should be 'seen and not heard' and a popular motto was 'spare the rod and spoil the child', whereas today emphasis is on listening to children, and there is pressure to make any physical punishment illegal. Parenting beliefs and practices vary over time and across cultures, and research findings need to be interpreted bearing this in mind. The work of Deater-Deckard *et al.* (1996) suggests that while for white Americans not smacking children is associated with the lowest rates of conduct problems, in African-Americans not smacking is associated with an *increase* in antisocial behaviour. None the less, a strong association has repeatedly been found between particular styles of parenting and child antisocial behaviour. Harsh, inconsistent discipline, high criticism, rejection and neglect are implicated for children at all ages, with lack of supervision becoming especially important as the young person spends more time out of the home (Patterson *et al.* 1992). Longitudinal studies indicate that these factors are predictive of later antisocial behaviour even after allowing for the initial level of aggression (Patterson *et al.* 1992), suggesting a possible causal role, although other explanations are possible. The role of positive parenting practices has more recently been shown to make an independent contribution, with warmth, involvement in children's activities, praise and encouragement being associated with lower levels of antisocial behaviour (Pettit *et al.* 1997). Once a moderate level of positive parenting prac-

tices is present, however, it appears to be the presence of negative parenting that seems most influential.

Operant learning theory

Despite the many influences on child socialization, an overarching principle in parent training has been operant conditioning. Patterson's detailed observational work (Patterson 1982) showed that in families with an antisocial child, two processes maintained aversive child behaviour. First, it was frequently reinforced by parental attention, usually negative remarks such as nagging and criticism. A pattern of negative coercive interactions between parent and child led to escalation by both sides. Secondly, having made repeated unpleasant threats, the parents often failed to carry them through and would retreat, thus reinforcing the child's escalation by stopping being unpleasant. Detailed sequential observational analyses showed that within parent-child dyads, when parents behaved coercively (as defined above) child antisocial behaviour became more frequent, whereas when parents desisted from this, difficult child behaviour diminished (Patterson 1982; Snyder & Patterson 1986). Therapeutic programmes were therefore developed to encourage parents to extinguish unwanted behaviour through selectively ignoring it, and to follow through calmly on punishments, which might include withdrawal of privileges and 'time out' from any positive reinforcement.

In tandem with the need to reduce unwanted behaviour, learning theory stressed the need to promote appropriate behaviour. Attention and rewards for desired behaviour are a major part of training programmes, encapsulated by the motto 'catch your child being good' (Becker 1971). More recent observational studies confirm that parents who reward prosocial behaviour have children with fewer behaviour problems (Gardner 1987), even when controlling for harsh parenting (Pettit *et al.* 1997).

Classical learning theory and the antecedents of child behaviour

Operant learning theory is more concerned with the *responses* to a spontaneously emitted behaviour than with the prior setting events that may *elicit* a behaviour. Classical learning theory puts more emphasis on stimuli that trigger behaviour. From this perspective, antisocial behaviour may not simply develop from being unwittingly rewarded once it has occurred, but may have been precipitated by antecedent events, regardless of consequences. This approach is reflected in behavioural manuals that refer to *stimulus control*. They encourage parents to keep a diary of their child's problem behaviour, so that with the therapist they can look for precipitants and make suitable changes (Herbert 1987). Surprisingly, many parent training programmes make little use of structuring the day and planning ahead with routines to avoid trouble. Yet most parents and clinicians would see this as an essential part of effective parenting, e.g. giving active children opportunity to run around after school, avoiding demanding tasks when children are tired or hungry, taking toys or books

to occupy the child when a long wait is likely, and so on. Involving children in constructive pastimes within the home such as painting or cooking, and outside such as football or swimming, can offer the opportunity to enhance confidence and build social skills, thus reducing the likelihood of oppositional behaviour. The development of instruments to measure such activity is underway, e.g. the Parent–Child Joint Activity Scale (Chandani *et al.* 2000).

Social learning theory

Processes other than stimulus–response psychology are involved in the integration of a child into the social world, such as imitation in early childhood and identification in middle childhood (Bandura 1977). These mechanisms of social learning have seldom explicitly been drawn upon in parent training. However, some recent programmes address parents' own aggressive behaviour with each other and teach them to solve their own problems, so their children can learn from them via imitation, aided by direct modelling (Webster-Stratton 1994a).

Cognitive processes

The behaviourist approach is mainly concerned with the external events impinging on an individual, and takes less account of how they may be thinking or feeling. Indeed, a central tenet is the lack of a need for introspection or understanding of what is in the 'black box' inside an organism (Skinner 1953). This has made it especially useful for dealing with animals and babies, but ignores the fundamentally human phenomena of language and thought. In contrast, over the last 30 years particular cognitive styles have been shown to be characteristic of children and young people with disorders such as depression and conduct problems. In interpersonal encounters, the latter are more likely to perceive the intentions of others as hostile, generate fewer solutions to conflicts, and to believe an aggressive solution will be more effective (Dodge & Schwartz 1997). Individual cognitive and problem-solving programmes have been developed (Lochman & Wells 1996), and can be used with parent training programmes, as discussed below.

Less work has been carried out mapping the cognitive processes of parents with disruptive children. Unsurprisingly, parents of antisocial children have more negative beliefs about them and attribute more negative intentions to them; rates of depression amongst mothers are high (Sanders & McFarland, 2000). Some parent training programmes incorporate techniques from cognitive therapy. Parents may be encouraged to monitor their own 'self-talk' or 'inner voice' and to check on hopeless and defeatist cognitions, and be helped to find ways of replacing these with more positive statements that facilitate coping (Webster-Stratton & Hancock 1998).

However, parents of children with behaviour problems may not just think differently, they may perceive events differently too. Experiments showing videotapes found that these parents not only failed to see many episodes of positive child behaviour

but, surprisingly, also saw fewer episodes of *negative* child behaviour. This suggests that rather than just being biased to see child behaviour in a bad light, these parents are also less attuned to perceiving *any* child behaviour accurately, and hold global non-specific negative feelings towards their children (Wahler & Dumas 1989). The implication for parent training may be that parents need to be helped to perceive their children's behaviour more accurately, and become more attuned to nuances of their child's mental state, rather than just being offered management skills. Parent training programmes that use videotaped sequences of parent–child interaction incorporate this.

Peers and academic influences on child outcome

Longitudinal studies have shown that independent of the initial level of antisocial behaviour and parenting quality, deviant peer associations (Fergusson *et al.* 1999; Poulin *et al.* 1999) and lower IQ and academic underachievement further influence antisocial behaviour (Hinshaw 1992; Patterson *et al.* 1992; Fergusson & Lynskey 1997; Rutter *et al.* 1998). While some programmes aimed at antisocial outcomes have added on components to address these issues, e.g. by promotion of prosocial peer affiliation (Conduct Problems Prevention Research Group 1992; Dishion & Andrews 1995) and special tuition (Conduct Problems Prevention Research Group 1992; Barkley *et al.* 2000), parents also can have some influence on these processes, which could be incorporated into parenting programmes. This would envisage a model of parenting that goes beyond a good interactional style and prudent management within the home, to playing a part in helping the child cope with the outside world. This may include programme elements to enable the parent to negotiate with school (Webster-Stratton & Hancock 1998), to coach better peer relationships through 'play dates' (Frankel *et al.* 1997), or to raise child literacy through training parents to use specific reading techniques with their child (Scott & Sylva 1997). At a broader level, parents can help select the environment to which the child is exposed, by encouraging certain friendships to flourish and discouraging others, by choosing an appropriate school for the child's needs, and by helping learning through providing a facilitative home environment. These aspects of parenting are seldom parts of parent training programmes, although they feature in some 'self-help' books on parenting.

Natural history, genes and environment

Studies of the natural history of serious antisocial behaviour used to suggest that it peaks in late teenage or young adulthood, when most offending occurs. However, as Tremblay (2000) has pointed out, the age when physical aggression is maximal is around 22 months (and not 22 years!). From this perspective, it may be pertinent to ask not what causes antisocial behaviour to develop, but rather, why did the usual peak at around 2 years not reduce? What are the usual mechanisms that cause antisocial behaviour to diminish after this age? They may turn out to be the

same mix of parent and child factors already identified, but studies are needed to see whether antisocial schoolchildren were more disruptive than others before the age of 2, or only after.

Better characterization of antisocial behaviour has revealed at least two reliable subtypes. In one, antisocial behaviour is manifest early, typically by 3 years of age, carries on throughout life ('early onset–lifetime persistent' pattern; Moffitt 1993), and is associated with hyperactivity, impulsiveness, irritability and emotional problems, and lower IQ. In the other, antisocial behaviour begins in adolescence often as part of peer group rebelliousness, and desists in adulthood ('adolescence-limited' type). The early onset pattern appears to have a substantially higher heritability than the adolescence-limited type, where environmental influences, especially shared ones, are more prominent. More complex typologies of antisocial behaviour usually include a type with multiple comorbid psychopathology and neuropsychological deficits, where the heritability can be as high as 96% (Silberg *et al.* 1996). Some might conclude that changing the parental environment will have little effect where genetic influence is high.

This is erroneous for several reasons. First, the cause of a problem and solutions to ameliorate it may operate through quite different mechanisms, e.g. phenylketonuria is a genetically caused condition but responds to environmental manipulation, namely a low-phenylalanine diet. Second, genetic studies measure the variation in environment occurring naturally in the study population, which may not be very great for most members, whereas intervention often allows the level to be experimentally changed to a greater extent. Thus, early onset type antisocial behaviour might not vary much across the range of environments found in most families, but if very different environments are applied (as obtained, say, in treatment foster-care or an inpatient unit) it may change substantially. Thirdly, there is now good evidence of an interaction between child predisposition to antisocial behaviour and rearing environment. Infants with more negative temperaments (assessed independently from their parents) are more susceptible to poor parenting as shown by the development of more externalizing problems by age 3 than would be predicted from just adding the effects of temperament and parenting (Belsky *et al.* 1998). Likewise, adoption studies suggest that children with higher genetic risk (as indexed by parental criminality, antisocial personality or substance misuse) are far more likely to develop criminal behaviour in families with difficulties (e.g. criminal, psychiatric or legal problems) than predicted by just adding the genetic and rearing risks (Cadoret *et al.* 1995; Bohman 1996). The implication for parent training is that rather than being *less* effective for children with severe types of antisocial behaviour with high genetic liability, it may be *more* effective for them.

Taylor *et al.* (1996) conducted a community study of 7-year-old children with hyperactivity who were followed up aged 17. Subsequent analyses have shown that the 7-year-old hyperactive children whose parents were highly critical had developed far higher levels of conduct problems by 17 than those whose par-

ents were not unduly critical. This suggests that children with disruptive behaviour that has a substantial inherited component can nevertheless be parented in a way that makes a considerable difference to their psychosocial outcome.

Parental factors that influence parenting

Not all parents start with the same level of skills for parenting, and not all are able to change to the same degree. A number of risk factors are relevant, and the question arises whether outcome is better if they are addressed through adding specific components to parenting programmes.

Generalized learning disability

There is no intrinsic reason why people with IQs under 70 should parent poorly, although as IQ gets lower, especially below 60, general impairment of social functioning becomes more and more evident (Scott 1994). Empirical evidence is patchy, but children deemed by local authorities to be at risk from parental abuse or neglect are more likely to have parents of lower IQ (Dowdney & Skuse 1993). Parental IQ has not been studied as a predictor of outcome in parent training although, as with any new learning task, it is likely to have a moderating effect.

Parental mental disorder

Any mental disorder of moderate or severe degree may interfere with parenting ability. However, harm does not appear to be done through the parent having a mental disorder unless it leads to poorer care for the child (Rutter & Quinton 1994). Conversely, ameliorating the disorder will not necessarily lead to a great improvement in parenting skills, unless they were at a good enough level previously. Maternal depression leads to less sensitive responding and less cognitive stimulation for the child (Murray & Cooper 1997) but, unless severe, is not a contraindication to parent training. Indeed, some studies have shown significant improvement in depression levels compared with controls after parent training (Sanders & McFarland, 2000). One mechanism may be the increased sense of self-efficacy and reduced helplessness about child management that parents report after programmes (Sanders *et al.*, 2000a).

Interparental discord

Cross-sectional studies have found that interparental discord adds to the prediction of child antisocial behaviour, over and above parenting practices (Webster-Stratton & Hammond 1999). While genetic transmission of aggressiveness may well be a component, the child is also likely to learn antisocial habits of conflict resolution and see fewer examples of prosocial skills and negotiation. Therefore gains from a parenting programme may be limited if the child is still exposed to interparental conflict.

Some programmes have a specific component to address inter-parental relationships, as reviewed below.

Poor living conditions

In the UK there is a gradient of increasing prevalence of child disorders with lower social class as defined by occupation of chief breadwinner in the household (Meltzer *et al.* 2000). This gradient is especially marked for conduct problems. The extent to which this has a direct effect on children, or is a marker for other mechanisms, is not fully resolved. In some studies, once quality of parenting is allowed for, poor living conditions are not associated with further levels of disorder (reviewed in Rutter *et al.* 1998). However, such an analysis does not allow for the possibility that poor conditions *lead to* poorer parenting. It is not difficult to imagine that living in adverse housing conditions with few facilities and no money to buy practical support, such as child-minding, could disrupt calm and constructive parenting, especially for, say, a lone parent with a mental health problem. Studies indicate that child psychopathology increases with psychosocial adversity (Rutter 1995), and Patterson *et al.* (1992) showed a strong association between deprivation and poor parenting. Improving living conditions is usually beyond parenting programmes, although some offer practical support to help parents engage with housing and benefits agencies.

Social isolation

Social isolation is associated with poorer parenting and with a worse response to parent training (Dumas & Wahler 1983). Amongst what Wahler termed 'insular mothers', most adult contacts were with official agencies and their own mothers who were critical and negative. On days when this occurred, the mothers' harsh and inconsistent parenting of the children rose severalfold. Moreover, while they did as well as non-insular mothers in the immediate outcome of parent training, at follow-up nearly all the gains had been lost. Attempts have been made to add social support systems to parent training programmes (Dadds & McHugh 1992), and to address their despondent cognitions and narratives about themselves (Wahler *et al.* 1993), as discussed below.

Parents who experienced poor parenting as children

Many neglectful or abusing parents experienced little good care themselves, so have little experience to draw upon with their own children. However, this does not mean that they inevitably are unable to become good enough parents. Quinton & Rutter (1988) studied girls who had been brought up in children's homes who subsequently became mothers. Their own experience of parenting had been poor in two ways: first, the reason they were in the homes was their parents' inability to care for them adequately; and, secondly, at the time children's homes were run on very institutional lines without a great deal of close

personal contact between staff and children, and a high turnover of staff made the development of long-term trusting relationships with them unlikely. Despite this and probable associated genetic risk factors, half the women with this background were parenting satisfactorily as judged by interview and direct observation measures. Current attachment research, using the Adult Attachment Interview, is linking parents' own attachment status to the quality of their upbringing (Main 1996). There do not appear to be studies using parents' own upbringing (as opposed to parents' attachment status) as a predictor of intervention outcome.

Particular beliefs about one child

So far, parenting has been discussed as a general ability. However, the quality of relationship between the same parent and different children in the family varies. Adoption studies show that children who were scapegoated in comparison to their siblings in their family of origin do especially badly in terms of outcome (Rushton *et al.* 2000). While some of this may be because of inherent characteristics of the child which led them to become criticized or scapegoated, it is likely that the negative environment further added to their difficulties, particularly in light of the evidence of the interaction between child vulnerability and harsh parenting described above. In clinical practice it is not uncommon to uncover resentments around what the child represents, e.g. an antisocial boy who is seen by his mother to resemble his father whom she hates because he beat her. The implication for intervention is that, in addition to imparting skills, beliefs about the child need to be explored and attempts made to help the parent view the child more positively.

Programme delivery

Engaging families

A sympathetic and effective approach to engaging families is crucial if parenting programmes are to work. This is a major issue for providers of mental health services, because the populations that may benefit the most are often the most reluctant to attend. Several approaches have been taken to improve acceptability and accessibility of programmes. First, the general approach now preferred is to form a *collaborative* relationship characterized by working with parents to achieve their goals by recognizing and building on their existing strengths. This is in contrast to an instructional relationship whereby after an assessment where they are informed of what 'the matter' is with their child, and what is 'wrong' with their handling, parents are 'told' the 'right' way to bring up children. Features of a collaborative approach include asking about child strengths as well as difficulties, praising parents for good aspects of parenting, respecting them as the expert on the individual characteristics of their child, listening carefully to, and showing

understanding of, their beliefs about their child's behaviour, working on solutions parents generate themselves, and normalizing the problem behaviour where possible (Herbert 1995).

Secondly, many practical steps can be taken, e.g. home visits to parents, holding the groups in the local community setting, providing transport, offering a crèche, holding the sessions outside working hours, rewarding parents for attendance through payment or prize draws, telephoning parents between sessions to check on progress and give encouragement, getting parents to ring each other between sessions for support, sending cards to parents who miss sessions, encouraging parents to bring their partner or a friend to sessions, etc.

Format of programmes

Individual work

Here the parent(s) and child are seen together, as in traditional psychological therapies. This has the advantage of allowing the therapist to go at the pace of the parent, observe precisely how they are relating to their child, and modify the intervention accordingly. This can be especially helpful where the child responds differently from the majority with conduct problems, e.g. if he or she is hyperactive, has a hearing or learning disability, or has autistic traits. An individualized approach enables the therapist to do some in-depth work on other issues impinging on parenting, such as interparental consistency, sibling relationships, coming to terms with abuse in the parent's own childhood, etc. In sessions at the Maudsley Hospital, we spend about half of each session addressing such personal issues, and about half working on the behavioural programme. For hard-to-engage families, the programme can be delivered in the family home.

Group work

In the last two decades there has been a strong movement towards parenting groups, and much recent research has been using this format (Barlow 1999). Usually the parents of 6–10 children are seen without their children being present. Therefore therapists have to rely on parents' descriptions of what goes on and cannot practise new approaches 'live'. However, parents can role-play any situation, and report this as being a highly effective component of change. In groups there is less opportunity to explore deeper personal issues but, against this, other parents can offer experience and solutions that are usually more credible than those from professional therapists, and there is often considerable support offered by group members to each other. More intensive programmes may include an element of coaching parents 'live' with their children in addition to parenting groups (Puckering *et al.* 1994; Conduct Problems Prevention Research Group 1999), or may offer a group for the children simultaneously with a group for their parents (Webster-Stratton & Hammond 1997). Contrary to the notion

that individualized treatment would be best, head-to-head comparisons suggest that they are equally effective, as described below.

Written materials, videotapes, broadcasts and self-administered programmes

Most of the well-known programmes have a written manual for therapists, and hand-outs or a book for parents (Webster-Stratton *et al.* 1988; Forehand & Long 1996; Barkley 1997). Some use professionally made videotaped vignettes of parents and children in life-like situations to help parents become sensitive to patterns of behaviour and to show them alternatives (Webster-Stratton 1981b; Sanders *et al.* 1996; Sharry & Fitzpatrick 1999).

Content of a typical programme

Most basic programmes take 8–12 sessions lasting 1.5–2 h each. For details, see manuals by Forehand & McMahon (1981), Barkley (1997), Sanders & Dadds (1993), Webster-Stratton & Herbert (1994) or Hembree-Kigin & McNeil (1995). The programme used for individual work at the Maudsley Hospital is fairly typical and runs as follows.

Part 1: Techniques for promoting a child-centred approach

First session: play

The programme starts with this fundamental aspect of improving the relationship with the child. Parents are asked to follow the child's lead rather than impose their own ideas. Instead of giving directions, teaching and asking questions during play, parents are instructed simply to describe what the child is doing, to give a running commentary on their child's actions. The target is to give at least four of these 'descriptive comments' per minute. If the parent has difficulty in getting going, the practitioner suggests precisely what they should do, e.g. by saying 'I'd like you to say to Johnny "You've put the car in the garage."' As soon as the parent complies, the practitioner gives feedback, 'that was a good descriptive comment'.

After 10–15 min, this directly supervised play ends and the parent is 'debriefed' for half an hour or more alone with the clinician. How the parent felt while doing it is explored, and reservations and difficulties that arose are addressed. The effect of their behaviour on the child during the training session is usually soon observed by the parent. Experiencing this close non-judgemental attention is surprisingly powerful for children, who at best feel they are 'the apple of their parent's eye'. For cases where virtually all communication with the child has become nagging and complaining, play is an important first step in mending the relationship. It often helps the parent to have fun with the child and begin to have some positive feelings towards

him or her. Parents are asked to practise these techniques for 10 min every day.

Second session: checking progress with homework; elaboration of play skills

For the first 20 min, the previous week's 'homework' of playing at home is discussed with the parent in considerable detail. Often there are practical reasons for not doing it ('I have to look after the other children', 'I've got no help') and parents are then encouraged to solve the problem and find ways around the difficulty (solutions arrived at might include doing the play after the younger sibling has gone to bed, getting the oldest child to look after the baby while the parent plays with the toddler, etc.). For some parents there may be emotional blocks ('It feels wrong—no one ever played with me as a child') that need to be overcome before they feel able to practise the homework.

After this discussion, live practice with the child is carried out. This time the parent is encouraged to go beyond describing the child's behaviour and to make comments describing the child's likely mood state, e.g. 'You're really trying hard making that tower', or 'That puzzle is making you really fed up.' This process has benefits for both the parent and the child. The parent gets better at observing the fine details of the child's behaviour, which makes them more sensitive to the child's mood. The child gradually gets better at understanding and labelling his or her own emotional states, a crucial step in gaining self-control in frustrating situations.

Subsequent sessions

These follow the same pattern of:

- 1 reviewing the previous week's homework;
- 2 direct training of interaction with the child; and
- 3 discussion afterwards of how it went.

The speed at which the content is covered depends on progress. Later sessions cover the following ground.

Part 2: Increasing acceptable child behaviour

Praise and rewards

The parent is required to praise their child for lots of simple everyday behaviours, such as playing quietly on their own, eating nicely, getting dressed the first time they are asked, and so on. In this way the frequency of desired behaviour increases. However, many parents find this difficult. First, they may say, 'But he *should* be doing these things anyway, without being praised for it—there's really no need.' Second, when their child has misbehaved earlier in the day they are still cross, and this prevents them praising good behaviour when it occurs. Third, some parents find that even when they want to praise their child, the whole process feels alien to them as often they never experienced praise themselves as a child but, with directly coached practice,

it usually becomes easier. Later sessions go through the use of reward charts.

Part 3: Setting clear expectations

Commands

A hallmark of ineffective parenting is a continuing stream of ineffectual nagging demands for the child to do something. In the programme, parents are taught to reduce the number, but make them much more authoritative. This is done through altering both the manner in which they are given, and what is said. The manner should be forceful (not sitting down, timidly requesting from the other end of the room; instead, standing over the child, fixing him or her in the eye, and in a clear firm voice giving the instruction). The emotional tone should be calm, without shouting and criticism. The content should be phrased directly ('I want you to . . .') and not indirectly or as a question ('Wouldn't you like to . . .'). It should be specific, labelling the desired behaviour which the child can understand, so it is clear to the child when he or she has complied ('Keep the sand in the box') rather than vague ('Do be tidy'). It should be simple (one action at a time, not a chain of orders), and performable immediately. Commands should be phrased as what the parent *does* want the child to do, not as what he should *stop* doing ('Please speak quietly' rather than 'Stop shouting'). If a child is in the middle of an activity, rather than abruptly ordering a stop, a warning should be given ('In two minutes you'll have to go to bed'). Rather than threatening the child with vague dire consequences ('You're going to be sorry you did that'), *when-then* commands should be given ('When you've laid the table, then you can watch TV').

Part 4: Reducing unacceptable child behaviour

Consequences for disobedience

Consequences for disobedience should be applied as soon as possible. They must always be followed through—children quickly learn to calculate the probability they will be applied, and if a sanction is only given every third occasion, a child is being taught he or she can misbehave the rest of the time. Simple logical consequences should be devised and enforced for everyday situations. If water is splashed out of the bath, the bath will end; if a child refuses to eat dinner, there will be no pudding, etc. The consequences should 'fit the crime', should not be punitive, and should not be long term (no bike riding for a month), as this will lead to a sense of hopelessness in the child who may see no point in behaving well if it seems there is nothing to gain. Consistency of enforcement is central.

Ignoring

This sounds easy but is a hard skill to teach parents. Whining, arguing, swearing and tantrums are not dangerous to children and

other people and can usually safely be ignored. The technique is very effective. Children soon realize they are getting no pay-off for the behaviours and soon stop and vice versa; if acting this way gets them attention and shows them they can annoy and wind-up their parents, they will continue to hone their skills in so doing. Ignoring means avoiding discussion, avoiding eye-contact and turning away, but staying in the room to monitor. As soon as the child begins to behave appropriately, it is essential to attend and give praise. This is central to shaping desirable behaviour. Many parents find this difficult as they are often still angry with the child.

Time out from positive reinforcement

The point here is to put the child in some boring place, away from a reasonably pleasant context. This will not be the case if the home is generally negative, when being sent to a room alone will be a relief and not a punishment. Equally, if the room has lots of interesting toys it will also not be a punishment. Time out should be for a previously agreed reason (hitting, breaking things, etc., not minor infringements) for a short time (say, 1 min for each year of age). However, the child must be quiet for the last minute—if the child is still screaming, he or she stays in for as long as it takes until he or she has been quiet for a minute. Parents must resist responding to taunts and cries from the child during time out, as this will reinforce the child by giving attention. Time out provides a break for the adult to calm down too.

Part 5: Strategies for avoiding trouble

These include *planning ahead* to avoid troublesome times of day and situations, *negotiating* with the child how to accommodate their wishes while fitting in with the family goals, and *developing a problem-solving approach with the child* to promote independence, along the lines of problem-solving approaches taught directly by professionals to children (Petersen & Gannoni 1992).

Effectiveness

Methodological considerations

Several general issues are relevant before discussing particular trials (Kazdin 2001). First, different measurement methods and informants will give different effect sizes (Scott, in press). As a rule, teacher-rated questionnaire ratings of child antisocial behaviour are more predictive of later antisocial behaviour than those that are parent-rated, and methods that use objective standardized criteria, such as semistructured interviews or direct observation, are more predictive than questionnaires (Bank *et al.* 1993; Patterson & Forgatch 1995).

Second, statistical significance does not equate to clinical significance. The latter can be assessed from the original dimensional measure of psychopathology statistically in terms of the *effect size* (the mean change in the treated group minus

the change in the control group, divided by the pooled pre-treatment standard deviation; according to Cohen's (1988) guidelines that are widely accepted, an effect size of 0.2 SD is small, one of 0.5 SD moderate, and one of 0.8 SD is large; or by the proportion of the groups that improve by more than 30% (Webster-Stratton 1989), or by more complex formulae that compare the change in the treated sample with general population means (Jacobson & Truax 1991). Clinically significant change can also be assessed in terms of the proportion of the sample who no longer meet criteria for a diagnosis, or by using a measure that assesses the impact of the problem on social functioning or quality of life (Gowers *et al.* 2000). Clinical significance has only relatively recently become reported in studies, but for most described below it was possible to calculate an effect size.

Third, there is usually substantial attrition in trials with families of children with conduct problems. Two reporting strategies artificially inflate effectiveness: only reporting those who attend the majority of treatment sessions, and dropping those who are lost to assessment after entering the trial. The former is becoming less common, but the latter is still widespread. It should be mandatory to at least publish both the results for all those on whom data was collected, and a second analysis including those on whom post-treatment data is missing but adjustments made, e.g. assuming no change since the last data point. Otherwise it is impossible to estimate how much change one can expect if a treatment modality is introduced to a service.

Fourth, the sample used is crucial. Volunteers who respond to advertising campaigns are more likely to be motivated, to have space to think about and implement programmes, and be better off financially. Those referred to specialist parenting clinics may also have been deemed suitable by the referrer, or be self-referred. Some university-based trials exclude children with significant comorbidity, thus dropping those who are likely to do worst. This is in contrast to those referred to generic mental health clinics, who may be more multiply disadvantaged and have more severe and comorbid symptoms (Woodward *et al.* 1997). Even these clinics may miss the most disadvantaged. This is particularly important now that services are starting to target whole populations.

Lastly, many of the cited trials have taken place in university clinics run by highly motivated originators of programmes who supervise carefully chosen therapists intensively in demonstration projects. In the meta-analysis of child psychotherapy trials by Weisz *et al.* (1995) those conducted in university clinics had a large mean effect size of 0.7 SD, whereas all the clinic-based studies reviewed since 1950 did not have any significant effects. It might be concluded that 'the good news is that child psychotherapies work, but the bad news is that they don't work in real life'. Therefore, to be considered robust, findings need to be replicated in ordinary clinical settings by therapists who are part of the routine service and independent of the originator of the programme (Weisz & Hawley, 1998), as occurred in the replication of the Webster-Stratton programme by Scott *et al.* (2001a).

Outcome studies

Individual parent training programmes

For the programmes given individually, several well-designed studies showed substantial changes in observed parent practices and in reported and observed child oppositional behaviour, in comparison to untreated controls (Patterson & Reid 1973; Wells *et al.* 1980; Eyberg & Robinson 1982; Webster-Stratton 1984; Sanders *et al.*, in press). Improvements have typically been of the order of 0.5–0.6 SD on direct observation measures, and 0.6–0.9 SD on parent-report measures. The gains have been substantially maintained at follow-up 1 year later (Patterson 1974; Kazdin *et al.* 1992; Webster-Stratton *et al.* 1989) and over the longer term; Forehand & Long (1988) reported follow-ups of 4–10 years, and Long *et al.* (1993) reported a 14-year follow-up with no relapse of antisocial behaviour.

Group parent training programmes

For group programmes, again there are several good studies. The meta-analysis by Serkitch & Dumas (1996) calculated a mean effect size of 0.86 SD for child behaviour change; that by Hoag & Burlingame (1997) 0.69 SD. The systematic review by Barlow (1999) found 255 studies of group parent training, but only 16 were of a high standard methodologically. In these, the mean effect size of child behaviour change compared to waiting list controls rated by *parents* ranged from 0.4 to 1.0 SD. *Direct observation* showed an effect size of 0.4–0.6 SD, somewhat smaller than parent-report results. Surprisingly, none of these studies used semistructured interviews or structured ones. Follow-up at 1–3 years has shown that significant gains remain, with rather little loss in most programmes. Drop-out rates were typically in the range of 10–20%, lower than the usual 30% plus or so found in usual clinical practice. Weisz *et al.* (1995) have pointed out the lack of effectiveness studies in ‘real-life’ clinics, but the multicentre trial by Scott *et al.* (2001a) found an effect size of 1.06 SD for clinically referred cases using regular clinic staff to administer the intervention.

Self-administered programmes

Sending parents a book and then offering regular telephone advice led to reasonable gains on parent questionnaires and direct observation in two small studies by Sutton (1992, 1995). In a larger study, Webster-Stratton (1984) invited parents to come into the clinic regularly and follow the self-administered version of her videotape series with clinicians on hand to offer help if requested. Gains of around 1 SD compared with waiting list controls were found on parent-report, which was as great a gain as in the clinician-led comparison group. However, on direct observation there was no change, whereas the clinician-led group did 0.4 SD better than controls.

Multilevel programmes

Sanders *et al.* in Brisbane, Australia (Sanders 1999) have developed a comprehensive set of ways of delivering their Positive Parenting Programme (Triple P). Level 1 comprises a universal strategy of providing an entire population with information through television advertisements and entertaining TV programmes specifically made to reinforce good parenting practice, with the opportunity to call for a tip sheet. Level 2 comprises brief (one or two 20-min consultations) with a primary health care worker who has 3 days’ training, reinforced for the parent with four videotapes on parenting and tip sheets. Level 3 is similar but offers more consultations in primary care. Level 4 offers a fuller 10-week traditional parenting programme that can be delivered as self-administered, individualized at clinic, or group. The self-administered programme comprises a book of instruction and a workbook of exercises, which can be supplemented by telephone calls. Level 5 (enhanced) is a further 10-week programme added on to the individually administered clinic programme that comprises addressing in an individualized way parental factors that get in the way of effective parenting, and addresses marital communication, mood management and stress coping skills. It is given to those who have not progressed sufficiently with lower levels of intervention, and includes home visits.

Evaluation of the different ways of delivering the standard Level 4 programme has been carried out in a trial with 305 3 year olds (Sanders *et al.*, 2000a). Participants were volunteers screened to meet criteria that included having an elevated score on the Eyberg Child Behaviour Inventory and at least one index of family adversity; parents were predominantly lower class, but mostly not highly disadvantaged. They were allocated to receive the standard basic clinician-administered 10-week programme, self-administered, or an abbreviated version of the enhanced programme. The results showed that, on direct observation, only the enhanced condition reduced antisocial behaviour (ES = 0.5 SD) compared to waiting list controls. However, on the Eyberg questionnaire all treatment conditions produced an improvement, with a trend towards a larger effect in the enhanced (enhanced 1.0 SD, basic 0.7 SD, self-administered 0.5 SD). However, the self-administered programme showed improvements on only two out of five child behaviour measures. One-year follow-up showed further improvements in all three treatment groups, but there were no controls at this stage.

A possible problem when interpreting this study was the differential attrition rates in post-intervention data collection between treatment and control groups. The attrition rates were enhanced 40%, basic 29%, self-administered 31%, but controls 8%. Careful analysis was carried out that showed attrition to be more likely in children with more severe behaviour problems, and mothers who were more depressed and had worse relationships with their partners. These are some of the risk factors associated with less change. The difference in attrition rates of 32% between the reportedly most effective intervention (enhanced) and the controls could be disguising a much

smaller treatment effect, if the missing 32% changed less than those followed-up.

Sanders *et al.* (2000b) evaluated an innovative 13-episode television series ('Families') that included elements of the Triple P programme interwoven into an 'infotainment'. The series had been broadcast to millions in New Zealand. In this study, however, volunteers with children aged 2–8 in Australia were allocated to watch the programmes on video at home, or were allocated to a waiting list. Parents were reasonably advantaged. Evaluation was by questionnaire only, and showed an effect size of 0.4–0.5 SD in antisocial behaviour, increased sense of parenting competence, and no loss at 6-month follow-up. Attrition was not reported.

In conclusion, there is reasonable evidence that self-administered programmes may help some families. Further research is needed to see whether more disadvantaged families benefit. This mode of delivery has the potential to be a cost-effective way of disseminating parent training widely.

Humanistic programmes

There have been a number of methodologically acceptable studies of humanistic programmes, although they have tended to use volunteer samples with better motivated parents and less severe child problems than in clinical samples. Sheeber & Johnson (1994) studied 3–5 year olds with 'difficult temperaments' and compared a parenting group based on understanding of child characteristics with waiting list controls and found no difference in Child Behaviour Checklist (CBCL) scores on externalizing behaviour, but an effect size of 0.6 SD on internalizing problems. Freeman (1975) compared an Adlerian group with a 'traditional' mothers' discussion group and a no-treatment control, and found that both treatment groups had significant reductions in total CBCL scores, but were not significantly different. These studies used volunteer samples with moderate levels of child difficulty; none used interviews or direct observation to evaluate outcome.

Direct comparison of behaviourally based with humanistic programmes

In head-to-head comparisons of humanistic vs. behavioural programmes, findings are mixed. Pinsker & Geoffrey (1981) compared a behavioural group with Parent Effectiveness Training (PET), a humanistic approach. They found that on parent-report the behavioural group showed a significant reduction in child problem behaviour, whereas PET and controls did not, but on direct observation both treatment groups did better than controls. Bernal *et al.* (1980) compared client-centred group with behavioural management and waiting list controls and found on parent-report the behavioural group did better than the other two, but on direct observation no group changed. Frasier & Matthes (1975) compared behavioural with Adlerian parenting groups and had a no-treatment

control and found on parent-report that none of the groups changed significantly. Again, all these studies used volunteer samples.

In contrast, Nicol *et al.* (1988) studied 38 families referred by local social services for active physical abuse and allocated them to individual play therapy for the child plus support from social worker for the mother (a traditional child guidance approach), or home-based work that offered elements of parent training plus parent support through 'casework'. Drop-out was high in both groups at 45%, but the intervention with parent training led to a greater reduction in parental coerciveness and aversive behaviour towards their children, measured using direct observation. Overall, the evidence for humanistic programmes is weak.

Generalization to home, siblings and school

Several studies used direct observation to show generalization of parent training from clinic to home (Peed *et al.* 1977; Forehand & McMahon 1981; Boggs *et al.* 1990) confirming parental reports of improved behaviour. Moreover, studies suggest that parents use the newly learned parenting behaviours with other children in the family, as well as the index child (Humphries *et al.* 1978; Eyberg & Robinson 1982; Eyberg *et al.* 1995).

Studies looking for transfer of improved behaviour to the school setting have been inconsistent. Cox & Matthews (1977), Horn *et al.* (1987), Webster-Stratton *et al.* (1988) and McNeil *et al.* (1991) all found reduced antisocial behaviour in the school setting following parent training, whereas Johnson *et al.* (1976), Forehand *et al.* (1979), Webster-Stratton *et al.* (1989), Kazdin *et al.* (1992), Webster-Stratton & Hammond (1997), Taylor *et al.* (1998) and Webster-Stratton (1998) found no change. This is important because, if only questionnaires are used, teacher-reports predict later antisocial behaviour better than parent ones (Bank *et al.* 1993). Therefore, in the development of programmes to prevent antisocial behaviour, school-based elements are now often included (Conduct Problems Prevention Research Group 1999).

Adding behavioural components to increase parental adherence

Studies suggest that adding explicit teaching of social learning principles to a programme (McMahon *et al.* 1981), or adding explicit monitoring of the achievement of parenting goals followed by self-reward (Wells *et al.* 1980), improves the change in parental behaviour and child compliance on direct observation.

Programmes that address factors interfering with effective parenting

General approaches

Wahler *et al.* (1993) developed an adjunctive treatment called 'synthesis training' for isolated mothers. Parents are

guided to identify and label their reactions to stressful events, understand their own reactions and feelings and the way they explain events to themselves, and change the way they treat their children accordingly. Studies suggest that this is an effective treatment and prevents drop-off in gains seen in insular mothers offered standard programmes. Blechman & McEnroe (1985); Blechman (1998) included communication skills and step-wise problem-solving to help identify and resolve problems arising from broad extrafamilial factors that interfere with parenting. Piffner *et al.* (1990) found a similar intervention enhanced the maintenance of gains with moderately aggressive children.

Multisystemic therapy (MST) was developed by Henggeler *et al.* (1998). It is a home-based clinical intervention that is intensive (only three to four clients per therapist), relatively short (3 months) and highly supervised. Therapy is given according to the 'system' that is assessed as showing weaknesses, e.g. parent-child, marital, peer relationship or social. The precise form of intervention may vary, but the approach incorporates many elements of structural family therapy. Brunk *et al.* (1987) compared MST with group parent training for abusive and neglectful families. Both interventions were associated with improvements in parental psychiatric symptoms and overall stress, and identified problems. Those receiving MST showed more improvement on observed parent-child interactions, whereas those receiving parent training showed more reduction in social problems, which the authors attributed to the group format. The parent training offered was described by the authors as 'mechanistic' and had no role-play element, sticking strictly to parental management. Therefore it would seem useful to take the best elements of both approaches, and offer MST with a major parent training component.

Maternal depression

Sanders & McFarland (2000) took 47 families with a depressed mother and a child with conduct disorder. They were allocated to either 12 sessions of individual standard behavioural parent training, or the same intervention but including cognitive therapy elements for depression. Both interventions reduced maternal depression and improved child behaviour, but the effects on maternal depression were stronger for the cognitive condition, with 72% as opposed to 35% moving into the non-clinical range; there was no difference in child behaviour improvement.

Partner discord

Griest *et al.* (1982) randomly assigned 17 families to basic parent training or basic plus an adjunctive treatment that included work on personal and marital adjustment and extrafamilial relationships. Greater changes were seen for the adjunctive treatment in child compliance and deviant behaviour, and for several specific parental behaviours. In an elegantly designed study,

Dadds *et al.* (1987) compared the addition of partner communication and support to basic individual parent training in 12 maritally discordant families and 12 non-discordant families, all of whom had children with conduct problems. Each condition received the same amount of therapist contact. The adjunctive treatment led to substantially enhanced gains at 6-month follow-up in the maritally discordant families but not in the non-discordant families. This suggests that intervention should be tailored to the presenting problem, and that a 'one-size fits all' preventive approach may not be efficient.

Adult social skills

Webster-Stratton noted that parents' own difficulties in their partner relationship was one of the most potent predictors of failure to improve parenting, so devised her 'advanced' programme to address adult relationship skills (Webster-Stratton 1994). She studied the outcome of her basic 12-week programme in comparison to the basic plus the advanced 14-week programme. While observed partner communication and child-generated solutions to hypothetical social problems improved more in the advanced group, directly observed parenting behaviour and all measures of behaviour improved equally in both groups.

Puckering *et al.* (1994) found a group intervention that provided mother support improved self-esteem, depression and social isolation, but not parenting style (Cox *et al.* 1990). They therefore developed an additional parenting skills component: Mellow Parenting. It was specifically devised to help highly disadvantaged mothers. The programme runs for a whole day a week over 16 weeks, and has three components. In the morning, a psychotherapeutic group is run for the mothers on their own that addresses past and current relationships and present feelings, and encourages members to reflect on how these link to being a parent. At lunch, mothers and children eat together, then the mothers are asked to become involved with their children in an activity, such as cooking or arts and crafts, and may be helped by staff. In the afternoon, mothers review videotapes of themselves with their children in everyday situations at home and work on specific parenting skills. Outcome using direct observation and questionnaires showed large improvements in reducing negative affect, promoting child autonomy and increasing maternal sensitivity (Puckering *et al.* 1994). Of the families on the local Child Protection Register, 83% were subsequently deregistered because their children were no longer judged to be at risk of abuse.

Social isolation

Dadds & McHugh (1992) offered a group parent management training programme to 22 lone parents recruited as volunteers but with substantial child behaviour problems. One group received a basic 8-week programme, called Child Management Training. The other group received the same 8-week manage-

ment training course, but were asked to recruit an *ally* who was present at the first meeting, whose role was to:

1 be available to offer support when needed;
2 communicate regularly with the parent and listen to them; and

3 be involved in problem-solving and solution implementation. This arm of the trial was named Child Management Training plus Ally Support Training. The results showed that parents in the combined condition did indeed use their allies to offer support, listen to them and help in problem-solving. However, although both groups made large improvements in child behaviour, the gains of the ally support group were no greater. This may be because although the parents carried out the support procedures, measures of *perceived* support did not increase. Whichever treatment was received, those parents who perceived they received substantial support from friends showed considerably greater improvement in child outcome. This confirms the importance of support as a predictor, but suggests it is not easy to increase it substantially in brief programmes. Equally, lack of support may well also be an indicator of less ability to create and maintain good relationships of all kinds.

Predictors of drop-out and response

Predictors of drop-out

Drop-out rates are typically high in families with children who behave antisocially, e.g. 45–65% in the review by Pekarik & Stephenson (1988). Even at dedicated centres of excellence it is often high, e.g. 37% in the series of 397 children described by Kazdin & Wassell (2000). Kazdin *et al.* (1994) and Kazdin & Mazurick (1994) found that pretreatment variables predicting drop-out in the *child* were more severe antisocial symptomatology, poorer peer relations and lower IQ. In the *parent*, demographic predictors of higher drop-out rates were younger mothers, lone-parent families, those on low incomes and of low socioeconomic status, and those from ethnic minorities. Parental psychiatric predictors included more negative life events, greater perceived stress, an antisocial history in mothers and more adverse parenting of the child. Unfortunately, many of these variables are intercorrelated, and it is not clear which are most important.

Prinz & Miller (1994) addressed retention of parents in treatment experimentally by comparing standard individual parent training with enhanced parent training that addressed wider family issues and feelings. Using a strict definition of drop-out as missing any session, the standard treatment had a 47% drop-out, whereas the enhanced 29%. However, they did not report whether the enhanced condition led to any better child outcomes for those who remained in treatment, nor give figures for less strictly defined drop-out.

Predictors of response

Child factors

Adolescents are generally found to do less well in parenting programmes. Bank *et al.* (1991) from Oregon Social Learning Centre (OSLC) found a far smaller effect size when using parent training with adolescents than with younger children at the same institution; Irvine *et al.* (1999) offered a parent training programme for 12 year olds and got inconsistent changes. More generally, the meta-analysis of 443 studies of a range of interventions for juvenile delinquency by Lipsey (1995) found the effectiveness was ‘perilously close to zero’. However, there is a possibility that studies on adolescents have only the most severe persistent cases. This notion is supported by the findings of Ruma *et al.* (1996) who compared response to treatment using the parent CBCL score for groups in early childhood (2–5 years), middle childhood (6–11 years) and adolescence (12–16 years). The adolescent group did slightly less well, but the difference disappeared on multiple regression analysis that showed that greater initial severity was the only significant predictor of poorer response. Within the prepubertal age group, Dishion & Patterson (1992) had expected to find parent training more effective for younger (2.5–6.5 years) than older children (6.5–12.5 years) assessed by direct observation. However, they found it was of similar effectiveness for both age groups, although drop-out was higher in the older age group. The meta-analysis by Serkitch & Dumas (1996) found that *across* 36 studies, effectiveness was greater in older children, within the range 3–10 years. These studies would appear to indicate that parent training is reasonably effective across the age range from 3 to 10 or perhaps 12, but that after this it may be less effective for severely antisocial adolescents, for whom more studies are needed.

Boys are as likely to improve as girls (Webster-Stratton 1996; Scott & Spender, submitted). More severe initial antisocial behaviour is often believed to reduce the size of change, and the study of Ruma *et al.* (1996) found this. However, Scott & Spender (submitted) found that the more severely antisocial children made similar improvements, whereas those with substantial hyperactivity did less well.

Parent factors

No effect was found for socioeconomic status in the meta-analysis by Serkitch & Dumas (1996) or in other studies (Webster-Stratton 1992; Ruma *et al.* 1996; Scott & Spender, submitted). Lone parenthood was found to be predictive by Webster-Stratton (1992) and by Ruma *et al.* (1996), but not by Scott & Spender (submitted). It is not necessarily synonymous with social isolation, which is generally predictive of worse outcomes (Dumas & Wahler 1983; Dadds & McHugh 1992). Likewise, maternal depression is associated with poorer outcomes (Webster-Stratton 1992; Sanders & McFarland, 2000), as is interparental discord (Dadds *et al.* 1992; Webster-Stratton & Hammond 1999). Parents’ expectations of what will happen

during treatment influences outcome (Morrissey-Kane & Prinz 1999).

Combining parent training with other interventions

Parent training and child social skills training

There are several reasons to compare child social skills training with parent training. First, because the referred patient is the child, trying to alter their behaviour directly is logical. Second, it has shown to be reliably effective in reducing antisocial behaviour in adolescents (Lochman *et al.* 1993; Lechman & Wells 1996; Lochman *et al.* 2000; Kendall 1998), although initial trials showed it to be less effective with younger children, say under 6 years (Denham & Almeida 1987; Coie & Koepl 1990). Third, some parents are either unable to change their parenting style, or are unwilling to attend sessions, yet may be prepared to put their children forward for treatment because they believe something is 'wrong' with them. Fourth, although parent training improves children's relationships with their parents, it does not reliably improve their behaviour at school, nor with their peers.

Kazdin *et al.* (1987) compared a programme of combined individual parent management training plus individual child problem-solving skills training vs. general discussion sessions of comparable duration in a sample of 40 7–12 year olds who were psychiatric inpatients because of antisocial behaviour. Results showed good improvements in the combined treatment group over controls, not only on parent-report ($ES=1.5SD$) but also on teacher-report ($ES=1.0SD$). No direct observations were made. There was no significant loss of effectiveness at 1-year follow-up. A subsequent paper (Kazdin *et al.* 1992) teased out the effectiveness of each component by comparing parent training alone, child social skills training alone, and both combined. All groups improved substantially, with improvements seen not only by parents at home, but also by teachers at school and self-reported offending by the young people. However, the combined treatment had greater effectiveness on nearly all measures, notably 0.5–1.1 SD greater effect than parent training alone on antisocial behaviour.

Webster-Stratton & Hammond (1997) used a group format with videotapes to compare parent training only with child training only, parent training plus child training, and a waiting list control group. Ninety-seven children aged 4–8 years specifically referred to a parenting clinic were studied with a thorough set of measures including direct observation at home, and observation of interaction with a friend. The intervention was relatively long (22 weekly sessions of 2 h) and attendance was excellent, with all cases attending at least half the sessions and most attending nearly all. There were no drop-outs. There were several important findings. First, on parent questionnaire, children in all three intervention conditions did considerably better than waiting list controls who did not improve significantly. The fact that *child training alone* led to improvements in child be-

haviour is important practically because there will always be some parents who are unable or unwilling to attend for intervention. Secondly, all interventions had an effect in reducing observed directive parenting behaviour. From a theoretical standpoint, it is interesting that child training led to less coercive parenting behaviour, confirming the hypothesis that for children with clinically significant antisocial behaviour (as for non-clinical children) child as well as parent factors are involved in driving parenting style; it shows that the coercive cycle of negative parenting and child defiance can be interrupted from either end.

Thirdly, parent training led to greater changes in parent-reported child behaviour problems than child training, whereas child training led to better improvements in the ratio of positive to negative strategies used by children when interacting with a friend on direct observation, and on laboratory tests of social problem-solving. Fourthly, the combined parent plus child intervention led to similar effect sizes as one would predict from either intervention alone in the domain in which they were most effective, but did not act synergistically. Thus, parent-rated child behaviour was no more improved in the combined condition than for child training alone, and observed child-peer behaviour was no more improved in the combined condition than with parent training alone. The exception was observed antisocial behaviour in the home at 1-year follow-up, where the combined condition had a greater effect than either alone. Unfortunately, although in all intervention conditions there was a good effect compared to controls for observed reduction in child behaviour at home ($ES=0.7-0.8$, total deviant behaviour reduced to half original levels whereas controls did not change), the variance was large (standard deviations greater than means in all cases) so none was significant.

Fifthly, all gains were maintained at 1-year follow-up, suggesting that the reduction in antisocial behaviour is lasting. Unfortunately, further follow-up to test longer term persistence of benefits will not be possible from this study as the control group were treated after the waiting period for ethical reasons. Finally, no intervention made any difference to teacher-rated child behaviour in either the short or longer term. This was partly because some of the children had no significant problems at school, but it nevertheless suggests that child behaviour may be fairly context-specific. This supports an interactional framework, whereby the contingencies and expectations in a situation influence child behaviour. Given that child behaviour at school is also a major predictor of later child antisocial behaviour, and that classroom disruption is a major issue for teachers because of its impact on other pupils, findings such as this have fuelled the search for interventions that include a teacher element.

Parent training and classroom intervention

Barkley *et al.* (2000) screened 3100 5-year-old children in kindergarten and selected the top 9.3% with attention deficit hyperactivity disorder (ADHD) and conduct symptoms. They were allocated to group parent training only, special treatment

classroom only, combined parent training and classroom treatment, or to no-treatment control. The parent training used Barkley's protocol (Barkley 1997) and lasted 10 weeks in the autumn term, followed by monthly boosters and was held at a medical centre. The special treatment classroom children spent a year at another school in a class that consisted of about 15 other similarly selected disruptive children. Teachers were highly trained and supervised in behaviour management techniques, and also were trained to deliver an accelerated curriculum aimed to advance academic skills; close supervision was provided. Children allocated to either of the classroom intervention conditions effectively received the full planned intervention in that context, but of those allocated to a condition with parent training, take-up was low: one-third of the parents did not attend at all, and only 42% attended five sessions or more. Crucially, the results of this study that targeted a whole high-risk population were analysed on an intention-to-treat basis. The outcomes showed no difference on parent-rated measures for any condition, and no difference on observed parent-child interaction or observed child attending ability. There were improvements in the classroom conditions on some teacher-rated measures, e.g. on the Teacher Report Form (Achenbach 1991) aggression and attention subscales, but not on the delinquency subscale or any of the internalizing subscales; some other scales measuring rather similar behaviours also showed no change. Direct observation of classroom behaviour showed reasonable (0.3–0.5 SD) improvements in externalizing behaviour. The authors attribute the failure of the parenting programme to low attendance at the parenting group, but do not give a dose-response curve or analyse the results of those parents who attended, say, half or more sessions. The classroom intervention had useful effects on some but not other measures. There were no cross-context or synergistic effects.

Parent training, child social skills and classroom intervention

The FasTrack project (Conduct Problems Prevention Research Group 1999) is a 'state of the art' multimodal intervention study. Five year olds in kindergarten were screened and the top 10% with antisocial behaviour selected. A total of 891 children were allocated to a multimodal intervention or to no intervention. The intervention included the following.

- 1 A universal element given to all pupils in the classroom that consisted of two to three lessons per week of recognizing emotions, friendship skills, self-control skills, social problem-solving skills, plus classroom management consultation for the teachers.
- 2 Parent training for 2 h per week over 22 weeks for which the parents were paid \$15 per session; for half an hour a reading tutor worked with the child on reading skills while parents watched.
- 3 Child social skills group for 1 h per week for 22 weeks.
- 4 Child reading skills for three 30-min sessions a week with a special tutor.

5 Home visits fortnightly, alternating with telephone calls to develop a close relationship with the parents and promote generalization of parenting skills.

6 A peer friendship promotion programme that paired the index child with another, low-risk child from the class for 30 min per week of constructive play time together.

Parental participation was relatively high: 72% received more than half of the sessions, and 81% received at least half the home visits.

Given this massive input of resources, and thorough coverage of theoretical risk factors, the outcomes were very modest. Anti-social behaviour was assessed on eight measures: on all but one, there was no significant change; the mean effect size across all was 0.11 SD. Only two of the five social behaviour measures changed significantly, with a mean effect size across all of 0.18 SD. Social cognition tests showed gains on four of five measures (mean ES = 0.28). Reading attainment scores showed no improvement, although a reading process test ('word attack') did, and grades for language arts improved (mean effect size for all three was 0.33). As for parental behaviour harsh discipline did not change on questionnaire or observation, although did on a hypothetical test of responses to vignettes; appropriate and consistent discipline did not improve according to parental report or event-recorded observation, though did on coder impression of the observation. Warmth increased on direct observation but not according to parental report. Thus, of the eight measures of parenting behaviour, three changed significantly (mean effect size for all eight was 0.17 SD). The intervention is ongoing and the hope must be that the children will show bigger changes later, although such a comprehensive, prolonged and intensive intervention is likely to be too expensive to replicate.

Conclusions

Effectiveness

Parent training has moved on a long way from its origins 40 years ago. Programmes have become more responsive to parents' own views, and can now address contextual and mental health issues that impair 'good enough' parenting. Scores of careful studies attest that programmes lead to improvements in the way parents relate to their children *and* to reduced antisocial behaviour in the children themselves, thus giving them access to more satisfying relationships and better chances for successful adjustment. Combining parent training with child social skills training appears to increase the benefits outside the home. However, problems remain in making programmes acceptable to the most needy parents, and population-based prevention programmes have so far shown only modest benefits.

Future research

While the effectiveness of parent training in referred cases is firmly established, the precise mode of action is not. From the

evidence reviewed above, it seems likely that humane empathetic interpersonal skills are necessary to engage and retain parents, but good inculcation of behavioural skills is necessary to bring about changes in parenting style and child behaviour. Studies suggest that parental mood, beliefs about the child, expressed emotion towards the child, and behaviour all change. Which is the active ingredient, or are changes in all necessary? Which aspects of parenting are most crucial: sensitive responding and communication, encouragement of prosocial behaviour, setting of clear boundaries, or effective punishment for misbehaviour? Does child attachment status become more secure as parenting is improved? Is the child's capacity for empathy increased, and is the likelihood of developing antisocial personality reduced? One hopes that future studies may answer these questions.

Service delivery

Children with antisocial behaviour cost society a great deal of money. An economic analysis found that those with conduct disorder aged 10 cost 10 times as much as controls by age 27 (Scott, *et al.* 2001b). Therefore there is a strong financial incentive to invest in these children's futures, as well as a humanitarian one. In the USA and the UK there is considerable governmental interest in early prevention. However, to stand a chance of being effective, several characteristics need to be in place. In addition to choosing empirically supported interventions (which is far from always the case), staff need to be supervised to deliver them to a high standard, otherwise efficacy is lost (Henggeler *et al.* 1997). Management needs to be good, with reasonable staff morale and training. A total population has to be targeted, not just those who are motivated to turn up; an assertive outreach strategy needs to be pursued to reach the most needy families. Currently, group parent training is more cost-effective than individual work. Scott *et al.* (2001a) found that a 12-week programme cost £571 per child, no more than standard individual treatment for six sessions.

Given that, say, 5% of children have conduct disorder with impairment (Meltzer *et al.* 2000), and up to 20% have DSM-IV oppositional-defiant disorder (Kazdin 1995), parenting programmes could not possibly be delivered by mental health professionals to most of the population who would benefit. A change in the culture around parenting is necessary, plus a stepped approach to intervention. The broadcast programmes of Sanders *et al.* suggest that this might be achieved, backed up by a carefully graded range of services, starting with self-administered programmes and only working up to intensive approaches for those who do not respond. Schools will need to focus more on children's behavioural and social development and implement approaches shown to work. If this occurs and the culture changes towards more informed and effective parenting, there is a prospect of making a considerable reduction in children's misery and of helping them to achieve a balanced way of life integrated with their family, friends and school.

Introduction

For the non-specialist, family therapy and systems theory can be infuriating. It is steeped in theory that does not articulate well with what actually works and there has been fierce rivalry over the years both with other approaches and internally. Despite this, it has some successes in empirical research and is seen as an important approach in child mental health treatments because the child has to live in the context of their family, affects it and is affected by the behaviour and beliefs of other family members. This sets the context for treatments and for this chapter.

The purposes of this chapter are to outline the approaches taken by family therapists, to provide access for those that wish to inquire further into the literature and to provide a brief review of what seems to be effective from research carried out thus far.

Gorrell Barnes (1998) succinctly summarized the aims of family therapy. It examines *current context*, what is going on in people's lives now as well as earlier. It 'listens to the ways in which current relationships, as well as former relationships, come to form patterns and conversations in people's minds and therefore influence their daily beliefs and practices'. Notice that she immediately linked behavioural and belief systems in this framing of family therapy. She stated that 'the practice of family therapy encompasses a number of different activities in relation to these ideas of context and mind:

- 1 a philosophy of how to observe and frame relational events;
- 2 methods of description that explicitly make connections between people and their wider social context;
- 3 a relational approach to treating dilemmas and problems in families; and
- 4 a number of therapeutic methods addressing these, with particular skills devolving from each approach' (Gorrell Barnes 1998).

The development of a systemic family therapy needs to be understood historically. It originally rejected oversimplistic and reductionist accounts; but in the mean time mainstream child psychiatry has produced increasingly complex interactional models of the development of disorders.

It is worth remembering that, in common with many new fields of endeavour, the proponents of systemic family therapy had to define themselves as essentially different from what had gone before. This led to a rejection of previous thinking and a reframing of concepts, often with their own new vocabulary and tiresome jargon. It seems to take some decades for the new

thinking to allow itself to re-examine what has been rejected, to begin to integrate concepts and approaches that have previously found to be useful. This process of integration now seems to be happening to an extent in the field of systemic thinking, both internally between different schools of thinking and therapy (Sprenkle *et al.* 1999), and externally with other approaches to thinking about child mental illness and family distress. However, the process is still fluid.

Definitions

Gorrell Barnes (1998) listed characteristics of the systemic approach as follows.

- People in families are intimately connected, and focusing on these connections and the beliefs different members hold about them can be a more valid way of understanding and promoting change on problem-related behaviour than focusing on the perspective of any one individual.
- People living in close proximity over time set up patterns of interaction made up of relatively stable sequences of speech and behaviour.
- The patterns of interaction, beliefs and behaviour that therapists observe and engage with can be understood as the 'context' of the problem and be considered as both the 'cause' and 'effect', acting as feedback loops that create the 'fit' between problem and family. These are often referred to as 'circular patterns of interaction', in contrast with the cause and effect 'linear' thinking of the psychology from which early systems thinkers were trying to break free. Such patterns involve mutual influence and mutually regulated learning.
- Problems within patterns of family life are often related to dilemmas in adapting to some environmental influence or change.
- The minute details of the ways in which families describe such changes—the language within which constructions of problems, both past and anticipated, are generated—are of key importance in understanding the nuances of family thinking; the 'discourses' or discussions about family life and its problems and solutions. These take place both within individuals and between them. All the adults who form part of the family may carry different discourses in their minds which, while often unspoken in the room, nevertheless carry powerful imperatives for action or restraint in their thinking about themselves and the processes they are engaged in.

Other definitions have been offered by Gurman *et al.* (1986) and Reimers & Street (1993). The latter is particularly inclusive of all therapies aiming to bring about change in a family. This is helpful in some ways but it makes defining the boundaries of research into this domain of therapeutic endeavour difficult. Perhaps a wider overview of the field suggests that it should call itself ‘systemic psychotherapy’ to acknowledge that practitioners now work both with individuals and with organizations as well as working with families. In each case the interpersonal connectedness of individuals in the system is an organizing principle of the work.

Beginnings

Family therapy has evolved considerably since its inception about the middle of the twentieth century. Its beginnings were rooted in the era after the Second World War on the West coast of the USA in the Palo Alto project headed by Bateson *et al.* From a variety of disciplines, they began to observe family interactions and to analyse the patterns they saw. They noticed that these patterns could be seen as repetitive in some families. There appeared to be difficulties that they came to regard as redundant communications. Later it was realized that repeating patterns of interactions can be seen in all families and that difficulties can occur when these patterns are inflexible in the face of new information.

The concepts presented below have been important in the evolution of systems thinking and lie behind many of the intervention styles that have been conceived.

General systems theory

At its heart, systemic thinking rejects a simplistic view of causality: that one thing directly causes another to happen. Hoffman (1981) gave a typical account of the rejection of linear models, as they were seen by systemic theorists to apply to psychiatric approaches to mental illness during the middle part of the twentieth century. She wrote:

Mental illness has traditionally been thought of in linear terms, with historical, causal explanations for the distress. Efforts to explain symptomatic behaviour have usually been based on either a medical or psychodynamic model. The former compares emotional or mental distress to a biological malfunction or illness. Treatment consists of finding an “aetiology” of the so-called illness (a typically linear construct) and then instituting a treatment, such as administering drugs or devising other means of altering or blocking those bodily processes which are considered responsible for the patient’s state. The people in charge of this treatment would of course be doctors, and the setting would often be hospitals.

She gave a similar account of the psychodynamic approach to mental distress and then went on to say, ‘These two models typically see symptomatic distress as a malfunction arising either from biological or physiological causes, or from a repressed event in the past. In both models the individual is the locus of the

malfunction and the aetiology is connected with an imperfection in his genes, biochemistry, or intrapsychic development.’

A useful account of general systems theory was given by Watzlawick *et al.* (1967). This description was written as the theoretical model was being developed for application to the domain of family interactions. The concept was proposed by von Bertalanffy (1950). It defines a system as ‘a set of objects together with relationships between the objects and their attributes in which the objects are the components or parts of the system, attributes are the properties of the objects and relationships “tie the system together”’. Hall & Fagan (1956) distinguished between closed (sealed and self-contained) as against open systems, with the latter characterized by an exchange of energies and information with the environment.

In summary, Watzlawick characterized an open system as being more than the sum of its parts; that change in any part of the system at one time or over time produces change elsewhere in the system to balance it. There are feedback loops operating and the system exchanges information with the outside world. This brings us to the second group of important influences—observations on communication and the theory that evolved to explain them.

Communication theory and practice

At many places in the USA an interest by clinicians and others in studying families in their homes and then through the use of the one-way mirror in clinical settings seemed to blossom during the 1950s and 1960s (Riskin & Faunce 1972; Bateson 1979; Hoffman 1981). Work with families where there was supposedly a schizophrenic member produced the concept of the double bind (a situation where there were two different levels of communication in conflict with one another, e.g. verbal and non-verbal, in the same interaction). It led to a rapid growth of observations of communication patterns in such families (Jackson 1967a,b; Watzlawick *et al.* 1972).

There were a number of difficulties with this work, not least the later realization that the definitions of schizophrenia used at that time in the USA were unhelpful. They were abandoned for much narrower ones. The dyadic model of double bind communication was too simplistic for family communications (Weakland 1976). Bateson extended this approach to talking about inherently unstable patterns of alliances in the communication patterns in families with a schizophrenic member (Bateson 1973). One outcome from this work was that of Vaughan & Leff (1976) on expressed emotion. For our purpose, although the double bind hypothesis for the aetiology of schizophrenia was wrong (Hirsch & Leff 1975), it was influential in bringing about a paradigm shift to thinking about communication patterns within families as having an aetiological or maintaining role in mental distress.

Psychodynamic origins

A third important strand in systemic thinking came from the

psychoanalytic field. Family therapy emerged in opposition to psychoanalytic thinking, which had a particularly firm stronghold on the thinking of therapists in the USA in the 1950s. Nevertheless, many early leaders in the family therapy field came from a background of psychoanalytic training (Dreikurs 1949). They variously incorporated their previous training into their subsequent practice or ostentatiously rejected it. This use sometimes went unacknowledged. It has taken about two decades for a better assimilation of the strengths of the psychoanalytic models into systemic work. Interestingly, this has been a two-way process, at least conceptually, as psychoanalysts have promoted the interpersonal aspects of their work (Casement 1985).

Psychoanalytic theory has addressed the couple relationship and the interacting mutual projective identifications that are involved (Giovacchini 1958; Dicks 1963; Zinner & Shapiro 1976). This is relevant to family life (Bowen 1965; Boszormenyi-Nagy 1967; Framo 1970; Box *et al.* 1981) as the complex interaction between unconscious and conscious processes continue around family formation and development. In essence they are describing variants of projective identification (Klein 1946; Hinshelwood 1989). This can be generalized to family development. Dare (1988) suggested that psychoanalytic theories, 'all have in common a view of a person as having mental structures that transport personal history with them as important organizers of present and future personal relationships. Parents may in daydream or unconscious fantasy seek to set a child up as of equal or more importance than the co-parent in conflict with the interparental relationship.'

The notion of fixation points has also been used in psychoanalytic family therapy to describe the concept of unmet or painful relationship experiences which tend to repeat in subsequent phases of life. Family life can get stuck at transitions when these systems become activated in the minds of individual family members and are then enacted between them (Skynner 1981; Nichols & Schwartz 1991).

Kernberg (1966) described pathological processes in which splitting of the ego leads to marked compartmentalization of different ego states (or partial objects). These can be triggered by perceived threat and result in the expression of two mutually conflicting patterns of behaviour formed either side of the unresolved internal conflict. For example, a parent may unexpectedly acquiesce in the face of their child's assertive behaviour but equally may react the next time with unpredictable rage. Whatever the explanation, such patterns are quite often seen and produce an atmosphere of anxiety and uncertainty in a family.

Boszormenyi-Nagy & Ulrich (1981) wrote of the concept of ethical accountability within families—fair and responsible behaviour by parents tending to engender loyalty in the children. However, one parent can demand unfair conflicts of loyalty and invisible loyalties can be demanded or offered at the expense of the child's developing autonomy. Nichols & Schwartz (1991) suggested that the 'sick' or identified child in such families is 'chosen because of a trait that makes them a target for the parents' projected emotions. These children should not be thought of as helpless victims. In fact, they collude in the projected iden-

tification in order to cement attachments, assuage unconscious guilt or preserve the parents' shaky marriage.' Such views are not proven but they fit with the way that families describe themselves in treatment in their scripts, family stories and myths (Ferreira 1963; Byng-Hall 1995).

Family typologies

An idea that has been disproved but that led to serious research was that particular types of family difficulties would be associated with particular ways of family functioning. This idea probably arose from the study of schizophrenic families but extended rather more widely (Lewis *et al.* 1976). Later research suggested that there were broad aspects of family functioning that were associated with certain ways of being in families. This research approach also showed that it was very difficult to tease apart the *causal* factors from those *maintaining* the pattern. Helpfully, this research led to description of factors (Lewis *et al.* 1976; Skynner 1981) that seem to be indicative of family health. They include:

- a clear but flexible power structure in the family, with parents collaborative and in charge but consulting their children increasingly as they get older;
- spontaneous, open, honest and clear communication;
- relationships characterized by trust, mutual satisfaction and tolerance of ambivalence;
- self-image of family consistent with that of other's view of them;
- a positive emotional atmosphere with low levels of criticism and hostility; and
- tolerance of change over time as the life cycle progresses and a transcendent family value system.

Two questions arise from these beginnings in systemic thinking: first, how did these influences link with developing practice in family and systemic therapies; and, secondly, is there any evidence that any of this is more than theoretical hot air? The first question can be more completely answered at the moment than the second, although evidence for efficacy of family therapeutic approaches is accumulating (see below).

In essence, family therapy thinking has developed in three phases, reflecting changes in the therapist's supposed position in relation to his or her clients and, perhaps more importantly, reflecting changes in society's requirements and acceptance concerning the position of therapists, doctors and other healers. The first phase was characterized by the therapist as expert observer and manipulator to produce systemic change. The second and third phases see a gradual shift to a less hierarchical, expert position.

Influential approaches in family therapy

Within the first phase of development of family therapy the Mental Research Institute (MRI) at Palo Alto was particularly important. They developed a brief therapy based on the ideas of

general systems theory but also on the ideas of Gregory Bateson. He had observed factors producing stability and sudden change in Iatmul culture in New Guinea (Bateson 1958; Hoffman 1981, pp. 38–40).

The rationale for this approach was that change in interactions between people in one part of a family would usually produce one or more compensating changes elsewhere that in effect cancelled out the effect of any innovation (Jackson 1957). At other times patterns of interactions amplified change, producing real discontinuous change in the relationship with a breaking of the overarching rule, so-called ‘second order change’. More commonly, the amplification would build to a certain level and then abort. They wished to harness this tendency to lasting change. Labelling a family member as being unwell with a diagnosis counteracted potential for change in their view. It had unhelpful consequences for the development of the ‘sick’ individual (Hoffman 1981, p. 64). The attempted solutions of the family had become part of the problem, inadvertently helping to maintain it.

Fisch *et al.* set up the Brief Therapy Centre at MRI. They set themselves a limit of 10 sessions with a family, focusing on the interactions around the target behaviour and the underlying rules governing these patterns. They set tasks between sessions, often reframing the symptomatic behaviour as helpful, to try to unbalance the crucial family rules that seemed to be maintaining the symptoms. They focused on removing the symptomatic behaviours.

What would such a therapist do? He or she concentrated on the problem as presented and did not overtly aim to alter the family structure. The therapist might see only part of the family living at home at a time. He or she might set mutually conflicting tasks for different members or subgroups of the family and try to utilize the current experience of different family members to lend momentum for changed interactional patterns. The therapist would focus on the presented problem and withdrew once that changed. He or she would offer ingenious rationales for asking people to try different behaviours or to try to get them to act in opposition to his or her suggestions.

Structural family therapy

This was the next major influence in the early development of family therapy. As with other early approaches, there was no question who was in charge of the therapy—the therapist or often the supervisor behind the one-way screen.

Minuchin *et al.* (1967) began working in poor Puerto Rican families where there was a degree of disorganization and delinquency. They developed a way of working with these families that was in part educational, providing them with information and encouraging links between them and others in the community, and partly it was a very active series of techniques to improve the communication skills between members of the family. These techniques formed the basis of what was later called the structural approach. They were extended in work with other family problems at the Philadelphia Child Guidance Clinic

resulting in three influential books (Minuchin 1974, 1978; Minuchin & Fishman 1981). A colleague (Aponte 1976), regarded these families as underorganized rather than disengaged.

The aim and rationale for this approach is based on a normative model, characterized by distinct but permeable boundaries between the parents and children with a clear hierarchy. Similarly, there will be boundaries between siblings and their parents and there will be functional effective boundaries between the family, the wider family network and the outside world. Minuchin, as others, emphasized the changing family life cycle and the changes in family structure that are necessary to accommodate the different stages within this. Minuchin viewed behavioural patterns as reflecting structure in the family. Changed behaviour would lead to structural change (persistent relationship changes).

How would such a therapist work to achieve change? In the clearest account of the techniques that they used, Minuchin & Fishman (1981) described techniques for taking small elements of interaction in the therapeutic interview and using them to achieve change by strongly encouraging family members, often parents, to make them happen differently then and there. The view was that by changing such small elements of behavioural interaction a new interactional pattern could be enabled. Minuchin used other techniques to increase the flexibility of the belief system in which the behaviours were embedded. For example, a father may come to believe that he is peripheral in the family and that that is the fate of all boys. He may apparently be uninvolved with his son but be covertly encouraging his young adolescent son to be rebellious and difficult with the child’s mother. In the course of therapy a structural therapist might speak positively of the father’s covert encouragement of his son’s behaviour, talking of it as helping the son not to drift out of his mother’s mind. The therapist might encourage the father to do more of this. He would hope that the father would react against this at some point. The therapist would choose his moment to encourage the mother to draw in the father to help her parent their son more directly. Through this the therapist hopes to help the family re-establish a healthier pattern of functioning, strengthening the parental alliance. The therapist would be trying to get the parents to change their pattern of behaviour around the son in the room by setting agreed rules and sanctions in the session. There would be homework for the family to demonstrate to themselves and the therapist their ‘newly learned’ skills. Minuchin would see himself as re-establishing the parental boundaries, amending the current family belief systems and opening new realities for them through expanding their interactional repertoire.

Minuchin believed that the family’s constructed story of their beliefs for why certain things happen at home and in relation to the outside world should be linked using their language. This should be reformulated using their beliefs as justification for the new behaviours. Many of the ways of working with families help them find alternative belief systems. For Minuchin it is an active harnessing of beliefs to push for changes that the therapist thinks are necessary in the structures and hierarchies in the

family and the associated communication patterns between family members.

The structural approach does not concentrate only on communication patterns, but rather on the permitted relationships in which these patterns come to form and in which they are embedded. Much skill and some delicacy of touch is required from the therapist to ensure that the approach is helpful and not experienced as coercive.

Variations of the structural approach were also adopted by Bowen (1965), Haley (1973, 1976) and Madanes (1981, 1984, 1990).

Psychodynamic approaches to family therapy

A parallel but rather separate stream of development in family therapy came from psychodynamically trained therapists who saw benefit in sustaining a concern with unconscious processes and the internal worlds of each family member. The rationale of such therapy was described by Nichols & Schwartz (1991) as being 'to free family members of unconscious restrictions so that they will be able to interact with one another as a whole, healthy persons on the basis of current realities rather than unconscious images of the past'. Some took the view that the therapy needs to uncover deep material, especially that which is hidden, unconscious and from the past (Framo 1970; Nichols & Schwartz 1991). Such therapists try to apply the detailed listening skills of psychoanalysts to the family therapy situation. This non-directive style may be more applicable in marital therapy with adult couples (Dicks 1963, 1967).

Others, including Dare (1988), took the view that therapy should be limited in time and scope, using much more active techniques. It can be usefully informed by psychoanalytic concepts such as those intended to guide the family formulation.

- *The structural qualities of the family*: coalitions and alliances; family hierarchy; distances of family members from each other; quantity, quality and direction of communication; boundaries within and around the family; control, organization and affective tone.
- *Some identifiable 'functions' for the symptoms*: usually the protection of aspects of the family organization from the change consequent on life cycle developmental and other crises of loss or addition.
- *Thoughts about what might be the 'risk' to the family of losing the symptoms*: fear of dissolution of the family; pain at the loss of special closeness; dread of responsibility having to be taken for past disasters.

These ideas were based on a related but distinct formulation developed by Bentovim & Kinston (1981), Bentovim & Jacobs (1988) and Bentovim (1992). Such therapists assemble observations from short detailed behavioural sequences. They build through descriptions of subsystem relations to the development of meaning systems. They will craft their interventions to attend to the holistic formulation: they will try to attend to behaviour and meaning systems as well as their view of unconscious elements that may be working to sustain the present family

dynamics. They will want to provide a forgiving rationale for the present situation while outlining alternative possibilities to the family.

Milan systemic family therapy

The so-called second wave of family therapy styles was heralded by the Milan approach. This group of therapies became more collaborative in their style with the family but still maintained the hierarchy of the therapist being the expert.

The rationale for this therapy was to address the belief systems that operate between family members, often across several generations, and that shape current interpersonal behaviour patterns (Selvini Palazzoli *et al.* 1978). Two key facets of this approach were a highly ritualized series of steps in each session and a particular style of questioning. Each session would follow the form of a pre-session discussion of the therapy team to produce a hypothesis for that session; the interview itself; and then a break. Feedback, with the purpose of construing the symptomatic behaviours in a positive light in the context of the family belief systems, was finally followed by a case discussion once the family had left. Sessions were commonly spaced at 4–6-week intervals as the therapy team had the idea that the family would often produce its own solution to the tensions between the current symptoms and the uncovered beliefs concerning their relationships with each other (Selvini Palazzoli *et al.* 1980; Boscolo *et al.* 1987; Cecchin 1987).

The team originally thought that the crucial element in their practice was the intervention message. However, they, and others (Penn 1982), came to believe that the style of questioning was a powerful intervention in its own right. This format was intended to be overtly neutral throughout the session. The style of circular questioning asks questions of one person about the relationship between two other people in the family around a particular issue, event or behaviour pattern. The answers to such questions then form the basis of subsequent questioning in the same style. Making unspoken beliefs explicit elicits further curiosity in the family about their relationships and can be a strong force for change. The method of using the interview itself as a form of intervention was further delineated by Tomm (1987a, 1987b, 1988) in a series of articles. This style has been influential in the UK (Campbell *et al.* 1983, 1991; Campbell & Draper 1985). Elsewhere it has influenced many and was part of the movement that led to what came to be called 'second order' family therapy (Hoffman 1985).

This style of work has also proved useful in considering other complex systems, such as work organizations and teams and the way in which they perform their core tasks (Campbell 1985; Coppersmith 1985; Lindsey 1985; Nitzberg *et al.* 1985). Many clinicians experience this as a much more respectful approach to families than directive problem-solving procedures. The approach emphasizes the inclusion of the therapist him or herself as an active participant during the elaboration of the therapy.

There is not a body of empirical research that directly exam-

ines the effectiveness of the Milan approach, but a style of therapy partly based on this approach has been used in some family research where there are teenage problems, such as drug abuse, and has proven effective (Quinn *et al.* 1988; Joanning *et al.* 1992).

Solution-focused therapy

In 1969 de Shazer *et al.* at the Milwaukee Brief Family Therapy Centre started developing the brief problem focused model of the MRI group and devised their own brand of brief solution-focused therapy.

De Shazer initially retained the exploration of the problem but moved on to concentrate much more stringently on the times when the problem was not occurring, believing that careful analysis of these exceptions and their behavioural sequences would highlight where the solutions lay. Identifying exceptions allowed the clients to repeat successful behaviours and take control of their problems (de Shazer 1985, 1991; de Shazer & Berg 1992).

De Shazer has, unlike others, attempted quantitative evaluation of his work (Fisher 1984; de Shazer *et al.* 1986). Using a self-report form (with the weaknesses that entails), they found that 72% of clients either met their own goals for therapy or felt significant improvements had occurred so that therapy was no longer necessary.

Constructivist and social constructionist systemic therapy

The third wave in family therapy began in the early 1980s. The changes were fuelled from a variety of sources within the social, scientific and biological realms. The objective certainty of 'reality' was challenged, and Capra (1983), a physicist, suggested that one can only approximate objectivity in measuring reality. With Maturana (1978) and Maturana & Varela (1980) this led to the idea that biology would constrain the ways in which information could be used. Some, rather optimistically, applied this to family systems.

Mendez *et al.* (1988) proposed that family systems could not be taught or directed to change. This view opposed the directive style of the time and suggested to some a very different therapeutic style, one in which change was evolved through a mutual construction between client and therapist. Social constructionism (Gergen 1982, 1985) correspondingly focused more on social interaction, e.g. 'Problems are stories people have agreed to tell themselves' (Hoffman 1990). In retrospect, these trends can be seen in a societal context in which there has been increasing distrust of experts. Perhaps they provided the 'logical' rationale for a stepping down from the teacher position, with a certain amount of shedding of assumed hierarchical power of the therapist over the client. With the acceptance of the possibility of multiple 'truths' it became much harder for professionals to hold on to the position that their views or 'truths' are superior to those of their clients. Other theorists supported

this view from various perspectives (Von Foerster 1981; Von Glaserfeld 1984).

Therapists began to ask: 'How can specific techniques be employed with the hope of a specific outcome if there is no way of predicting how an individual or family unit may respond?' The task of the constructivist therapist became to perturb the system with the hope of producing but not being able to predict the direction in which that change might occur. For the social constructionist, the task became the art of the narrative therapeutic conversation (see below).

The 'observing systems' perspective brought a need for self-reflexivity and an examination by the therapist of what issues they were bringing to the therapy with what value systems? There was a return to thinking about things in ways that were not dissimilar to the ideas of identification, projection, transference and counter-transference used in psychoanalytic therapy but which systemic therapists had long ago rejected.

The writings of feminists were influential at this time, and there was an increasingly strong voice of women within the family therapy field (Goldner 1985; Boss & Weiner 1988; Perelberg & Miller 1990). In particular, issues of power and gender became a focus with a need to look at working with families and acknowledging the power differential between men and women. This provided an influential perspective on, among other issues, sexual abuse and family violence (Goldner *et al.* 1990; Gorrell Barnes & Henesy 1994).

Narrative therapy

Narrative approaches drew strongly on the work of Gregory Bateson. An important premise informing these schools is that we do things, not because we are driven, but because we see no alternatives. Information that does not fit within a particular belief system is discarded. Alternatives, which may hold the solution to problems, can often not be incorporated into the family's thinking because the difference is too great. Only as a rigid system becomes perturbed to the point of discontinuous change can it accept new information to enable it to change, so-called 'news of a difference'. The therapeutic task in this framework then becomes how to make the difference big enough to make a difference, but not so different that it is rejected.

Solution-focused therapists tackle the problem behaviourally but show that the difference can be tolerated because actually it is being done already and it is simply a case of recognizing the different successful behavioural sequences and increasing them. The Milan school attempted to make space for the difference by trying to change belief systems so that they were more in line with the difference, and the difference could then safely be incorporated.

Narrative approaches (Anderson *et al.* 1986; Andersen 1987, 1990; White & Epston 1990; Hoffman 1993; White 1995) are based on the idea that human beings make sense of their lives by telling the story of their experiences. The only way we tell our stories and the way in which stories become dominant or subjugated depends on such factors as culture, gender, family and

social norms. Once these narratives have been formed it can be difficult to see alternatives. Eventually they are not only an account of our lives but they also begin to dictate what happens in our lives. This effects a constraint.

Individual stories are always heavily influenced by the more dominant societal stories: what we are told to believe by society (Foucault 1980). Those in helping professions often uphold these dominant discourses. They can inadvertently marginalize members of the community who may hold different beliefs.

The narrative theory of change suggests that people are likely to encounter difficulties and thus seek therapeutic help when the narrative they hold about themselves no longer 'fits' all or a certain aspect of their lived experience. The therapeutic aim is then to form a collaborative respectful alliance. The therapist works with the client first to deconstruct the constraining narrative and then to 're-story' or 're-author' their experiences in such a way as to highlight success already present or change the meaning of their experiences, so that these experiences have a better 'fit' within the client's larger narrative. This style of therapy is another one that works at the level of family belief systems rather than at a behavioural intervention level.

Anderson & Goolishian (1988, 1992) also put forward the 'not knowing position' in which therapists subsumed their expertise in order to allow clients to reclaim their own knowledge. In Norway, Andersen (1987) developed the idea of the 'reflecting team', a process whereby the therapy team will discuss hypothesis and their construction of what happened in the therapy session in front of the family. The purpose of this is to demystify the therapist's position by making their work transparent. It also ensures that therapists always speak in respectful empowering ways when they discuss families, instead of slipping into the all too familiar pathology-riven professional jargon that sometimes abounds. Families that have been interviewed about the therapeutic process prefer this and feel included, both in hearing the discussion and in being able to ask their own questions of the team.

Byng-Hall has had an interest in family scripts that predates the narrative movement, although much of his current work is influenced by the ideas of Michael White and others. He was initially interested in theories of attachment and worked closely with Bowlby. His ideas developed into an interest in the ways in which family patterns and behaviours were transmitted linguistically. His early work centred on ideas of myths and legends in families (Byng-Hall 1973, 1995). He also saw the relevance of Main's work on adult attachment to this style of intervention (Main *et al.* 1985).

Behavioural family therapy

Behavioural techniques have become quite widely used in family therapy. A helpful account of the applications of behavioural methods to family therapy can be found in Nichols & Schwartz (1991). Observations of the family interactions and behaviours become part of the structural family therapy approach, with the use of manoeuvres to achieve within-session changes in behav-

our followed by tasks for the family between sessions. Similarly, strategic family therapists use a problem-solving approach, concentrating on altering the behaviours between family members. However, both schools make active use of the belief systems in the family as a lever for change and recognize them as potential blocks to change. By contrast, behavioural family therapists focus on the behaviours and are not concerned with the metaphorical meanings of these behaviours (Crowe 1982). They adopt a psychoeducational approach but try to mobilize the efforts of the family to solve the particular behavioural difficulties.

Patterson developed behavioural interventions for use in the classroom and at home which he delivered as a form of behavioural family therapy (Patterson 1971a,b). This work has evolved into various forms of parent training and working with oppositional-defiant children and children with conduct disorder (Webster-Stratton 1984; Kazdin *et al.* 1992). Contingency contracting was utilized early by Stuart (1971) in his work with delinquent adolescents and has become a feature of many subsequent programmes.

Alexander & Parsons (1982), working with delinquent adolescents, used the family systems' conceptual framework to assess the function of the target behaviours for the family as a whole, as well as for the individual family members. They used very recognizable behavioural techniques to effect change. In their functional family therapy model, they worked to alter the contingencies at home in response to wanted and unwanted behaviours from the young person, as well as working on the expectations and attributions in the family, introducing a cognitive element to the treatment. Kazdin (1997), in reviewing the literature, came to the conclusion that functional family therapy, parent management training and multisystemic therapy are among the more promising treatments for adolescent conduct disorder.

A behavioural family therapy approach was found to be an effective treatment of school refusal (Blagg & Yule 1984). Others (Barrett *et al.* 1996) used behavioural techniques, such as tokens, verbal reinforcement and planned ignoring within a family therapy context as part of their programme for the treatment of anxiety in childhood.

Special topics

Separation, divorce and step-families

The effects on family relationships of separation, divorce and the evolution of step-families are increasingly becoming a norm in modern Western society. More than a half of children whose parents separate before they are 16 years old will come to live in a step-family while they are still growing up. Cockett & Tripp (1994) found that fewer than half of children had continuing contact with their non-resident parent 2 years after a separation. Agreement and continued conversation may often be impossible between ex-partners. Simpson *et al.* (1995) found that this was

the case for over one-quarter of 400 families in their Newcastle study.

Gorrell Barnes & Dowling (1997) and Gorrell Barnes *et al.* (1998) have written in some detail about the transitions that take place in family life through these processes and the repercussions down the subsequent years. As they pointed out, children are also required to keep secrets, to 'not know' and, at times, are subject to uncertainty about the end of the relationship and what arrangements there will be for parenting them for considerable lengths of time (Gorrell Barnes 1998). These can easily lead to distress and the keeping alive of quite unreal expectations. Family therapists have developed clinical approaches to helping divorcing and divorced families (Robinson 1997) but the research in this area seems to focus mainly on behavioural, parent management training and helping children with problem-solving training rather than systemic family therapy approaches (O'Halloran & Carr 2000).

Difference and the need for self-reflexivity

Britain is no longer a predominantly homogeneous society with variations mainly in socioeconomic and regional differences. There is now a huge diversity in the population, including differences in race, ethnicity, religion and also differences in family forms with large increases in lone-parent families, reconstituted families and families headed by same sex couples. Although culture is often associated with race and ethnicity, many of the above groups also have distinct culturally defined norms and expectations.

Cultural differences must therefore be taken into account when trying to understand areas as diverse as customs, food preferences, gender roles, child-rearing practices and the expression of emotion. Self-reflection becomes paramount as the therapist recognizes that they are as culturally influenced as their clients and that cultural issues affect us all and are not purely located in minority groups. Family therapists have acknowledged the need to become aware of their culturally determined biases and prejudices, to ensure that 'difference' does not become equated with 'abnormal'. There must also be a recognition of the large differences in power that various groups have and how this affects their ability to have their norms acknowledged and validated. It is very easy for a lack of understanding of different cultural norms and experiences to lead to a pathologizing of the unknown; examples include family governance, appropriate individuation or closeness in family networks and the effects of racism.

Falicov & Brudner-White (1983) have described how dominant dyads vary greatly from culture to culture. In Western culture there is a view that the parental couple should have an executive function, but in other cultures the executive position may be held by mother and son, or father and son. These cross-generational alliances could easily be seen as pathological if seen through a Westernized/Eurocentric lens.

Similarly, beliefs about appropriate levels of closeness and individuation are very culturally determined. Western views hold

that the successful completion of the adolescent phase of the life cycle results in the young person individuating, and becoming independent and autonomous, whereas many cultures view success as the acceptance of continued involvement in, and responsibility for, the family. If these beliefs are not taken into account, families can often be pathologized as enmeshed, undifferentiated or overprotective.

Societal context is also relevant. Closeness and protectiveness may be very appropriate responses to living in a hostile environment.

It is important that differences are acknowledged, because attitudes seeking to 'treat everyone the same' will lead to everyone being judged by the current dominant social norms, which may not be applicable.

Cultural specificity involves identifying discrete cultural groups and then attempting to describe their norms, customs and beliefs. McGoldrick *et al.*'s (1996) study contained detailed culture-specific information about working with a large variety of different cultural groups. This approach has been useful as it has challenged the idea that there can be universal family norms. However, it also carries a risk of stereotyping and it must be remembered that there is always considerable intercultural diversity (Ho 1987).

Multiculturalism proposes that therapists adopt a culturally sensitive position with every family, even those that appear to be of similar culture to their own. The aim of this approach is to reduce the risk of making false assumptions. The family will be the best guide as to what is or is not appropriate for them. The maintenance of a respectful interested position on the part of the therapist is likely to produce the most accurate source of information. For instance, rather than trying to learn the cultural norms of black families—within which there is obviously a huge diversity—it may be more useful to have an awareness of some of the likely shared experiences that minority ethnic groups face such as language barriers, cultural shock, living with prejudice and discrimination, feelings of powerlessness sometimes resulting in hopelessness, depression, rage and suspicion.

Similarly, when working with gay and lesbian couples, a recent survey showed that the following were areas in which couples felt that therapists should be sensitive.

- The invisibility of their relationship.
- Having to deal with 'coming out' whether it be in their personal lives or working environment.
- Having to live with homophobia and the fear of verbal or physical attack purely on the basis of their sexual orientation (Long 1996).

However, in all considerations of cultural issues there can remain a tension between avoiding creation of 'pathology' and the overlooking or minimizing of problems by seeing them purely as cultural differences.

Family therapy and psychosomatic illness

Family therapy has been an approach of choice in the treatment

of anorexia nervosa and bulimia nervosa for the past two decades. This has probably come about because two influential approaches within family therapy suggested specific ways to treat such cases (Minuchin 1978; Selvini Palazzoli 1978). Anorexia has been increasingly recognized and has worried professionals and families because of its life-threatening nature and because previous styles of treatment, involving rigid behavioural approaches in inpatient settings, were thought to be ineffective in the longer term, although they could achieve immediate weight gain, and such treatments became unacceptable as an intervention style. The family typology proposed by Minuchin has been refuted (Kog *et al.* 1985, 1987) but this work served as the stimulus to therapeutic advances and there has amassed a significant research evidence-base that involving the family in the treatment of child and adolescent cases of anorexia nervosa improves outcome (see below) although this is less clear in adult cases. For bulimia nervosa there are few trials of family therapy that have been included in recent meta-analyses (Hartmann *et al.* 1992; Wilson & Fairburn 1998).

Research on the family

Regrettably, the development of family therapies has occurred without much attention to empirical research findings. Nevertheless, such findings are relevant. Four main issues need to be considered. First, despite claims to the contrary, there is substantial evidence that family adversities of various kinds provide an important environmentally mediated psychopathological risk (Rutter 2000; see also Friedman & Chase-Lansdale, Chapter 15) that is best demonstrated with respect to family discord and negativity, a lack of continuity in personalized caregiving, and a deviant social ethos. Secondly, the reality of social group processes, both within the family and outside (Bronfenbrenner 1979), is well established (Rutter 1999a). That is, the functioning of families has to be considered in dynamic terms with the interaction between any two individuals having an effect on others in the group (Patterson 1982) and with each person's behaviour affected by who else is present (Clarke-Stewart 1978; Dunn & Kendrick 1982; Hinde & Stevenson-Hinde 1988). Thirdly, it is clear that risk and protective processes involve individual as well as family features; accordingly, it would seem that therapeutic interventions should be able to consider both (Rutter 1999b; see also Jacobs, Chapter 58; Brent *et al.*, Chapter 54). Fourthly, there is a paucity of evidence on whether the specifics of family therapy strategies constitute the most effective means of providing a remedy for the family risk processes. Thus, a systematic randomized controlled trial provided convincing evidence that family therapy was superior to individual psychotherapy in the treatment of anorexia nervosa in adolescents, although not in adults (Russell *et al.* 1987; Eisler *et al.* 1997). Nevertheless, a small-scale randomized control study by the same researchers seemed to show that comparable benefits were obtained by family counselling (Le Grange *et al.* 1992). The question is less whether family therapy can be effective (be-

cause there is reasonable evidence that it can; see below) but, rather, in which circumstances it is the treatment of choice and in which it is not. Even more crucially, we lack good evidence on which elements of family therapy constitute the essential agents of change.

Efficacy of family therapy

In a major meta-analysis of family and marital therapy, Shadish (1992) and Shadish *et al.* (1993) examined 163 studies, recruiting subjects until 1988 of marital ($n=62$) and family therapy ($n=101$) with random assignment of participants. They found an overall effect size of 0.47 compared with untreated controls ($n=44$ studies of family therapy). Family therapy was effective for 'general childhood conduct disorders' and for childhood aggression but it was ineffective for delinquency. They also found evidence for the effectiveness of this form of treatment for global family problems, communication/problem-solving, with some evidence for efficacy in phobias, schizophrenia and 'global psychiatric symptoms'. They did not find that different theoretical orientations with family therapy approaches made a difference to outcome.

Manualization of the treatment appeared to improve the outcome (Shadish *et al.* 1995). They found very few studies of effectiveness in a general clinical setting as opposed to the efficacy in university research settings. In the later review they also found a different result with regard to interventions for conduct disorder and school problems, with individual approaches proving more effective than a family therapy approach.

Carr (2000) recently reviewed family therapy research from an evidence-based perspective, examining several areas of child mental health practice. He pointed out that there are now a number of studies validating family therapy as an approach to treatment of child mental health problems. Most of the examples (apart from anorexia nervosa and substance abuse) involve behavioural and cognitive methods applied in a family setting. He also emphasized that a multisystemic approach is effective in many circumstances. This approach, pioneered by Henggeler & Borduin (1990), links a variety of different approaches to treatment in a tailored package over time for the particular needs of the family and child's situation. Thus, a child may need individual attention to improve coping mechanisms. His parents may need teaching cognitive behavioural skills as a couple or in the whole family setting and a programme may need to be introduced into the school setting that goes beyond the usual liaison skills practised in child mental health. Work may need to be undertaken to improve peer group skills, to enable the child to move away from a dysfunctional group of peers to a healthier set. Carr saw this attention to detail as illustrating a family and systemic perspective. The other area that he highlighted throughout this review is the attention of a family therapy perspective to communication between family members. Whether this is between parents in improving their discipline strategies or between parents and the identified child in improv-

ing negotiation of boundaries and a sense of fairness, this is probably a contribution that the family therapy perspective has contributed to treatments in child mental health.

Emotional disorders are responsive to family approaches, sometimes combined with other interventions including medication. For example, obsessional-compulsive disorder has been treated with a combination of clomipramine and a family therapy approach based on the work of White (1989). This uses his technique of 'externalization of the symptoms' in a programme called *How I ran OCD out of my land* (March & Mulle 1998). They found that they could produce a clinically significant improvement in 80% (12/15 cases showed a 30% improvement on Yale-Brown Obsessive Compulsive Scale with no relapses at an 18-month follow-up) of cases (March *et al.* 1994). The programme included coaching the children with anxiety management and relaxation training to work with their difficulties in a hierarchical approach, together with helping the parents to avoid reinforcing the rituals.

Blagg & Yule (1984) found that a behavioural hierarchical desensitization family-based programme produced a better outcome than an inpatient treatment programme (93 vs. 38% successful outcome at 1-year follow-up). The outpatient treatment programme was provided on an intensive basis with negotiation with the school to ensure a rapid return.

Other studies for specific anxieties and for generalized anxiety disorder (Graziano & Mooney 1980; Barrett *et al.* 1996) have taken a family approach. Those studies reported quantitatively have tended to use behavioural components applied in the family context.

Grief reactions following the death of a parent have been treated with home-based family therapy and showed both short-term and longer term improvements (Black 1987; Sandler *et al.* 1992).

With regard to psychosomatic problems, family-based approaches have been found to be effective in several areas. Thapar *et al.* (1992) reviewed the treatments for encopresis and found that a combination of dietary fibre increase, medication and behavioural family therapy was the most effective approach. White (1989) developed a treatment in which the soiling is characterized as another individual who is trying to subvert the child and family. The aim of therapy is to overcome and defeat this character. The programme was researched by Silver *et al.* (1998) and was found to be more effective than a purely behavioural approach.

Family therapy has been found to be useful as an adjunct to medication in the treatment of several disorders, including asthma (Lask & Matthew 1979; Gustafsson *et al.* 1986), attention deficit hyperactivity disorder (ADHD) (with other components of a multimodal treatment; Barkley 1990; Barkley *et al.* 1992; Hinshaw *et al.* 1998) and obsessive-compulsive disorder (March *et al.* 1994; March & Mulle 1998).

The effectiveness of family therapy interventions in the treatment of physical illness has been reviewed by Campbell & Patterson (1995). Methodologically poorer studies of family therapy intervention have not used control groups but have

shown changes with intervention for asthma (Liebman *et al.* 1974; Minuchin *et al.* 1975) and for conversion symptoms (Turgay 1990). Better studies included those by Lask and Gustafsson already cited. Psychoeducational approaches working with the family have been better researched and shown to be effective for compliance for diabetic control, management of asthma, recurrent abdominal pain and helping families manage chronic physical illnesses.

Psychoeducational approaches have also been found to be useful in preventing relapse in schizophrenia (Leff *et al.* 1982; Leff & Vaughan 1985; Goldstein & Miklowitz 1995). This is based on pioneering work by Vaughan and Leff's earlier studies of factors leading to relapse in schizophrenia (Vaughan & Leff 1976). This work has been applied to early onset schizophrenia in adolescence although its impact on relapse has not yet been properly researched.

In a series of trials (Russell *et al.* 1987; Le Grange *et al.* 1992; Eisler *et al.* 1997; Robin *et al.* 1999), family therapy has been found to be a treatment of choice for anorexia nervosa. Structural and Milan systemic family therapy approaches have formed the basis of family treatments provided, but they have been modified with time to take account of the acute sensitivity of such families to expressed emotion and critical comments. For some families, this has meant that a more effective approach has been to provide separated family therapy in which the parents are seen separately from the adolescent but a systemic stance is maintained with both (Eisler *et al.* 1997).

In reviews where parent management training (PMT) has been included in the broad definition of family therapy, it has repeatedly been found to be effective for oppositional-defiant disorder and childhood conduct disorder. (Estrada & Pinsof 1995; Kazdin 1998). The latter authors also concluded from their review of the literature that PMT reduces the non-compliance and aggression in children with ADHD but that it does not really improve the core symptomatology of the disorder. Satterfield *et al.*'s (1981, 1987) studies were the exception to this finding in that the addition of family therapy to a pharmacological intervention did improve the outcome in their cohort.

Chamberlain & Rosicky (1995) reviewed several recent studies' use of family therapy approaches to adolescent conduct disorder. They emphasized the importance of a manualized approach. All the recent studies seemed to involve a social behavioural learning approach (Bank *et al.* 1991), a structural family therapy approach (Szapocznik *et al.* 1989) or one that combined the social learning approach with other individual components for the young person to improve social cognitive appraisal and other peer-related processes (Chamberlain 1990; Henggeler *et al.* 1992). They referred to the latter as multi-target ecological treatment (MET). They discussed two types of study. The first involves the youngster spending time with a specially trained foster family while their own parents undertake a course of parent management training and a reintegration of the young person to the family. Very close attention is paid to managing the child's contact with school and peers during this programme. It has been successful in preventing young people being

incarcerated and in reducing their subsequent antisocial behaviour (Chamberlain & Reid 1991; Chamberlain 1994).

The second approach reviewed by these authors, the family preservation services (FPS) model, has the young person remain at home with their parents but with very intensive home-based and community interventions. Taking place over 2–4 months, it requires many hours of professional time each week. It has a mixed outcome (reviewed by Rivera & Kutash 1994). The latter authors also pointed out that a significant proportion of conduct disordered families drop out of treatment. Families that drop out typically show high rates of various risk factors such as stress, maternal depression, social isolation, low socioeconomic status and were referred for treatment by an external agency.

In substance-abusing adolescents, reviews by Waldron (1996) and by Cormack & Carr (2000) indicate that family therapy approaches are more effective than individual or group approaches and at least as or more effective than parent training. The approaches used included a structural family therapy and strategic approach. Liddle & Dakof (1995) reviewed 10 studies of family-based approaches to adolescent drug abuse. All showed positive findings, both in terms of engaging families and subsequent outcome. Two studies indicated a better outcome when comparing this with a peer-based approach. Henggeler *et al.* (1991) showed a reduction in drug-related offences in a 4-year follow-up study of a multisystemic approach that included family therapy.

Hampson & Beavers (1996) asked which families respond best to which family therapy approach. In general, they found that underorganized families do better with more structured directive approaches while families that are relatively well functioning benefit from more narrative/social constructionist approaches.

Conclusions

Family therapy has come a long way since its beginnings. There is a research literature developing but it is still far too sparse for comfort. There is a dearth of process research and the outcome research is slanted towards behaviourally based interventions at present. This can lead to the ‘truth’ that only this type of family interventions work. It may just be that it is largely investigators with this background that have carried out the studies thus far. One of the difficulties that the field faces is the rapidity with which theoretical ideas move on, to be followed apace by clinical self-reinvention. This means that there is rarely time for the development of manualized treatment approaches, let alone randomized clinical trials before the next ‘leap forward’ occurs.

Despite these reservations, family therapy can take pride that many of its ideas have become incorporated into the thinking of child and adolescent mental health practice so that many other professionals take for granted a systemic approach to their work even if they are not practising family therapists.

There is a recognition among family therapists that there are

links between elements of behaviour through increasingly complex ways of assembling these to individual belief systems, family scripts and societal ones. The choice then becomes at what levels interventions can and may be made. With this synthesis it becomes much more possible to integrate thinking about families. It allows the use of elements from behavioural approaches through interpersonal narrative ones and to include psychodynamic thinking to produce a more holistic formulation. This could appear muddled but there does appear to be benefit from the family’s viewpoint of the giving up of territorial wars and the harnessing of skills from many domains—psychosocial and biological—in the treatment of families.

There is a recognition among clinicians that a rather more structural behavioural-based approach is taken with the problems of families that involve younger children while a shift to more inclusion of belief systems of both adults and youngsters occurs as the child reaches adolescence. This can be seen in the greater evidence for such styles in working with those with anorexia nervosa and young people who are substance abusers.

The one thing that is striking but often forgotten is that the family and child that we treat are the same whatever spectacles we choose to view them through. We may elicit different aspects of their world but all the aspects are there to be understood.

It is sad that in a recent family therapy journal review of the research, Carr (2000) felt it necessary to insert paragraphs justifying an evidence-based approach in the context of a current preoccupation with a social constructionist view of systemic thinking. Surely an aim for the future must be to work beyond the constraints of acceptable theory at any one point in time.

Introduction

This chapter considers individual and group treatments that are used directly with children and adolescents and that are based on psychodynamic principles, relationship concepts or social skills approaches. The starting point is that, whatever the style of therapy, there are basic considerations that will influence clinical delivery. Therapists often feel pressed to break new ground and to emphasize how what they do is different from anything that has gone before. This tension over the need to differentiate among treatments that appear to have much in common has led some commentators to note the ‘non-specific’ effects of psychological therapies. In the adult field, some have claimed that the largest effects derive from the therapist–client relationship rather than from any specific intervention components (Lambert 1992; Hubble *et al.* 1999). Similar considerations may be applicable to treatments of children, with the additional complication that children rely on adults for both access to treatment and understanding of the treatment processes.

Although the claims regarding the predominant importance of non-specific effects seem overstated, clearly it is the case that treatment methods involving personal interaction will depend on the skills of empathy, of pacing, of responsiveness to cues and of active listening that span different approaches. To different degrees, and in varying ways, all psychotherapies bring together interpersonal microelements, behavioural patterns, conscious and unconscious applied to recurring or new situations, and belief systems about their own and others’ actions. Treatments differ on the levels on which they focus and differ even more on the elements they emphasize as crucial. Psychoanalytic psychotherapy stresses the importance of unconscious thought processes and the extent to which the present is shaped by the past, but therapist–client interactions will be subject to the behavioural influences that constitute the central justification of behaviour therapies. Similarly, modern behaviour therapies recognize the role of thought processes, of thinking patterns that derive from past experiences, and they make use of qualities in the therapeutic relationship. This is most apparent with cognitive behaviour therapies (see Brent *et al.* Chapter 54) but it applies also to other behavioural methods (see Herbert, Chapter 53).

Individual psychodynamic approaches

Aims and history

Psychodynamic psychotherapy seeks to help children process the cognitive and affective components of memories that may be distortions of actual events or which are one-sided in their focus. Children are helped to obtain some sense of mastery and understanding of their lives and learn to manage themselves without having to resort to troublesome defensive (self-protective) strategies. The aim is to restore ‘normal’ psychological development when this has gone awry and to strengthen internal psychological resources. Psychodynamic approaches all accept the idea of unconscious parts of the mind where normal everyday logic does not apply and where quirky links are made among thoughts, feelings and memories in odd idiosyncratic ways.

Psychodynamic theory may sometimes appear rather opaque. In part this may reflect outmoded theory, but in large degree it stems from the difficulty of describing the feeling states and fluctuations in feelings attached to memories that constitute the heart of the therapeutic process. The complex patterns of communication between child and therapist are perhaps more akin to music than to language.

A particular problem for psychoanalytic theory has been that it was mostly developed in work with adult patients looking back towards childhood, providing a very different perspective from that of the child looking forwards. Classical psychoanalytic theory has undergone many changes over the years (Spillius 1988; Rayner 1990; Tyson & Tyson 1990; Sandler *et al.* 1992). Although the concept of ‘drives’ (a central feature of early psychoanalysis) may have some validity, its limitations are now widely accepted.

Object relations theory has been helpful in thinking about the internal world of the child and of the people—distorted through the child’s own defence mechanisms—that inhabit that world. These defence mechanisms are important to the child in helping him or her to obtain mastery and some sense of control in phases of life when he or she has very limited actual control, but they can become a liability. The development of object relations theory was charted by Greenberg & Mitchell (1990), and its modifications in relation to children by Sandler *et al.* (1980) and by Spillius (1988, particularly Vol. 2, part 3).

Increasing attention has been paid to the findings that have emerged from developmental psychology. The writings of

Brazelton, Emde and Stern (Stern 1985) have been particularly influential. Very much briefer accounts of psychodynamic theory, as applied to work with children, have been provided by Lanyado & Horn (1999) and by Jacobs (1997).

In essence, psychoanalytic theory is increasingly taking into account the findings of the developmental psychology of early life. This requires a rethink of many concepts; for example, it is now evident that newborn infants are sentient beings with thought processes and learning that show rapidly increasing complexity over the early childhood years. This was not realized in earlier psychodynamic writing.

Another important element in the modernization of psychodynamic thinking as applied to children has been the development of attachment theory and its helpfulness in bringing a theoretical framework that can more easily be tested empirically (see O'Connor, Chapter 46). This latter framework has led to the development of instruments that are thought to measure activation of the attachment system, normal and abnormal, at various ages from early to middle childhood (Bretherton *et al.* 1990; Goldwyn *et al.* 2000; Green *et al.* 2000). Although not yet well tested, these instruments offer the potential to measure changes in attachment patterns and, in particular, the degree of attachment disorganization (Hesse & Main, *in press*) that takes place with various approaches to treatment of childhood disorders.

The replication in therapy of emotional scripts that are enacted outside therapy and that often seem to have a history from early in the child's development provides much of the material for the therapy. Gradually enabling a child to feel less threatened and more able to relax rigid defence patterns, to become more flexible in the way that he or she understands and approaches, and reacts to approaches from others, forms much of the work of therapy. This, together with reducing the child's need to use defences that have become developmentally outdated is one central aim of child psychotherapy.

Working with parents to enable them to support the child's therapy is seen as an essential component of the work. Sometimes this work may be more intensive in its own right; at other times group work with parents seems more appropriate. It has been found to be particularly useful when the parent is isolated in reality or through a sense of failure with their child. Meeting others in a similar predicament can be very supportive (Rustin 1999; Tsiantis 1999).

Therapeutic strategy

Parents need to understand and support the nature of the therapeutic contract for a child to be brought to therapy on a regular basis. Interruptions in therapy are very disruptive, particularly those occurring at short notice. Most child psychotherapists see children at fixed times each week for sessions lasting about 45 min. These times may be reduced for younger children. The therapist provides a range of toys to allow the child to build an imaginary world with animals (wild and domestic) and people (Hartnup 1999). Many therapists prefer not to have construc-

tional toys or board games. These can easily lead to a child 'avoiding' an engagement with their inner world that is more likely to occur through less structured activities. Other therapists, it has to be said, have found that constructional toys can be helpful to anxious children and that in due course the child comes to use them in fantasy to represent other things. Most therapists will provide each child with their own box of toys and play materials including paper, glue, plasticene, drawing materials, etc. For adolescents, a more adult setting is usually demanded (Wilson 1991) but it can be helpful to have creative materials available.

It is important that therapists negotiate their role with the child or adolescent including the knotty issue of confidentiality. Complete confidentiality cannot be offered; issues of child abuse may arise in therapy. How such matters are dealt with need careful negotiation with the child so that they can feel supported safely rather than being betrayed. Equally, adults who bring children for therapy must feel reassured about the issues of confidentiality but also understand its importance for the child and therapist in the normal working of therapy. Reviews of therapy are commonly built into the method and form part of the process of deciding how and when to end treatment.

In sessions the therapist generally takes the stance of an interested observer. Periodically, he or she will ask questions about what is happening in the child's play and will make comments about possible links to other elements in the play and, perhaps later in the therapy, to issues in the child's own life. Depending on the style of psychodynamic therapy, some therapists will make more interpretations about possible links to conflicts in the child's inner world and oppositions between wishes, desires and fears. The therapist hopes to induce a curiosity in the child about why he or she thinks, feels and behaves as he or she does and whether he or she wants to continue thus or decide to change these patterns.

Therapists will be careful to monitor their own behaviour towards the children they see and the effect that each child has upon the therapist. Combined with information arising from the child's activities and behaviour in the session, this will provide some insight into how the child sees the external world through the distorting lens of his or her own internal world. This can give a lead as to how the therapist might intervene to try to describe this process and through this to begin to 'challenge' it.

A therapist must be able to tolerate 'not knowing' the meaning of a child's play or behaviour for some time until it becomes clear. Prematurely putting the matter into words can distort the real meaning and lead to a loss of confidence by the child or the creation of false memories.

The child psychotherapist must be able to accept and tolerate intense feelings generated by the child. Tolerating these projections that often are generated non-verbally, sometimes in silence with little action, can require considerable containment and ability for self-reflection by the therapist. Not acting at such times but reflecting and gradually trying to come to understand the meaning of such 'feeling storms' can be crucial to the outcome of therapy.

Applications

Child psychotherapy in the UK has had to adapt to the NHS framework, with children being seen once or twice weekly. The indications for such work and its limitations are well described by Parsons *et al.* (1999). Only a small number of children are seen intensively (Green 1999). Child psychotherapists carry out significant consultation work with other professionals in social services (Hughes 1999; Hunter 1999), education and therapeutic communities (Flynn 1999; Wilson 1999). In addition, they are increasingly working directly with youngsters who are in the local authority care system. This has been a new venture for child psychotherapists as there was a time when the lack of stability of placement for such children was seen as an insuperable impediment for any work except brief consultation (Hunter 2001).

Child psychotherapists have found a place in specialist paediatric departments and provide direct assessment and on-going work with patients as well as support for the staff who are often working with children who have emotionally distressing conditions. Ramsden (1999) gave a helpful account of such work with several clinical examples. Some empirical evidence for such work is described below (Fonagy & Moran 1990; Moran *et al.* 1991).

Empirical review

Overall, there is evidence that psychodynamic approaches to treatment are effective, although there are disputes about the degree of effectiveness and their relative efficacy compared with other psychological treatments for children and adolescents.

An early empirical review (Levitt 1957) was not encouraging, suggesting that child psychotherapy was no more effective than the passage of time. This was challenged on the basis that the studies showing improvement without treatment were poor and the definitions of the children's symptomatology were inadequate by today's standards (Kolvin *et al.* 1988; Roth & Fonagy 1996, p. 279). By the early 1980s there was weak evidence in favour of child psychotherapeutic approaches (Kashudin 1974; Tramonata 1980, p. 32; Rutter 1982).

One careful meta-analytic review (Kazdin 1990) has described effect sizes of 0.88 comparing those who receive any child psychological treatment against those receiving no treatment. This reduced to an effect size (ES) of 0.77 when there was a placebo control treatment. Others (Casey & Berman 1985) have found much smaller effect sizes (0.21) for child psychotherapy compared with a client centred approach (ES=0.49) or a behavioural approach (ES=1.00).

However, this low effect size for child psychotherapy was based on five studies only, largely (75%) non-clinic referrals (Saxe *et al.* 1986). The behavioural treatments were assessed using measures that are similar to the intervention leading to the possibility of 'training' (Casey & Berman 1985). Here and elsewhere (Weisz *et al.* 1987), removing studies that use outcome measures that closely relate to the therapy task from the analysis

shows behavioural and non-behavioural interventions to have similar effect sizes.

Shirk & Russell (1992) also demonstrated an allegiance effect and the importance of relating the treatment to actual clinical practice. They reanalysed data from Weisz *et al.* (1987), looking at the 24 studies with 29 treatments that involved non-behavioural methods. They showed that many studies had three or more significant methodological flaws (62%). The more rigorous studies had double the effect size (0.6 vs. 0.3) and those non-behavioural studies carried out by therapists with an allegiance to non-behavioural approaches had an effect size of 0.56 compared with 0.17 when behaviourists tried to carry out non-behavioural therapies (often as control/comparisons for their own behavioural treatments).

Furthermore, in other studies (Koocher & Pedulla 1977; Silver & Silver 1983; Snow & Paternite 1986; Kazdin *et al.* 1990), group treatments for non-behavioural approaches seemed to be frequently used while such approaches were rarely reported in clinical practice with children. The effect size from these group-based treatments was also much less than when the child saw a therapist individually (0.27 vs. 0.8).

The studies also failed to show evidence of efforts to maintain treatment integrity; only six of 29 samples showed such efforts. The brief non-behavioural interventions contrast with longer term individual psychotherapy that was a common approach at the time of the study. Finally, the research populations used in the 29 samples differed in their origin from most clinical samples; a disproportionate number of studies came from institutional settings rather than outpatient clinics.

When can individual psychodynamic psychotherapy with children help?

There are several studies that suggest that intensive psychodynamic psychotherapy with children can be of benefit. These have included single case methodology and small group comparisons. Lush *et al.* (1991) and Boston & Lush (1994) have shown that it is possible to develop a methodology to examine psychoanalytic psychotherapeutic treatment for severely deprived children in local authority care, asking whether it improved their adjustment in family placements. The result suggested, in a very preliminary way, that this might be a group of youngsters who can benefit from a psychotherapeutic approach.

Moran & Fonagy carried out several investigations of the treatment of brittle insulin-dependent diabetes mellitus with child psychoanalysis in conjunction with the physical management of the illness (Fonagy & Moran 1990; Moran *et al.* 1991). This small series of case studies showed that it was possible to produce operational definitions of a set of conflicts and psychological symptom categories specific to the patient. Independent ratings over a 3-year psychoanalysis offered some support to their hypothesis that brittle diabetes is related to unconscious conflicts. Improvements in diabetic control were clearly followed 1–3 weeks later by increased psychological symptomatology. Conversely, themes of conflict often foreshadowed periods

of improvement in the diabetic control. In a subsequent small group comparison study using glycosylated haemoglobin (HbA_{1c}) as a marker for diabetic control and a less intensive psychodynamic psychotherapeutic approach, it was found that the group offered psychoanalytically informed psychotherapy showed a significant ($P < 0.01$) reduction in HbA_{1c} that largely persisted at 1-year follow-up. While the possibility remains that it was the therapeutic attention that these children received rather than the specific therapy that was the important factor, these studies do suggest that this approach warrants further investigation for what can be an intractable and dangerous situation.

The final small but elegant study used an experimental design in three single cases of brittle diabetes with significant growth retardation. Growth was used as a biological outcome. An increase in growth velocity leading to increased predicted adult height of 5–10 cm was observed to accompany psychodynamic treatment. These findings were associated with improvements in HbA_{1c} levels. Again, although this work was on a small scale, it was rather suggestive that psychodynamic psychotherapy can have a role in the management of brittle diabetes.

Systematic examination of the case notes of the Anna Freud Clinic in London also provide some clues as to which children may benefit from intensive or less intensive psychodynamic psychotherapy. In an uncontrolled study, Fonagy & Target (1994) and Target & Fonagy (1994) found that younger children with behaviour or emotional disorders did better than older ones. Intensive treatment seemed to be important in establishing change for the younger behaviourally disturbed children. This was untrue for the emotionally disturbed youngsters. For the disruptive children the length of treatment and the presence of an emotional disorder were positively linked to improved outcome. Comorbidity of anxiety and behaviour disorder improved the outcome for these children whereas other diagnoses worsened the outcome. As anxiety has not generally been associated with a good outcome in oppositional-defiant disorder and conduct disorder, this may be a feature of the psychoanalytic intervention.

Contextual factors are important in the treatment of behavioural disorders. Those that the Anna Freud Clinic could address were parental support during therapy and admission of high-risk children to their nursery at a young age. The holding of the family in longer term treatments has also been found to be an important element in other centres, e.g. Satterfield in his work with boys with attention deficit hyperactivity disorder (ADHD) where those who were engaged in various treatments for 2 years or longer had a much improved outcome (Satterfield *et al.* 1981, 1987).

Of the emotionally disordered patients, depressed youngsters were significantly less likely to show remission, measured by a persisting dysfunctional Children's Global Assessment Scale (C-GAS) score. Children with anxiety disorder, depression or mixed disorders of conduct and emotion did better with the more intensive treatments. Equally, when the children were divided into severe cases and less severe cases the former group did

better in the more intensive treatment while for the latter cases this seemed less important.

Non-random assignment of cases that is likely to have occurred clinically makes this result only suggestive at this stage. For example, it is possible that those children with less stable home settings/in care but who had severe problems might be differentially placed in less intensive treatment because of the worry that the treatment might be prematurely stopped. Intensive treatment was also associated with a reduction in the proportion of cases where there was no change or deterioration over the course of treatment.

Taken together, the studies suggest (but remembering that they are uncontrolled and non-random in assignment) that psychoanalysis can be an effective intervention for some situations in childhood. Given the high cost in morbidity and financial costs to families and to society of some of the disorders, particularly in the behavioural disorders spectrum, it may be a justifiable intervention, particularly with younger children with behavioural difficulties. However, the costs of this treatment are high and there may be more effective ways of using limited financial resources. It is not yet clear whether there are particular cases of mixed disorders of conduct and emotion in younger children that may benefit from this resource that will not benefit from less costly interventions.

In the educational field, Heinicke (1969) and Heinicke & Ramsey-Klee (1986) studied children who had educational difficulties of a degree that required supplementary help; some subjects had been held back in school. They met criteria for anxiety with attention deficit and half of the children were also hyperactive. In this very small study, they showed that the group of children having once weekly individual therapy made greater gains during the study. However, boys exposed to four times weekly psychodynamic psychotherapy for 1 year as part of the 2-year treatment made the greatest gains in reading by the time of the 1-year follow-up. The authors offered tentative evidence that the boys who had four times a week therapy made greater gains in effective adaptation, self-esteem, their capacity for relationships, their ability to tolerate frustration and ability to work (weak evidence) and in flexible adaptation. The number of measures, the qualitative nature of the assessments and few subjects mean that caution must be taken in interpreting statistically significant results. None the less, the results accord with those of Fonagy & Target in suggesting the gains that may be made from intensive child psychotherapy. They also, incidentally, are an example of effects appearing during follow-up that were previously masked. This seems to be occurring more frequently in child mental health studies and challenges the scepticism that had built up in the research community regarding so-called 'sleepier effects'.

Thus, as summarized by Roth & Fonagy (1996, pp. 285–6) as the result of their meta-analytic review of the literature, the evidence shows 'consistent differences between treatments in terms of effect size. Behavioural treatments show significantly larger effect sizes than non-behavioural ones, humanistic/existential and family based treatments obtaining somewhat better

effect sizes than individual psychodynamic interventions.’ They also conclude that ‘Between treatment differences are seriously confounded by the use of measures to assess outcome that favour behavioural treatment. There are very few studies of psychodynamic interventions in the pool available for meta-analysis, and these are unrepresentative of practice because of their brevity and the predominance of group-based treatments.’ They emphasize the difficulty of investigator allegiance and that of the gap between so-called laboratory-based studies with convenience samples and clinic-based studies with more severe cases. A later meta-analytical review by Carr (2000) for a number of areas in child and adolescent psychological treatments does little to alter this situation.

Richardson (1998) discussed the hurdles of evidence-based medicine, pointing out that child psychotherapy is not alone in not yet meeting the standards of evidence demanded by the clinical effectiveness agenda. He illustrated a fallacy of this approach in which good research can fail to be included in a meta-analysis because it fails to meet one particular criterion of the reviewer’s selection system, e.g. the degree to which the diagnostic group is defined. Other methodologically flawed research is included because it does meet all the selection criteria. This is a general point about the meta-analytical approach and highlights the crucial stage of setting the initial inclusion criteria.

In summary, psychodynamic treatments are beginning to show some evidence for their effectiveness, with effect sizes between 0.5 and 0.6, producing benefit relative to an untreated population in 69–73% of cases. There is still a dearth of controlled studies with random assignment. The conditions in which it is the treatment of choice have still to be delineated and a strategy that used less intensive resources *in the first instance* would currently be sensible, although there should still be room for clinical judgement. Well-conducted clinical trials to determine the specific uses of a psychodynamic approach are urgently needed. Work such as that by Moran may well be justified because of the life- and health-threatening nature of brittle diabetes and its frequent resistance to more ordinary approaches.

Place of psychodynamic psychotherapy in training

It would be far too early to consign psychodynamic approaches with children to a few specialist centres; the evidence does not support this. In the present author’s view, it is important for trainees to get experience of treating children psychodynamically under supervision from fully trained child psychotherapists. This experience will help to teach the trainee the skills that are necessary to deliver this specific therapy, as well as skills that are applicable in other modes of therapy that they are more likely to use themselves during their careers. It can improve their empathic abilities and other technical skills as well as providing a unique opportunity to experience the emotional forces that a child can muster. The effects on trainees are both expected and unexpected and their capacity to think when offering supervised child psychotherapy is revealing for them. Such experience provides an insight into ways in which children’s minds operate,

which can be very valuable throughout a child mental health career. Adults, including professionals, too often forget the child’s perspective in producing compromises that work for adults.

A gradual realization that there are many more links between behavioural approaches to treatment and the more psychodynamic approaches is likely to produce benefit for the evolution of therapeutic styles in the next few decades.

Interpersonal therapy for adolescents

Interpersonal therapy (IPT) was developed for adult use by Klerman *et al.* (1984), and was adapted for use in adolescents (IPT-A) by Mufson *et al.* (1993, 1996). The therapy is designed as a once weekly therapy carried out individually with the adolescent over 12 weeks. The originators describe three phases of treatment. During sessions 1–4 the aim is to assess the depression, the family and social context for the adolescent and then negotiate a treatment contract. The responsible parent is used as a resource during the assessment. In the second phase, the therapist works with the patient and, where necessary, conjointly with other family members to address one or two of the problems identified earlier. These may include grief, role disputes or transitions, interpersonal deficits and the particular difficulties of living in a single-parent family.

The style of the therapy is that of a collaborative approach to problem-solving. However, there are links to a brief focused psychodynamic approach, as well as differences (Fombonne 1998; Markowitz *et al.* 1998). The patient is allowed a limited ‘sick role’ to reduce self-blame and criticism from other family members while at the same time encouraging the adolescent to maintain as many social roles as possible and engage in activities from their previous lifestyle. The final phase of therapy (sessions 9–12) mainly addresses relinquishing the therapist and establishing a sense of competence to deal with future problems.

The evidence for the efficacy of IPT-A is increasing. Robbins *et al.* (1989) tried using adult IPT with adolescents in an open trial for depression among adolescent inpatients and found that 47% made clinically significant improvements. Adding tricyclic antidepressants to the treatment protocol for non-responders obtained a final response rate of 92%. An open clinical trial (Mufson *et al.* 1994) showed good attendance by the adolescents, with significant decreases in depressive symptomatology. Symptoms of physical and psychological distress reduced accompanied by improvement in psychosocial functioning.

This team have now completed a randomized control trial (Mufson *et al.* 1999) in which patients were offered the active treatment or were assigned to clinical monitoring. Therapists were given a brief treatment manual instructing them to refrain from advice-giving or skills training, and to use the 30-min sessions to review depressive symptoms, school attendance, assess suicidal ideation, and just listen supportively. An intention-to-treat analysis revealed that the IPT-A group had significantly fewer symptoms on the Hamilton Scale for Depression at the end of therapy while the self-rated Beck Depression Inventory

failed to reach significance at the same time point. They showed better problem-solving skills at the end of the therapy than the clinical monitoring group and they rated their social adjustment as better in relation to peers and dating; there were no self-rated differences between the groups in family relationships or their school adjustment at termination. Unfortunately, no follow-up data are reported and the data must be regarded as preliminary still because of the sample size, the attrition rate in the control group, the exclusion of most comorbid disorders except anxiety, and the population treated (mainly older adolescent female Puerto Ricans). None the less, this individual psychological treatment continues to look promising.

Group therapy

Group therapies have been surprisingly limited in their application and in the research associated with them in child and adolescent psychiatry. Surveys of clinicians in the USA have found that they do not think of group approaches as their preferred methods of treatment of children and adolescents (Koocher & Pedulla 1977; Kazdin *et al.* 1990), yet some investigators have shown that they can be effective interventions (Kolvin *et al.* 1981).

Early history

Kymissis (1997) provided an interesting history of the development of group therapy for children and adolescents from the beginnings in 1932 in Vienna (Dreikurs 1959). Slavson, in the mid-1930s, used *activity group therapy* in which he thought that the patient's 'ego could be repaired through self-directing and self-generating participation by patients in the group' (Slavson & Schiffer 1975). Aichorn (1935) treated delinquent youngsters using groups with a psychoanalytic approach, defining the therapist's role as neutral and non-punitive with unconditional acceptance of group members. This type of approach continues today (Reid 1999) although very clear limits are set around acceptable behaviour in the room.

Overarching theoretical considerations

Attempts have been made to classify the factors that may be operating in the group approach as used with adults (Corsini & Rosenberg 1955; Evans 1998). Nine groups are evident: acceptance, altruism, universalization, reality testing, ventilation, spectator therapy, transference, interaction and intellectualization. This work was taken further for adult groups by Yalom's (1985) delineation of 'curative factors'.

The lack of empirical evidence means that we have to rely more upon theoretical positions and the comments of clinicians who use a group approach about the advantages and dangers that they have found in working with groups of children and adolescents.

Reid (1999), writing about psychodynamic style groups

for children and adolescents, described helpful aspects of group therapy that may be useful for adolescents:

- acceptance by therapist and peers;
- the safety of group boundaries;
- the opportunity to make friends in a protected setting;
- observation of the strengths and weaknesses of other group members as a yardstick to assess oneself;
- enhancing of self-worth;
- observation of and feedback about the effects of one's behaviour on others;
- modelling;
- realization that one's difficulties are not unique;
- the opportunity to treat some youngsters who could not tolerate an individual treatment;
- an increase in self-responsibility through peer interactions;
- the opportunity to take treatment to the child in a variety of settings where it would otherwise be very difficult; and
- economy of treating several young people at once.

Some groups have been designed for youngsters trying to come to terms with specific issues, such as sexual abuse. Ben-tovim *et al.* (1988) wrote of group work that avoided replication of the secrecy of the abusive experience. The group offers specific support around the conflicts engendered by such abuse. The experience of not being alone in having been abused is thought to be important for these youngsters. A separate psychoeducational function in these groups is to help the young people distinguish between needs for affection/care and sexual feelings, and to help them learn to manage their urge towards sexual 'acting-out'. The group provides peer-based social support, an opportunity to work out what they want to achieve in their relationship with their parents and, finally, to help them to improve their self-esteem.

In all the descriptions of group psychotherapy as applied to children and adolescents, one finds adaptations of content and process to the appropriate developmental stage of the young people concerned. In this regard, groups should probably have a restricted age range because of developmental issues (Kymissis 1997). For adolescents, some suggest that groups should be composed of same sex members because the anxiety of heterosexual issues may interfere with the group climate (Kennedy 1989). This latter position would not be accepted by all.

In summary, where they have been used in psychotherapeutic work, groups use the interpersonal peer and social learning opportunities in addition to the common psychotherapeutic factors that run through most forms of psychotherapy and the specific focus engendered by a particular psychotherapeutic approach.

Psychodynamic groups and non-directive relationship-based therapies in groups

These are considered together because the theoretical frameworks within which they operate have drawn together in many ways over the years. Strict psychoanalytical interpretations are less commonly used now, although consideration by the group

leader of unconscious processes within the group is common. A clearer focus on current interactions is common.

Strategies for relationship-based groups

Thinking about the needs of group members and some aspects of group processes using a psychodynamic developmental framework can be useful (Evans 1998). In his active analytic group therapy, Evans has been concerned with both the impact of stressors on the youngster and their maladaptive (defence-driven) responses.

There is a need to balance overall accessibility with the style best adapted for a particular youngster. A practical consideration is that adolescents tend to lose their impetus for change unless they get a quick response. Thus, an active analytic group therapy can offer a pragmatic and responsive style. Its aims include the following.

- 1 Achievement of age-appropriate tasks:
 - development of a viable adult identity or sense of self;
 - achievement of a level of independence of parents no more and no less than is appropriate for their age and culture;
 - coming to terms with strong sexual feelings; and
 - making optimal and effective use of their increasingly powerful assertive (aggressive) drives.
- 2 Improved object relations through acquiring the resources to abandon immature style of relating to people. This will lead to greater empathy and ability to form trusting relationships.
- 3 Improved coping mechanisms and defences with reduction of anxieties: learning to notice the styles that they use and to encourage the use of more mature styles of managing stress.
- 4 Improving their capacity to tolerate anxieties and frustrations.
- 5 Improved reality testing.
- 6 Removal of fixations: ceasing to use patterns of behaviour that have become age-inappropriate.
- 7 Recovery of repressed memories. In general, this is less important for adolescents but for particular youngsters it can be very helpful.

Kymissis (1997) gave guidance on selection and exclusion criteria for children and adolescents in psychodynamic groups, suggesting that 'strong indications for candidacy include children with separation anxiety, poor self-image and poor social and interpersonal skills or non-assertive and isolated youngsters'. Exclusion criteria may include:

- patients who actively insist on using chemical substances or alcohol are not ready to join the group;
- those who have active psychotic symptoms (delusions, hallucinations) may not be able to develop a cohesive bond with the group;
- patients who are actively suicidal may become a threat and present a difficult issue to deal with in the group setting; and
- violent, aggressive or impulsive patients need to be carefully evaluated for inclusion in the group, and should only be accepted on the condition that they will be able to comply with the group rules.

Young people may sometimes instigate a coherent attack on the group's function. This can prove too exciting to be resisted by the rest of the group. If one child's difficulties are too different from the group norm then the flexibility offered by an individual approach may be preferable for that child.

The techniques used in children's groups include drawing, painting puppets and group games. Adolescent groups may use fewer accessory materials. The group therapist must attend to certain group processes. Failure to do so can easily result in an ineffective group and a poor outcome. The conductor should carry out the following.

- Act to develop good group cohesion recognizing that there are two complementary but separate meaning systems at work: first, one relating to developmental strivings for the children or adolescents in everyday life and, secondly, a therapeutic group culture collaboratively created by the youngsters and the therapist. The latter often is only achieved after much resistance over many sessions.
- Establish a work group that does focus on the difficulties of its members rather than a work-avoidant group. This requires some skill and an attention to diversions, recognizing them as such.
- Be willing to set limits to acceptable behaviour. A permissive style is inappropriate when lacking clear boundaries in children's and adolescent groups.
- Provide a setting in which individual identities can develop.
- Encourage coherence and individuation in the group discussion and activities. Evans (1998) aptly likened this to the complexity of music in harmony and in contrapuntal sections.

Client reports and therapist observations suggest that interpretations of patient behaviour and transference in groups in terms of childhood experiences is less useful and much less appreciated than understandings based on current situations (Corder *et al.* 1981).

Empirical evidence

The number of studies of child and adolescent psychodynamic groups is few. Very few studies have used random assignment in well-controlled studies to compare relationship-based group treatments with 'general child and adolescent services' for referred clinical cases. Those that have (Trowell *et al.* 2000) tended to focus on particular issues, such as child sexual abuse, rather than study the heterogeneous psychodynamic groups that have been run in various clinical settings for some decades. Reviews of psychodynamic and non-directive relationship-based group therapies for children and adolescents include those by Abramowitz (1976) and Henry & Kilmann (1979). Tillitski (1990), in a meta-analysis of individual vs. group therapy, suggested that individual therapy was more effective with children whereas a group approach is more effective for adolescents. Against this should be set the findings of Mulvey *et al.* (1993), who noted in their review that group treatment for adolescents with conduct disorders and delinquency can make matters worse. They suggested that this occurs because of the opportu-

nity for maladaptive group learning. It may be particularly relevant for institutional settings for delinquent adolescents. The finding needs to be treated seriously and is a particular reason for limiting the numbers of such children in relationship-based group therapy.

However, it can be overinterpreted to suggest that such youngsters should not be included in a heterogeneous group. As will be seen from the above account, this is possible with care over group composition and with skill in the management of the group. Further, Kazdin (1994) reviewed the issue of relationship-based groups with some alternative conclusions. He highlighted a study of group therapy with delinquent adolescent girls showing it to be more effective than normal treatment in the institution (Truax *et al.* 1966). Similarly, with delinquent boys, Persons & Pepinsky (1966) and Persons (1966, 1967) showed that delinquent boys randomly assigned to a treatment group involving weekly individual therapy and twice weekly group therapy (in a style that was initially non-directive and accepting but which gradually became more directive during the therapy) showed fewer parole violations over the next year than the control group that received the usual institutional management. The therapy used appeared to be something of a hybrid but also an effort was made to produce anxiety at the prospect of performing any antisocial activity.

Another inpatient group-based study, with younger children, was carried out by Kazdin *et al.* (1987). They were able to produce some improvements in antisocial behaviour, but not as great as those produced in cognitive-behavioural approaches. Abramowitz *et al.* (1974) addressed the issue of directive or non-directive group styles for internalizing and externalizing disorders.

In summary, there is only limited evidence on the effectiveness of group psychodynamic or relationship-based therapies for children and adolescents. This should lead to care and caution in setting up such groups in clinical settings. A clear theoretically informed framework for case selection and mode of running the group that involves clear boundaries and careful processing of interventions by the young people and the group therapist is necessary. A 'here and now' perspective is appropriate rather than a historical one that focuses on early childhood. It is wise, too, for anyone running child or adolescent groups to seek to appreciate the perspectives of the young people in the group.

Social skills groups (and problem-solving skills training)

History

Social skills training for children and adolescents developed during the early 1970s. Early attempts included both the teaching of micro-skills of social interaction (eye contact, smiling, body posture, etc.) (Argyle 1969; Spence & Marzillier 1979) and a focus on the macro-patterns of interactions (Spivack *et al.* 1976; Shure & Spivack 1978). In general, those programmes that focused on larger sequences of interaction seemed to be

more accessible and more useful to children. Accordingly, elements of the micro-interactions have become subsumed into the larger sequence style of social skills programmes.

At the same time as social skills programmes were developing, another strand of work led to the various social problem-solving programmes that currently exist (see Compas *et al.*, Chapter 55). Many programmes now use elements from both social skills training and from social problem-solving.

Rationale
