Child Abuse

Robert E. Emery and Lisa Laumann-Billings

Introduction

In this chapter, we discuss physical child abuse, neglect and psychological abuse, although for the sake of brevity, we frequently use the term 'abuse' to refer collectively to these three subtypes. We also distinguish between *child violence* (abuse that causes serious harm to a child) and *child maltreatment* (abuse that causes little or no serious harm). Child sexual abuse is covered by Glaser (Chapter 21).

Child abuse is a distressingly prevalent problem. The abuse of children has been ignored historically, and instances of abuse continue to be overlooked, minimized or wrongly perceived as minor, both in individual cases and in entire countries. The minimization of child abuse can lead to tragic results for individual children and for groups of children growing up in harmful and hurtful societal circumstances. Thus, the overriding goal of this chapter is to address the most important empirical, clinical and policy concerns in relation to the unacceptably high prevalence of child abuse and its adverse consequences for children. Shockingly, much of the world has yet to accept that child abuse is a widespread problem, and legal policies in many countries and social practices in many cultures continue to tolerate extreme acts of physical injury and/or neglect of children.

We also raise some cautions about the potential for overreaching in research and practice in regard to the emotionally and politically charged topic of child abuse, particularly in the USA. As we have detailed elsewhere (Emery & Laumann-Billings 1998), many estimates of the prevalence or incidence of abuse use broad definitions that include identified cases that depart widely from the everyday connotations of the term 'abuse'. In addition, evidence on aetiology highlights the contributions of life stress to the risk for abuse, while research on the consequences of abuse underscores the importance of considering the influence of third variables, such as troubled parenting. These empirical findings lead us to suggest that, especially in the USA, well-intentioned efforts have come to focus too much on physical abuse *per se*, and not enough on the correlates of abuse, such as social isolation, poverty, parenting problems and family adversity. Finally, and most importantly, we suggest that a balanced perspective on the problem of child abuse can lead to improved intervention. In the USA, law, policy and many treatment efforts have come to focus on policing abusive families to the exclusion of efforts to support these families under stress. Evidence on child abuse leads us to conclude that, whereas some families do require policing, many would benefit from a more

supportive stance in direct intervention and in broader policies, as has been the practice in the UK and much of Western Europe.

Because of problems at the extremes of ignoring abuse, and of overinclusive definitions, we have proposed that abuse should be divided into two levels of seriousness: child maltreatment and child violence (Emery & Laumann-Billings 1998). *Child maltreatment* involves intentional acts or omissions on the part of a caregiver that lead to minimal physical or psychological harm or endangerment of the child, whereas *child violence* involves intentional acts or omissions on the part of a caregiver that result in serious physical injury or profound psychological trauma (Emery & Laumann-Billings 1998). We recognize that numerous problems arise in defining the boundary between these two categories of abuse, and we only briefly address that thorny issue here. Nevertheless, as we review in this chapter, the distinction is supported by epidemiological studies, research on the causes and consequences of child abuse, and by the radically different intervention practices associated with the contrasting philosophies of whether abusive individuals and families should be policed or supported.

Definitions of child abuse

There are no universal legal or scientific definitions of child physical abuse, neglect or psychological abuse (Korbin 1997), but a useful starting point is to consider a general definition of each problem. The legal definition of physical child abuse in our home state of Virginia (USA) is:

A physical injury, threat of injury or creation of a real and significant danger of substantial risk of death, disfigurement or impairment of bodily functions. Such injury or threat of injury, regardless of intent, is inflicted or allowed to be inflicted by non-accidental means.

The state of Virginia actually defines six separate types of child neglect/psychological abuse: physical neglect; medical neglect; failure to thrive; mental abuse/neglect; educational neglect; and bizarre discipline. Physical neglect is defined as 'the failure to provide food, clothing, shelter or supervision for a child to the extent that the child's health or safety is endangered.' The state of Virginia defines mental abuse/neglect as 'a pattern of acts or omissions by the caregiver which result in harm to a child's psychological or emotional health or development.'

These definitions of abuse are typical of law in the USA (which can differ from state to state), and the definitions clearly include

many acts of violence. However, the definitions of physical abuse, neglect and mental abuse also are very broad, and problems of overinclusiveness become apparent when we consider them more closely. A literal interpretation might define spanking as an act of physical abuse, while the existence of a behaviour problem in a child could be interpreted to be sufficient to consider the child as psychologically abused.

Given the very broad nature of such definitions, it is hardly surprising that operational definitions of child abuse for research and practice are the source of much scientific, legal and cultural controversy (Straus & Gelles 1990; Wald 1991; Finkelhor 1995). In the USA, statutory definitions differ from state to state (Wang & Harding 1999), and broad differences in the definition of abuse and neglect are found across the world. For example, in Sweden, Finland and Norway (but not Denmark), the corporal punishment of children by teachers and parents is illegal (Roberts 2000). At the other extreme, China has no government programmes to identify or prevent child abuse, no legal mechanisms for removing children from abusive homes and, in fact, even cases of infanticide can be overlooked under the 'one couple, one child' regime (Littlewood 1997; Fitzgibbon 1998).

Intermediate examples include Japan, where corporal punishment by parents and teachers remains common, and recent governmental efforts to address child abuse have been impeded by a strong tradition of family privacy (Kozu 1999; WuDunn 1999). In 1994, for example, only 1961 cases of abuse were officially reported in Japan, and only one case resulted in the loss of custody rights (Kozu 1999). In England, child abuse is defined similarly as in the USA, but the social service system tends to focus more on the provision of services than on the identification of abuse. For example, home visiting programmes are universal in England but scattered in the USA and, in contrast to the USA, the reporting of suspected cases of abuse is not mandatory in England (although failure to report may lead to disciplinary actions; Berridge 1997).

Such observations make it clear that definitions of child abuse are based on social judgements, not immutable objective standards (Emery 1989). It is also true that definitions of abuse can vary depending upon their purpose. For instance, demographers often employ broad definitions when assessing the prevalence of maltreatment in the general population, whereas child protection workers more typically apply a stringent definition when recommending coercive interventions for abusive parents. Such differences are understandable but, at least for research purposes, there is a need for a consensual *operational* definition of different categories of child abuse in order to facilitate communication and avoid misunderstanding (National Research Council 1993). The importance of such a definition becomes evident in examining evidence on the epidemiology of child abuse.

Epidemiology of child abuse

Child abuse is disturbingly common, even given the most stringent definition: an estimated 1200–1500 children (0.018 per

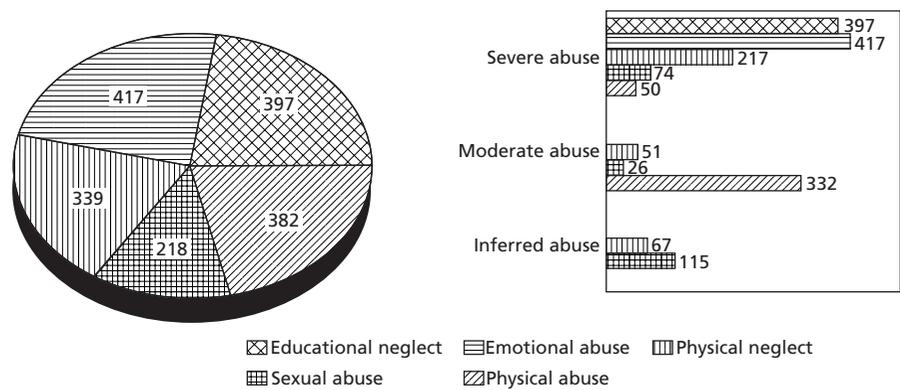

1000 children) are killed in the USA each year by their parent or parent figure (Sedlak & Broadhurst 1996; Wang & Harding 1999). However, extreme instances of child abuse comprise only a minority of identified cases in epidemiological studies. For example, consider the National Incidence Studies (NIS) that are based on official reports of child abuse and surveys of a nationally representative US sample of community professionals who come in contact with maltreated children (e.g. teachers, paediatricians). These studies are widely regarded as among the best estimates of child abuse incidence. The third survey (NIS-3; Sedlak & Broadhurst 1996) estimated that between 1.5 and 2.8 million children (23–42 per 1000) in the USA were abused in 1993. The lower figure is obtained when abuse is defined as acts or omissions that result in demonstrable harm to a child, whereas the higher figure includes all of these children, plus children who were in danger of being harmed according to the views of community professionals and Child Protection Services (CPS) agencies.

The more serious (demonstrable harm) cases in NIS-3 were divided into serious, moderate and inferred categories. Serious injury was defined as 'a life-threatening condition or long-term impairment of physical, mental, or emotional capacities, or requiring professional treatment aimed at preventing such long-term impairment.' Moderate injury was defined as an injury that 'persisted in observable form (including pain or impairment) for at least 48 h (e.g. bruises, depression, or emotional distress not serious enough to require professional treatment).' Inferred harm was defined as 'the nature of the maltreatment itself gave reasonable cause to assume the injury or impairment probably occurred' (Sedlak & Broadhurst 1996, chapter 3, pp. 13–14).

Figure 20.1 illustrates how the NIS-3 estimates break down in terms of the number of cases in different categories of abuse, and the figure also includes a rating of the seriousness of abuse within each category. Consideration of this figure indicates, to the present authors at least, a pattern that seems inconsistent with everyday assumptions about the prevalence of child abuse.

First, consider the general categories of abuse (pie chart). Emotional abuse and educational neglect are the most common forms of abuse, whereas physical abuse comprises about one-quarter of all cases. Regular school attendance is obviously essential to children, but we are dubious about the benefits of terming educational neglect as 'abuse'. Secondly, consider further that only about 15% of cases of physical abuse were designated serious (bar chart). In 85% of the cases, a parent's punishment left the child with an observable bruise, pain or emotional distress that lasted at least 48 h, but professional treatment was not required (Sedlak & Broadhurst 1996). We do not condone, for example, a hard spanking that leaves a temporary mark, but such acts seem to differ from the popular conception of child abuse. In both the academic literature and the popular media, it is common, for example, to cite a statistic indicating a very high prevalence of child abuse followed by a case example of physical abuse involving torture. Such a pairing is misleading, and we believe that distorted popular ideas about

Fig. 20.1 A close look at subtypes of abuse (pie chart) and severity ratings within each type (bar chart) indicates that the category 'child abuse' is a broad one that includes many actions outside of the usual connotations of the term. Data are based on the Third National Incidence Study of Child Abuse and Neglect (Sedlak & Broadhurst 1996), a leading epidemiological study of child abuse in the United States conducted in 1993. Number of cases are presented in 1000s; all cases of educational and emotional abuse were severe by definition.

the severity of the more typical cases of child abuse can handcuff intervention efforts by generating only public wrath and no compassion for maltreating parents under stress (discussed below). We are not arguing that we should only be concerned with the 50 000 (0.74 per 1000 children) cases of severe physical abuse. However, we are arguing that commonly touted prevalence figures are misleading unless abuse is defined with great care.

The same sort of analysis can be applied to official reports of abuse in the USA. For example, the National Center on Child Abuse Prevention Research (NCCAPR) 50 State Survey found approximately 3 million cases (45 per 1000 children) of *reported* child abuse in the USA in 1998, but only one-third (1 009 000 or 15 per 1000 children) were *substantiated*, that is, determined by a case worker to have sufficient probability of abuse (Wang & Harding 1999). Moreover, the majority of the substantiated cases involved neglect (54%), the form of maltreatment most clearly associated with poverty (Pelton 1992). About one-fifth of the substantiated cases were of physical abuse, 10% were primarily sexual abuse, 3% were emotional maltreatment, and 14% did not clearly fall into any of these categories (Wang & Harding 1999).

Variations in reported cases across countries also reflect differences in definitions. Gilbert (1997) compiled child abuse reporting for various Western European and North American countries. Reporting rates ranged from a high of 43 per 1000 children in the USA to a low of 2.9 per 1000 children in Belgium. Rates in the province of Ontario, Germany, England (estimated), and the Netherlands were 21, 15, 13.6, and 4.9 per 1000 children, respectively. Cross-national comparisons are complicated not only by different definitions of abuse, but also by reporting laws (or the absence of reporting laws), the method of data collection and more general cultural factors. Nevertheless, the variations again call attention to the fact that the term 'abuse' is ill-defined, and in the USA at least, applied broadly at the reporting phase.

Reporting differences indicate large variations in definitions of child abuse, but they do not indicate with precision where a line is drawn between abuse and acceptable (if perhaps inadequate or problematic) parenting. One of the clearest sources

of evidence in the USA about specific acts that may be deemed abusive comes from a Gallup poll of a random, representative sample of 1000 families. The poll concluded that approximately 5% of children had been physically abused in the previous year. However, different rates can be computed for different operational definitions because the poll identified very specific acts. For instance, for those who consider spanking to be abusive (Finkelhor & Dziuba-Leatherman 1994), an estimated two-thirds of children in the USA are victims. When violence is defined as hitting with an object other than on the bottom (the definition used in the Gallup poll), the rate drops to 5%. The rate drops to about one-tenth of that level if one were to use a definition of serious physical abuse that included hitting with a fist, kicking hard, or beating up a child (Gallup *et al.* 1995).

Distinguishing levels of abuse

We do not encourage spanking or condone parental acts that hurt a child physically or emotionally. We do suggest, however, that the term 'abuse' connotes serious physical or psychological harm, yet mild to moderate acts account for most cases of abuse in most epidemiological surveys. Furthermore, most parents currently labelled as abusive are under a great deal of stress, and they are not endangering their children's long-term physical health and safety. Such families are more likely to benefit from interventions designed to support them through the challenges of parenting, not from interventions that first label them as abusive. Distinguishing between what we have termed child maltreatment vs. child violence could be an important step on the path to providing supportive interventions to those who might benefit from support, while pursuing forceful coercive interventions in the most serious cases.

In arguing for this distinction, we realize that there is not a 'bright line' between maltreatment and violence and that any specific definitions immediately create controversy. For these reasons, we offer no preferred definitions here. Instead, we note that a handful of states in the USA, including Virginia, Missouri, Florida, Iowa, North Dakota, South Dakota and Kentucky, are experimenting with fundamentally altering their child

protection programmes to allow for multiple responses to child abuse reports, depending on the severity level of the report (Weber 1997). In Virginia's experimental programme, for instance, serious cases undergo traditional CPS investigation, whereas other cases receive a non-adversarial family assessment that ends with referrals to appropriate agencies on a voluntary, not a mandatory, basis. In Virginia, 'serious' cases include: sexual abuse, child fatality, allegations of abuse against a child in the custody of the state or in a child care facility, children hospitalized because of suspected abuse or neglect, non-organic failure to thrive, shaken baby syndrome, multiple or old injuries characteristic of battered child syndrome, Münchhausen by proxy syndrome, and abuse or neglect resulting in disfigurement, fracture, severe burn or laceration, mutilation, maiming, forced ingestion of a dangerous substance, or life-threatening internal injuries. All other cases—the majority of CPS referrals—are offered assessment, and referral to other community agencies for supportive services (Community Partnerships for Protecting Children 1996).

Is family violence increasing?

In 1976, 669 000 cases of child abuse were reported to social service agencies in the USA (Besharov & Laumann 1996) but that number grew steadily to 3 154 000 reports in 1998 (Wang & Harding 1999). Similar increases in reports of child abuse were noted in the UK and other European countries during this time (Hess 1995). Much of the increased reporting was a result of increased recognition of child abuse, and this represents an important social achievement in these countries—one that needs to be repeated elsewhere in the world. In the USA, however, dramatic increases in child abuse reporting have created a new problem as they have solved an old one. Social service agencies are so overwhelmed with investigating reports of abuse, most of which go unsubstantiated, that they are left with few resources to offer supportive interventions (US Advisory Board on Child Abuse and Neglect 1993). In fact, as policing families for abuse has increasingly dominated social service agencies since the 1970s, the philosophy of offering support to families in need has been lost (Besharov & Laumann 1997). Thus, another reason to differentiate maltreatment from violence is the potential to reduce the resources devoted to adversary investigation and redirect efforts into supportive family interventions.

Although increased reporting largely reflects greater public concern with child abuse, there may have been some real increase in child abuse in recent years. The number of cases of moderate child abuse remained stable between 1986 and 1993 in the NIS, but the number of *serious* cases quadrupled from 142 000 to 565 000 (Sedlak & Broadhurst 1996). The number of cases of 'grave concern' also increased in the UK in the late 1980s (Hess 1995). If the increase was solely caused by 'definitional creep' (Besharov 1996), one would expect increases across all levels of severity. Researchers who believe that serious abuse is rising attribute the growing problem to increased use of illegal drugs, greater poverty, increased overall violence and the

disintegration of communities (Garbarino 1995; Lung & Daro 1996; Sedlak & Broadhurst 1996).

Development of child abuse

Many factors contribute to the development of physical abuse, neglect and psychological maltreatment, including individual personality factors, family interaction patterns, poverty and social disorganization, acute stressors, and the cultural context in which the family lives (Bronfenbrenner 1979; Vondra 1990; Belsky 1993; Cicchetti & Toth 1995). Bronfenbrenner's (1979) ecological model often has been used to integrate research on the multiple risks at four levels of analysis:

- 1 individual characteristics;
- 2 the immediate social context;
- 3 the broader ecological context; and
- 4 the societal/cultural context.

We briefly review research on each of these broad topics in the following sections. For the most part, the risk factors we review apply to physical abuse, neglect and psychological abuse, although we occasionally note exceptions.

Individual characteristics

Personality factors, such as low self-esteem, poor impulse control, external locus of control, negative affectivity and heightened response to stress, all increase the likelihood of child abuse (Pianta *et al.* 1989). Alcohol and/or drug dependence also play a part as both a background risk factor for all forms of child abuse and as an immediate precipitant of physical abuse (Kantor & Straus 1990). Although evidence is less consistent, some research has also suggested that child abuse *victims* share some common characteristics, including poor physical or mental health, behavioural deviancies and difficult temperament or personality features (Belsky 1993). The child's age also seems to have a crucial role. Children are at greatest risk for physical abuse and neglect between the ages of 3 months and 3 years, with a second peak in physical and psychological abuse during adolescence (Azar & Wolfe 1998). The increased risk for these age groups may be related to the developmentally related oppositional behaviour that both age groups display. This is supported by findings that physical and psychological abuse is commonly associated with child disciplinary situations that involve aversive child behaviours (e.g. non-compliance, aggressive behaviour, uncontrollable crying; Herrenkohl *et al.* 1983).

Related to this, there is evidence to suggest that child abusers may differ from non-abusers in how they perceive their children, being more prone to cognitive distortions and deficits concerning their children's behaviour. Specifically, studies have found that abusive parents tend to ascribe greater negative intentionality to their children's behaviour than do normal parents, even when the behaviour is within developmental norms (Larrance & Twentyman 1983; Plotkin 1983). Similarly, other studies have found that abusive parents have more unrealistic expectations

of what is developmentally appropriate behaviour in their children (e.g. 3-month-olds can stop crying on demand; Azar *et al.* 1984; Azar & Rohrbeck 1986). Abusive parents also tend to find their child's behaviour more stressful than parents who are not abusive (Frodi & Lamb 1980; Susman *et al.* 1985).

Substance abuse has been found to have a role in both the onset as well as the continuation of both child physical abuse and neglect (Kelleher *et al.* 1994; Harrington *et al.* 1995; Chaffin *et al.* 1996). In her review of the literature, Widom (1992) found alcoholism rates ranging from 18 to 45% in child-maltreating parents, which are much higher than matched controls. Substance abuse has also been shown to be a common outcome of the effects of early maltreatment in adulthood (Duncan *et al.* 1996). The association between alcohol abuse and family violence is complicated, involving the interplay of a number of other variables including personality style, the nature of the relationship, the type of alcohol problem and the degree of family conflict (Widom 1992; Murphy & O'Farrell 1994). An important question for further study is whether heavy alcohol use disinhibits aggression, interacting with personality type to predict violence (Murphy & O'Farrell 1994), or whether aggressive personality-types act violently whether or not they are drinking (Pernanen 1991).

Research also indicates that children who are victims of abuse are at an increased risk for becoming violent themselves as adults (Widom 1989). It is important to note that only a minority of physically abused or neglected children (perhaps one-third) go on to become violent in their own families (Kaufman & Zigler 1987; Widom 1989; Malinosky-Rummel & Hansen 1993). Furthermore, some (or much) of the familiarity of family violence may be accounted for by genetic rather than environmental risk (DiLalla & Gottesman 1991).

Immediate context

Characteristics of the immediate social context, especially the family, have important implications for the aetiology or perpetuation of child abuse (Emery 1989). Studies have examined a host of contributing factors, including family structure and size, acute stressors (e.g. the loss of a job or death in the family) and characteristic styles of resolving conflicts or parenting.

Research on family stress illustrates this area of investigation. In one of the few prospective studies of child abuse, Egeland *et al.* (1981) found that the number of stressful life events distinguished families who were reported for child abuse. However, most stressed families did not abuse their children; thus it was essential to distinguish stressed families who abused from those who did not. Holding life stress constant, abusers were found to be more aggressive, anxious and defensive, and less succorant, than their non-maltreating counterparts. Similar findings were found in later work (Egeland *et al.* 1988). Thus, it seems clear that coping style, as well as stress, contributes to the development of family violence.

High levels of marital conflict and aggression are also associated with child abuse (Straus & Gelles 1990; Cummings 1997).

A recent study found that in 30–60% of families where wife-battering is occurring, physical child abuse also occurred (Edleson 1999). This may be because the escalation of emotional arousal that often accompanies adult conflict carries over to interactions with the child. This is not surprising as marital conflicts most often arise over disagreements over child-rearing, discipline, and each parent's responsibilities in child care (Edleson *et al.* 1991). Children may be caught in the conflict between parents, or they may precipitate parental arguments by misbehaving (Jaffe *et al.* 1990).

Broader ecological context

Physical child abuse, and especially neglect and psychological maltreatment, are related to qualities of the community in which the family is embedded, such as poverty, absence of family services, social isolation and the lack of social cohesion in the community. As Garbarino & Kostelny (1992, p. 463) have noted, child abuse is 'a social as well as a psychological indicator'. The relation between poverty, social isolation and child abuse has now been well established across all categories of abuse (Garbarino 1977; Garbarino & Sherman 1980; Pelton 1981; Polansky *et al.* 1985; Zuravin 1989; Garbarino & Kostelny 1992; Gelles 1992; Pan *et al.* 1994). High levels of unemployment, inadequate housing, daily stresses and community violence also contribute to an increased risk.

Most poor parents do not abuse their children (Garbarino 1977; Bronfenbrenner 1979), so this relation is not simple or direct. Garbarino *et al.* have consistently shown that the principal difference between poor families who do and do not abuse their children lies in the degree of social cohesion and mutual caring found in their communities (Garbarino & Crouter 1978; Garbarino & Kostelny 1992; Coulton *et al.* 1995). For example, neighbourhoods with high concentrations of child abuse or neglect reports tend to suffer from severe social disorganization and lack of community identity. They also have higher rates of juvenile delinquency, drug trafficking and violent crime (Coulton *et al.* 1995).

Social isolation is one of the most commonly noted features of maltreating families (Garbarino & Kostelny 1992). Maltreating parents often lack social connections to others in their extended family, the neighbourhood, the community, and the social agencies most likely to provide needed assistance (Furstenburg 1993; Korbin 1994). Neglectful families are especially prone to isolation and insularity (Wolfe 1999). Some contend that individual personality factors cause this sense of social isolation and that selection factors contribute to these individuals living in more chaotic neighbourhoods (Polansky *et al.* 1985), but others argue that the causal arrow points in the opposite direction (Vondra 1990; Garbarino & Kostelny 1992; Cicchetti & Lynch 1993).

Societal or cultural context

A number of commentators contend that family violence is perpetuated by the broad cultural beliefs and values (e.g. the use of

physical punishment, extremes in family privacy, and violence) in the popular media (Garbarino 1977; Vondra 1990; Finkelhor & Dziuba-Leatherman 1994). As discussed earlier, some of these differences are reflected in the differing cross-national rates of reports of child abuse and in countries' different approaches to intervening in the problem and supporting families under stress. Societal policies may not *cause* family violence, but some practices appear to condone it. Unfortunately, there is little sound empirical evidence on how broad social policies and cultural practices affect the incidence of abuse.

Biological factors

Although they are often overlooked, biological factors clearly contribute to the aetiology of child abuse, both in terms of normative human propensities and individual differences in behaviour (Daly & Wilson 1980, 1988, 1995; Burgess *et al.* 1983; Burgess & Draper 1989; Malkin & Lamb 1994). In regard to normative increases in child abuse, evolutionary psychologists have pointed to the role of biological relatedness as one key risk (or protective) factor. As a dramatic example, Daly & Wilson (1988) reported that step-parents were responsible for a drastically higher rate of homicide of children in comparison to biological parents. Differences in risk were truly astronomical (a 10 000% or even greater increase; Daly & Wilson 1988, see fig. 1, p. 520) for infants and preschool-age children, who in general are at much greater risk of homicide than are older children. Even as we point to the fact that step-parents are over-represented among abusive parents, we also want to underscore that, while step-parenting poses many normative struggles, the majority of step-parents have good relationships with their stepchildren (Booth & Dunn 1994; Hetherington *et al.* 1998).

The evolutionary psychology approach offers an innovative framework for conceptualizing other contributing causes of child abuse (Daly & Wilson 1982, 1985, 1996b; Burgess *et al.* 1983). For example, the evolutionary perspective offers a thought-provoking twist on the well-documented link between poverty and child neglect (Pelton 1981, 1989; Straus & Gelles 1990). When resources are insufficient to meet basic needs, parents may differentially allocate their investment in and resources to their offspring. Evidence supporting this theorizing is inconsistent (Belsky 1993), but it is true that stepchildren, unplanned children, and children in larger families all are at greater risk for child abuse (Daly & Wilson 1988; Zuravin 1989).

Research on aversively stimulated aggression offers strong evidence on another normative biologically based propensity toward aggression. A variety of studies indicate that humans and other animals are prone to respond to a variety of unpleasant stimuli, including stressful family interactions, with aggression (Berkowitz 1983). Like evolutionary psychology, the aversively stimulated aggression perspective offers new conceptualizations for some conditions of child abuse. For example, it helps to explain why physical abuse is more likely in circumstances where child-rearing places added demands on parents,

such as in the care of infants, temperamentally difficult children or children with disabilities.

Finally, it should be noted that biological factors contribute to individual differences as well as normative tendencies in the risk for child abuse. The familiarity (or intergenerational transmission) of child abuse is consistent with biological as well as environmental models of causation, because families obviously share genes as well as environments (DiLalla & Gottesman 1991). Although we know of no behaviour genetic studies of the risk for child abuse, it is likely that at least some intergenerational risk is accounted for by genetic influences on personality (e.g. antisocial characteristics) and/or psychopathology (e.g. substance abuse).

Environmental implications of biological aetiologies

Strong objections have been raised about various aspects of biological theorizing in regard to the development of child abuse. Here, we wish to respond to only one aspect of these objections: that evidence on biological contributions to child abuse is irrelevant to the pressing task of intervention. In fact, just the opposite is true. Evidence on biological contributions suggests important new components to intervention.

Consider two direct implications of the evidence that step-parenting is linked with an increased risk for child abuse. First, step-parents (and biological parents) might benefit from recognizing that the bond with children can be different for step- and biological parents. If some problems are normative, then there is less reason for guilt, disappointment and recrimination in negotiating parenting roles in step-families. In fact, a recognition of normative struggles would seem to be an appropriate starting point for improving step-parenting through education or intervention. Secondly, recognizing the difference in step-parent-child relationships, single biological parents may want to alter their 'marital search strategies' so as to select potential mates based, in part, on qualities reflecting the individual's likely investment in children (e.g. patience, empathy).

An important practical implication stemming from the aversively stimulated aggression perspective is that frustration and anger are normal, not abnormal, parts of parenting. In raising our own children (without physical abuse or corporal punishment), we have come to recognize that the frustrations that sometimes end in physical child abuse are more familiar than foreign. For example, the demands of infants, especially when they cannot be soothed, can be extremely frustrating, particularly under conditions of stress (e.g. no sleep, multiple competing demands). Perhaps normalizing some of these feelings of frustration would prove helpful in preventing abusive acts. More generally, the framework that parents need to learn to recognize emotions and control normative impulses may help to improve intervention and public education. Research and intervention on child abuse have overwhelmingly emphasized the social learning of violence, but the focus needs to be expanded to include learning to inhibit or otherwise express the natural frustrations of parenting.

Multiple pathways: typologies of abusers

As a final point regarding aetiology, it is important to highlight that theorists increasingly recognize the importance of *multiple pathways*, as well as multiple risk factors, in the development of family maltreatment and violence. Early research on the aetiology of child abuse attempted to capture the ‘pathological’ personality of the perpetrator (Steele & Pollock 1968; Melnick & Hurley 1969), whereas later reviewers abandoned the psychopathological model (Parke & Collmer 1975; Emery 1989; Belsky 1993). More recent efforts have sought to identify the different typologies of abusers (so far focusing only on abusive men who batter their wives), some of whom suffer from psychological disorders and many of whom do not (Francis *et al.* 1992; Saunders 1992; Murphy *et al.* 1993, 1994; Gottman *et al.* 1995; Heyman *et al.* 1995; Jacobson *et al.* 1995).

No consistent typology has yet emerged, but the approach is promising and needs to be extended more into the area of child abuse. In their review of the literature, Holtzworth-Munroe & Stuart (1994) identified three primary types of spouse batterers. *Type 1*: generally violent, antisocial. Type 1 batterers tend to be violent across situations and potential victims. They also are more likely to abuse alcohol, be more belligerent and contemptuous, and have antisocial personality traits.

Type 2: family only. Type 2 makes up the majority of spouse abusers, who tend to abuse only in the family, commit less severe acts, be less aggressive in general, suppress angry emotions and feel remorseful. Type 2 abusers often are dependent and jealous and are unlikely to have personality or other disorders.

Type 3: dysphoric, borderline (emotionally volatile) batterers. Type 3 batterers also tend to be violent only within their family. However, they are more socially isolated and socially incompetent than other batterers and often are depressed, feel inadequate and are emotionally volatile. Type 3 abusers are more likely to have schizoid or borderline personalities.

Some initial research supports the value of dividing abusive men into these three categories (Waltz *et al.* 2000). Although this and other typologies are best viewed as tentative and have focused only on the issue of spouse abuse, they do imply that all child abusers—and all acts of abuse—are not the same. Increasing recognition of alternative pathways to child abuse is critically important to future research and intervention, and is broadly consistent with our suggestion of distinguishing child maltreatment and violence.

Consequences of child abuse

Child abuse can cause a wide range of adverse consequences, including serious physical injury, immediate and delayed psychological distress and/or disorder, and a variety of practical upheavals (e.g. placement in foster care). The consequences for children are a function of at least five broad classes of variables:

- 1 the nature of the abusive act, as well as its frequency, intensity and duration;
- 2 individual characteristics of the victim;
- 3 the nature of the relationship between the child and the abuser;
- 4 the response of others to the abuse; and
- 5 factors correlated with abuse which may exacerbate its effects or, in fact, may account for some of the putative consequences of abuse.

The number of variables involved, as well as methodological limitations (Kendall-Tackett *et al.* 1993; Malinosky-Rummell & Hansen 1993; National Research Council 1993), prevent us from reaching unambiguous conclusions about the consequences of child abuse, let alone for differences between physical abuse, neglect and psychological abuse. However, we are able to point to some general patterns concerning physical, emotional and practical outcomes.

Physical harm

Physical harm is a clear consequence of many instances of physical child abuse and neglect, but information on the prevalence of specific physical consequences of child abuse is surprisingly incomplete. As noted earlier, an estimated 1200–1500 children, most of whom are under the age of 5 years, die each year as a result of either physical abuse (52%), neglect (42%), or both (5%) by a parent or parent figure (Wang & Harding 1999). However, official data may somewhat underestimate actual deaths caused by child abuse because of misclassification of causes of death (McClain *et al.* 1993).

Information on non-lethal injuries is much more sketchy. According to NIS-3, nearly 50 000 children were victims of ‘serious’ physical abuse in 1993; that is, they suffered from life-threatening injuries, long-term physical impairment or required professional treatment to prevent long-term physical impairment (Sedlak & Broadhurst 1996). It has also been estimated that over 18 000 children become severely disabled each year as a result of severe physical child abuse (Baladerian 1991). We could not locate epidemiological data on more specific physical outcomes, such as the rate of non-organic failure to thrive (weight loss and psychomotor delays resulting from gross neglect) among infants or specific injuries such as broken bones. Clearly, we need more information on the specific physical consequences of child abuse (see Feldman 1997 for review of identifying signs of physical abuse vs. accidental injury during a physician’s examination).

Münchhausen by proxy syndrome

Münchhausen by proxy syndrome (MBPS) is a unique rare, but potentially very harmful, form of physical child abuse that merits special consideration. In MBPS a parent (98% of whom are female) feigns, exaggerates or induces illness in a child, often resulting in unneeded diagnostic tests, medication trials, hospitalizations and even surgery. In most cases, MBPS involves a

parent and young child. In the more benign cases, the parent simply fabricates the child's illness; in more serious cases, the parent actually induces illness. No prevalence data exist on MBPS, although since it was first diagnosed in the late 1970s, there have been hundreds of case reports. The most common fabrications or modes of symptom inducements in MBPS involve seizures, apnoea, failure to thrive, vomiting and diarrhoea, asthma and allergies, and infections.

A study in England used covert video surveillance to monitor parents bringing their children to the hospital with suspicions of induced illness (Southall *et al.* 1997). The results were alarming. Of the 39 children in the experimental group, video recording in the hospital captured 30 parents attempting to intentionally suffocate, one mother break her child's arm, and another mother attempt to poison her child with disinfectant. Alarmingly, of the 41 siblings of the target children, 12 had previously died suddenly and unexpectedly. After being confronted, four of the parents admitted to having suffocated these siblings. These results clearly illustrate that MBPS can be a severe and ultimately deadly form of child abuse.

Psychological consequences

Physical abuse, neglect and psychological abuse have considerable psychological importance, because these experiences happen as part of ongoing relationships that are expected to be protective and nurturing. Thus, the child is often faced with an emotionally wrenching dilemma: the child wants to be protected from physical and emotional harm but, at the same time, the child also has strong emotional ties to the parent. Another dilemma is that the parent may often oscillate between perpetrating physical violence or emotional abuse at one time and offering the child warmth and attention at other times.

A number of recent books and papers have reviewed the large body of research on the psychological adjustment of abused children (National Research Council 1993; Cicchetti & Toth 1995; Wolfe 1999). We can draw two global conclusions from this broad and sometimes conflicting literature. First, although some have found child neglect to be more psychologically harmful than physical abuse (Erickson & Egeland 1996), victims of child abuse are at an increased risk for a variety of psychological problems. Secondly, there may be a modest relation between the types of abusive acts and specific psychological outcomes; for example, physical abuse and aggression among victims (Widom 1989; Malinosky-Rummell & Hansen 1993). However, the more prominent finding is that child abuse is linked with diverse psychological problems ranging from aggression and anxiety to depression. Evidence on more specific psychological outcomes may be clouded by the need to consider:

- 1 risk factors correlated with family violence;
- 2 clusters of symptoms (e.g. post-traumatic stress disorder, PTSD) in addition to specific symptoms;
- 3 subtle psychological consequences that are difficult to document empirically, particularly among children; and
- 4 psychological processes (not just psychological outcomes)

set into motion or disrupted by the experience of family violence.

Correlated risk factors

Child abuse is associated with a number of factors known to place children at risk for psychological problems: poverty (Pelton 1992); troubled family environments (Egeland 1997); and genetic liability (DiLalla & Gottesman 1991). These risk factors may account for the apparent relation between child abuse and psychological problems, or their effects may interact with the consequences of abuse. Thus, research comparing abused and non-abused children may actually reflect the psychological effects of anxious attachments, social isolation or general family stress rather than the consequences of violence *per se* (National Research Council 1993; Cicchetti & Toth 1995; Egeland 1997). If so, interventions might appropriately focus on these risk factors in addition to, or even instead, of the abuse, particularly in cases where abuse is relatively mild.

Acute and post-traumatic stress disorders

Assessment at the level of psychological disorders, not just psychological symptoms, should also further understanding of the psychological consequences of child abuse. Recent research on PTSD illustrates the promise of such broader assessments. Several investigators have now documented PTSD among between one-quarter and one-half (or more) of child victims of physical abuse (Kiser *et al.* 1991; Famulro *et al.* 1992, 1994; Livingston *et al.* 1993). Moreover, the risk for PTSD increases when physical abuse is more severe and long lasting (Kiser *et al.* 1991). The PTSD diagnosis suggests new possibilities for psychological intervention, especially given recent research on the successful treatment of PTSD (Frueh *et al.* 1995; Rothbaum & Foa 1996; see also Yule, Chapter 32). However, the difficulties involved in diagnosing PTSD in children, as well as the need to develop sound measures of acute stress disorder, pose basic challenges to researchers and clinicians.

Subtle psychological effects on victims

The diagnoses of PTSD and acute stress disorder include symptoms such as re-experiencing and dissociation, and thus offer further impetus for studying some of the more subtle psychological consequences of child abuse (Friedrich *et al.* 1992; Wolfe *et al.* 1989). We also urge more attention to such reactions as guilt and self-blame in response to being a victim of abuse (Wolfe *et al.* 1994).

The vehement controversy over 'recovered memories' of abuse provides another rationale for research on more subtle psychological reactions (Loftus 1994; Koss 1995). A review of the recovered memories controversy is beyond the scope of this chapter, but we do note that there is now widespread agreement that many false memories have been implanted by recovered memory therapists; that there is no way to discern if a memory is

recovered or implanted in the absence of independent corroborative evidence; and that many professional organizations explicitly recommend against the use of techniques to recover memories (Kihlstrom 1998). At the same time, we recognize that one longitudinal study found that documented sexual abuse among girls aged 10 months to 12 years was not reported by nearly 40% of the victims when they were asked about their history as young adults (Williams 1994a). Our present concern is not whether this study documents dissociation or simple forgetting (Loftus 1994; Williams 1994b), but the need to increase our understanding of children's cognitive and emotional processing of abusive experiences over long periods of time.

We similarly are intrigued by the psychological mechanisms that may underlie other long-term outcomes, particularly the intergenerational transmission of abuse. Our main question in the present context is how a propensity toward violence might be carried forward in the child's psyche across the years from childhood to adult life. Because fear is children's most immediate response to abuse, we believe that processes more subtle than direct imitation must account for this continuity (Margolin 1998).

Process of adaptation

Most research focuses on the outcomes of child abuse, but the psychological consequences are best described as a process that unfolds over time. We need more adequate models describing this process. For example, Cicchetti & Toth (1995) have articulated how physical abuse and neglect may disrupt the normal tasks of child development, such as the formation of attachments, affect regulation, the self system and peer relationships.

Practical consequences

Finally, we must underscore the fact that child abuse—and interventions with abusive families—can have tremendously adverse practical consequences for children and families. For example, 254 000 children were placed in foster care in the USA in 1994, most as a result of abuse or neglect (Tatara 1996). Foster care placements are often less than ideal in many ways, but even excellent foster care causes considerable upheaval for children. In focusing on children's psychological concerns, mental health professionals must not overlook the practical consequences of well-intended interventions. When intervening with abusive families, it must be clear that a better alternative can be offered. When mental health or social service professionals can offer better alternatives, we suggest that supportive rather than adversarial intervention should be more effective—except in cases of serious abuse.

Prevention and intervention

In much of the world, the physical abuse, neglect and psychological maltreatment of children continues to be ignored, as it

was until relatively recent times in the USA and Western Europe. As has happened in the West over the last several decades, the task in preventing and intervening with child abuse in countries such as China must begin with public recognition of the problem, making acts of child abuse illegal, and offering publicly supported interventions that break some traditions of family privacy and autonomy in order to protect children. Obviously, these are difficult but extremely important goals, particularly because non-Western countries encompass the great majority of the world's population. Nevertheless, in drawing some implications for prevention and practice, we focus not on the need for increased recognition of the problem of child abuse in most of the world, but on the need for a moderation of the extreme adversarial legalistic approaches that have developed in some Western countries, particularly the USA.

In the West, attempts to prevent or stop child abuse, or treat victims or perpetrators, involve a huge array of interventions involving mental health, social service and legal professionals, as well as other professionals who have regular contact with children and families (e.g. teachers, family physicians). Unfortunately, the creation and implementation of new interventions has far outstripped research on their effectiveness, as previous reviewers have noted (National Research Council 1993; Becker *et al.* 1995; Melton *et al.* 1995; Wolfe *et al.* 1995). Especially in the USA, the child protection system has come to be dominated by identifying, reporting and investigating abuse with the expectation that something can and will be done to help children. Unfortunately, research does not point clearly to interventions that work, and the ever-growing investigative approach to child abuse has consumed so many resources that little is left for attempts to help abused children and families under stress.

Thus, while increased recognition of child abuse is the task for most of the world, it seems time for moderation in the USA. Specifically, we offer three recommendations, all of which relate to distinguishing levels of abuse and, more generally, to moderating the legalistic approach.

- 1** We urge clarification and revision of child abuse reporting laws.
- 2** We encourage the rediscovery of the helping model of social services for less serious cases of abuse and for families under stress.
- 3** We advocate for more forceful legal intervention in cases of serious family violence.

At the outset, we should note that the first two goals would bring policy in the USA closer to that of the UK, where reporting is not mandatory but is encouraged by the possibility of professional sanctions, and where, despite some problems with overreporting, the goal of supporting families under stress has remained in the provision of social services (Duquette 1992; Berridge 1997).

Child abuse reporting

By all accounts, child protective services in the USA are driven by—and overwhelmed with—the investigation of child abuse reports (Kamerman & Kahn 1990). As we have noted, over

three million reports are made every year in the USA, but less than one-third are substantiated. Moreover, social service workers are so swamped with reports and investigations that about 40% of *substantiated* cases receive no services at all (McCurdy & Daro 1993). Finally, only a small proportion of substantiated cases (<20%) involve any type of formal court action, with child protective workers encouraging the great majority of substantiated cases to enter treatment voluntarily (Melton *et al.* 1995).

Mental health professionals are in a rather ironic position in regard to reporting child abuse. Most cases involve only suspected or mild abuse, families are stressed and parents have indicated at least some interest in receiving help by virtue of their contact with the mental health professional. Yet, under existing law, mental health professionals are required to report these cases, while knowing that the likely outcomes are failure to substantiate, no provision of services, no legal action and, eventually, encouraging the family to seek treatment—exactly where they began the long expensive and intrusive process. Not surprisingly, mental health professionals commonly report that they have little faith in the reporting system and believe that it undermines therapeutic relationships (Zellman 1990; Levine *et al.* 1991). Indeed, one prominent group of commentators termed the resultant failure to report cases among American mental health professionals an action of ‘civil disobedience’ (Melton *et al.* 1995, p. 52).

Given this circuitous chain of events, a simple but not necessarily minor change, in the USA and other countries with similar requirements, would be to alter reporting requirements for mental health professionals in order to reduce investigations and improve services. Specifically, we would exempt mental health professionals from reporting less serious cases of abuse, whether known or suspected, when a family is actively engaged in treatment. We do not attempt to define these cases here, but we do note the need to define less serious cases (what we have called maltreatment) clearly in the law, as has been done in some experimental programmes. Such a change would be a first step toward the broader goal of refocusing the child protection system to supporting rather than policing more families under stress, while simultaneously pursuing more vigorous coercive intervention with cases of serious family violence.

Supportive interventions

A number of supportive interventions have been developed in an attempt to reduce child abuse, including individual and group therapies for both victims and perpetrators, parent-training and family therapy, and home visiting programmes for the prevention of child abuse. In general, the more serious and chronic the nature of the abuse, the less successful these programmes are in changing behaviours (Cohn & Daro 1987; Barth 1991; National Research Council 1993; Guterman 1999). However, with problems of mild to moderate abuse, multilevel programmes, which combine behavioural methods, stress manage-

ment, and parent–child relationship skills, lower stress in families and may reduce the likelihood of continued aggression in child abuse cases (Lutzker & Rice 1984; National Research Council 1993; Murphy 1994).

Until 30 years ago, treatment for maltreating families focused on intrapsychic approaches, guided by the belief that maltreating parents had deviant personalities that needed to be changed (Steele & Pollock 1968). It is now clear that only a small minority of abusive parents are significantly psychiatrically disturbed and, furthermore, that these approaches to treatment are too narrow and ineffective (Azar & Wolfe 1998). Behavioural approaches that focus on parent–child interaction patterns and take into account the family’s larger ecological context (e.g. nature of family life, environmental stressors affecting family, other parental problems and sociodemographic factors) have proven to be the most promising alternative (Wolfe & Wekerle 1994; Schellenbach 1998). Additionally, behavioural approaches tend to be less threatening to child abuse perpetrators, as they are more concrete and problem-focused.

Comprehensive family assessment is crucial in working with maltreating families, as this is a heterogeneous population and many of these families have additional issues that need to be addressed concomitantly (e.g. parental substance abuse, marital problems) for successful treatment outcomes. In assessing maltreating families, Azar & Wolfe (1998) suggested that clinicians need to consider at least four areas, in order of importance:

- 1 determination of danger to the child;
- 2 identification of general strengths and problem areas of the family system;
- 3 identification of specific parental needs vis-à-vis child-rearing demands; and
- 4 identification of child needs.

A number of behavioural strategies have been used with abusive parents, either alone or in combination. Such strategies include:

- 1 modelling and behavioural rehearsal, in which parents practice more appropriate responses to children’s aversive behaviour;
- 2 cognitive restructuring of distorted interpretations of child behaviour;
- 3 anger control management and relaxation training; and
- 4 skills-training which teaches parents contingency management principles (Azar & Wolfe 1998).

Some studies have found support for combining group parenting sessions with home visitation to promote generalization of new behaviours to the home environment (Azar *et al.* 1984). Treatment services that focus on maltreated children are much less common than parent-orientated interventions. Part of the reason is the age of the child, with the majority being preschool-age or younger. Another part is that parental behaviour is often the primary concern. Nevertheless, recent efforts have been made to address maltreated children’s developmental needs and reduce long-term impairments (Jones 1997; Kempe 1997). For

example, improvements in social behaviour and cognitive development were found in one preschool-aged programme which matched maltreated children who tended to be withdrawn with resilient peers (Davis & Fantuzzo 1989; Fantuzzo *et al.* 1996). Therapeutic preschools also show promising results (Kempe 1997). With older children, non-compliance and aggression is often addressed through parent training.

It is important for clinicians working with maltreating parents to recognize some of the characteristics of these families that may impede treatment. First, many maltreating families live very chaotic lives, affecting treatment in several ways, including missing appointments and failing to comply with treatment. Secondly, abusive parents typically do not identify themselves as having a problem, thus making the establishment of a therapeutic relationship especially challenging. Specific factors that lower the likelihood of successful treatment outcomes include:

- 1 parental personality disorder;
- 2 substance abuse;
- 3 lack of empathy for the child;
- 4 disordered attachment;
- 5 severe abuse/neglect;
- 6 Münchausen by proxy syndrome;
- 7 premeditated abuse;
- 8 child with developmental delay and/or special needs;
- 9 family with pervasive diverse family violence; and
- 10 extreme social isolation (Jones 1997).

Project 12-Ways, an intervention programme for maltreating families that has been operating in rural Illinois since 1979, addresses many of the above principles and has been shown to lower recidivism rates in families reported for child abuse and neglect (Lutzker & Rice 1984; Lutzker *et al.* 1998). With most of the services delivered in the home, this programme conducts a comprehensive family assessment and then provides a multitude of supportive services based on each family's needs. The services include: parent-child training; stress reduction; basic skills training for children; money management training; social support; home safety training; multiple setting behaviour management; health and nutrition; marital counseling; problem-solving; alcohol/substance abuse referral; and single mother services.

Some interventions show promise, but the need for early intervention and especially prevention is underscored by the difficulty of changing child abuse and the stressful life circumstances that promote it (Garbarino & Kostelny 1992; Pelton 1992). Home visitor programmes for new parents living in difficult circumstances are one especially promising form of prevention. Home visitor programmes simultaneously assist with material needs (e.g. cribs, child care, transportation), psychological needs (e.g. parenting education and support), and educational needs (e.g. job skills), and may both improve general family well-being and reduce child maltreatment (MacMillan *et al.* 1994). One controversy about home visitor programmes is whether they should be universal or targeted to families at greater psychosocial risk. Although the targeted

strategy is more economical, greater reductions in abuse have been found for the universal programme, perhaps because targeted families are less likely to benefit from home visiting (Guterman 1999).

An outstanding example of home visiting is the Prenatal and Infancy Home Visitors' Program which targeted low-income teen and single-parent mothers who were pregnant with their first child. Based on evaluations conducted during the programme (Olds, Henderson, Chamberlin, Tatelbaum 1986), 1–2 years following termination (Olds *et al.* 1994, 1995) and 15 years later (Olds *et al.* 1999), home visited mothers had fewer and less serious CPS reports, fewer subsequent births, spent fewer months on welfare, had fewer arrests and were less likely to abuse substances in comparison to control families. In large part due to such benefits, in 1992 the National Committee to Prevent Child Abuse launched a national initiative of home visitor programmes, Healthy Families America, in over 300 communities. Some programme evaluations completed to date suggest that Healthy Families America may be reducing reports of abuse and neglect. However, three randomized trials have failed to find differences between Healthy Families America participants and controls, although the null findings may be a result of relatively small samples and low statistical power (Daro & Harding 1999).

Coercive intervention

Although this has not been the main focus of this chapter, we should note that distinguishing between levels of abuse may also help to improve intervention in cases of serious and extreme child abuse. One benefit would be to free investigators and police to focus on the most serious cases. Shockingly, between 35 and 50% of all fatalities brought about by child abuse/neglect in the USA occur in cases already brought to the attention of law enforcement and child protection agencies (Wang & Harding 1999). Another benefit might be to help to clarify when coercive legal intervention is and is not appropriate. For example, many commentators have questioned the overriding goal of family reunification following child abuse, especially in cases of serious physical and sexual abuse. In extreme cases like these, the termination of parental rights and early adoption may be the appropriate intervention, especially given the many problems with the overwhelmed foster case system (Tatara 1996).

Distinguishing between levels of abuse should help to resolve controversy and thereby clarify the appropriate use of coercive legal intervention. The idea of termination of parental rights is far more threatening when our definitions of abuse include relatively minor acts, as they currently do. Clearly, it is difficult to draw a line between cases that should or should not lead to termination of parental rights (Azar *et al.* 1995), but the challenge of distinguishing between levels of abuse should not deter us from the task. What we have called maltreatment may be on a continuum with what we have termed violence, and both acts of abuse may differ from normal family aggression only by a

matter of degree. However, drawing distinctions between levels of abuse seems consistent with the state of our knowledge about the prevalence of abuse, its development, consequences and appropriate intervention.

Levels of abuse, present clinical practice and future research

As a final note, we highlight that our focus on distinguishing levels of abuse holds implications for present clinical practice and future research. Child abuse can be horrific but, in many cases, clinicians can understand and even empathize with the behaviour of parents who, to a mild or moderate degree, physically hurt, neglect or psychologically maltreat their children. Such families are more likely to benefit from a supportive rather than an adversarial stance in the clinical setting, in the provision of social services and in legal interventions. Child abuse should never be tolerated, but mildly or moderately abusive parents may benefit from disclosure, discussion, education and practical support with their children and with managing their own work and family lives.

In cases of serious abuse, clinical treatment of perpetrators may simply be inappropriate. Although parents who seriously abuse their children may have mental health treatment needs, family reunification seems to be an inappropriate and unattainable goal, at least in the more extreme cases. Distinguishing levels of abuse, accompanied by better triage of cases, should allow mental health and social services to concentrate resources and efforts on those cases most appropriate for supportive intervention, while the legal system focuses on those cases most appropriate for policing, termination of parental rights and prosecution.

Future research could help practitioners by working to develop a better typology of child abuse and of abusive parents. We recognize that the distinction that we argue for here is only a very crude initial grouping. We look forward to the development of far more refined categories of abuse.

Introduction

Sexual abuse is a physical act but its deleterious consequences are primarily psychological. It is a significant risk factor for the development of psychopathology in childhood, adolescence and adulthood. Familiarity with the phenomenon (including its presentation and treatment) is therefore of particular importance to the practice of child and adolescent psychiatry.

The hallmarks of child sexual abuse are its secret nature and the very frequent denial of the abuse by the abuser, once it is alleged to have happened. These two factors play a central part in the process of the abuse and in its aftermath. Sexual abuse includes a far wider spectrum than incest, occurs both within the family and outside it but, in either circumstance, the abuser is frequently already known to the child. Indeed, this acquaintance may be based on a deliberate befriending or ‘grooming’ of the child by the abuser for the purposes of preplanned abuse. Because it involves sexuality, this form of abuse is particularly emotive.

Child sexual abuse is not a new phenomenon. The incest taboo has been in existence for over 4000 years, first records being in the Babylonian code of Hammurabi (≈ 2150 BC) which referred to ‘a man be known to his daughter’ (Handcock 1932) where ‘known’ has been translated as ‘to conceive a child’ (ten Bensele *et al.* 1997). The laws of Moses (*c.* 3000BC) describe incest as a sin (Leviticus 18:6). General Booth, founder of the Salvation Army, wrote in 1890: ‘I understand that the Society for the Protection of Children prosecuted last year a fabulous number of fathers for unnatural sins with their children’ (Booth 1890). Despite sporadic earlier pronouncements, child sexual abuse only began to be noted as a significant form of child abuse in the 1970s. Increasing recognition came with the development of the women’s movement, reports by adult women survivors of their childhood abuse and a greater openness regarding sexuality. This pattern of increasing recognition has swept through successive countries, with reports appearing in the scientific press, in particular in *Child Abuse and Neglect, the International Journal* (Sariola & Uutela 1996; Luo 1998; Rhind *et al.* 1999).

The universal disapproval of child sexual abuse is exemplified in the UN Convention on the Rights of the Child. Nationally, this disapproval is expressed by the legal prohibition of incest and sexual contact between an adult and a child, and its inclusion as various offences under criminal law. However, some of the harmful effects of child sexual abuse, such as the denial of the abuse by the abuser, and guilt and self-blame by the victim, are

largely consequent on this expressed disapproval by society. Moreover, the fact that child sexual abuse is a relatively common experience for children and young persons implies a lack of protection and care for these vulnerable members of society. Despite the now repeated findings of very high reported rates of child sexual abuse (see below), most suspicions of sexual abuse continue to be met with caution, and disclosures are often regarded with suspicion. The fact that an apparently common phenomenon is so often doubted or disbelieved is probably explained by the social taboo surrounding adult sexual contact with children and by at least two further factors. First, the absence of non-involved witnesses to this (secret) activity helps to support the frequent denial of the abuse by the alleged abuser. Secondly, the potentially serious consequences for the alleged abuser if found guilty, govern the attitude to investigation. Alongside the high rate of reports of sexual abuse of children and adolescents, the rates of prosecution and conviction are low. In an English sample of 188 cases of contact abuse, the rate of prosecution was 36% with 17% convictions. A further 5% received a caution (Prior *et al.* 1997). Two independent studies from the USA found that less than one in five cases of alleged abuse reached the stage of prosecution (Tjaden & Thoennes 1992; Martone *et al.* 1996). The stringent test of the evidence in criminal law, ‘beyond reasonable doubt’, which is higher than ‘on balance of probabilities’ required in civil law, may help to explain this low rate. Many children who have been abused find difficulty in comprehending the lack of more frequent criminal convictions, especially when they have been prepared to testify in court.

Definitions

The most influential and time-honoured definition of child sexual abuse is by Schechter & Roberge (1976): ‘Sexual abuse is defined as the involvement of dependent, developmentally immature children and adolescents in sexual activities they do not truly comprehend, to which they are unable to give informed consent, or that violate the social taboos of family roles.’ Inherent, although not specifically stated in this definition, is the notion of coercion or a power differential between the abuser and the child. It is also important to note that the abuser’s intentions or motivations are not considered necessary to be included in many definitions. Despite the wide applicability of this definition, a myriad of definitions for legal, research and other purposes continue to be developed and used.

Cultural practices

The above definition refers to social norms. In our multicultural societies, the question of what is a culture-specific practice needs to be considered. This is particularly relevant where ethnic minority groups are living in a majority host culture whose norms differ. Cultural practices are expected to alter with time and context, and the dominant culture tends to set prevailing child-rearing standards (Korbin 1997). However, Ahn & Gilbert (1992), for example, found that among Koreans living in the USA, a grandfather touching the genitalia of his preschool-age grandson was seen as an expression of pride in the fact that this child would continue the family line. Cultural practices may not be benign and culturally sanctioned normative practices may affect adversely the well-being of children (McKee 1984). A particular case is the issue of female genital mutilation (Davis 1998; Eke & Nkanginieme 1999). There is also individual deviation in child care and other practices within cultures (Korbin 1981). Whereas it is important to avoid misidentifying culture as abuse and vice versa (Abney & Gunn 1993), this can be quite difficult in practice. An admittedly small sample (33) of Filipino, Asian and Pacific Island persons working in human services in the USA showed a divergence of opinion about the acceptability, for example, of fathers checking a girl's vaginal area for medical reasons; and for family members to kiss and fondle a baby boy's genitals as an expression of joy about his gender (Okamura *et al.* 1995).

Legal considerations

Under English civil law, child sexual abuse is recognized in the Children Act (1989) as a form of Significant Harm. For child protection purposes, a working definition employed in England is that:

‘Sexual abuse involves forcing or enticing a child or young person to take part in sexual activities, whether or not the child is aware of what is happening. The activities may involve physical contact, including penetrative . . . or non-penetrative acts . . .’ and ‘non-contact activities, such as involving children in looking at, or in the production of, pornographic material or watching sexual activities, or encouraging children to behave in sexually inappropriate ways.’ (Department of Health *et al.* 1999)

In criminal law, child sexual abuse is subsumed under a number of different offences. These include incest, which applies to vaginal intercourse between a male and a female whom the offender knows to be his (legal) daughter, granddaughter, sister or mother. Incest is thus not necessarily child sexual abuse. Other offences include indecent exposure, sexual assault, indecent assault, gross indecency, buggery, unlawful sexual intercourse (where one of participants is under 16 years) and rape. Rape requires proof of lack of consent.

In some jurisdictions, such as in England and the USA, civil and criminal proceedings can continue in parallel and independently of each other. This means that, in theory although

not always in practice, a child may be protected from an abuser by being moved from his care under civil law, when there has been no criminal trial and potentially even if a criminal trial failed to convict the alleged abuser. In other jurisdictions, child protective procedures will only be undertaken following the criminal conviction of the abuser. This confers considerably less protection on children, especially as the rate of convictions worldwide is relatively low compared with the number of allegations.

Epidemiology

From the perspective of mental health care planning, sufficient provision needs to be made for the treatment of the consequences of a common problem. Planning and resource issues also affect other related agencies, including social services, the police and the courts. However, the published figures for incidence and prevalence of child sexual abuse vary considerably according to the definition used, the source of data and the population studied (Finkelhor 1994). Whereas broad definitions point to the extent of the problem, they are less helpful in indicating severity and the kind of therapeutic services required.

Although annual reports of child sexual abuse could, in theory, indicate incidence, such figures are inaccurate underestimates. Many occurrences of child sexual abuse are not reported at the time of the abuse (Finkelhor *et al.* 1990) and some are not reported at all. Rates of reporting have increased over the past 30 years, both in the UK (Markowe 1988) and in the USA (Finkelhor 1991). More recently, the number of reports of child sexual abuse has decreased (Jones *et al.* 2001). Despite these reported variations, there is little evidence to suggest that the actual incidence has changed significantly (Feldman *et al.* 1991).

The most accurate prevalence figures are from population studies. Even here, responses to interviews or questionnaires may be underestimates, because there may be reluctance or a feeling of shame in describing previous abuse. For instance, Williams (1994) found that 38% of 129 women aged 18–31 years who were interviewed by her, did not mention their previous sexual abuse, which had been documented some 17 years earlier. Whether this represented lack of recall in every case, or some reluctance to talk is still debated. It has been suggested that interviews, which tend to yield higher rates of reported abuse, may be more specific in their questions and more likely to prompt recall of abuse (Wyatt & Peters 1986).

Prevalence of child sexual abuse

Nature of the abuse

Within the spectrum of sexual abuse, the first distinction that needs to be made is between non-contact and contact abuse (Peters *et al.* 1986).

Non-contact abuse

This includes deliberate exposure of children to adult genitalia or sexual activity, either live or depicted in photographs or film. It also includes intrusive looking at the young person's body, inducing children to interact sexually with each other and the taking of photographs for pornographic purposes. There has been debate about the point at which the threshold for Significant Harm or actual abuse is reached when the concerns are about non-contact sexual interaction. When considering the question of harm, it is important to ascertain whether the interaction was deliberate and the extent of coercion used, with greater coercion increasing the harm. Although the most serious effects of sexual abuse are associated with contact, and especially penetrative abuse, many young persons report the experience of being intrusively observed as humiliating and intimidating.

Population studies of adults that have included contact and non-contact abuse by age 18 have yielded rates of between 54% (Russell 1983) and 62% (Wyatt 1985) for women in the USA. In an English interview study of both men and women aged over 15, Baker & Duncan (1985) found 10% positive responses for experiences before the age of 16, whereas Kelly *et al.* (1991) found rates of 43% for women and 18% for men for at least one unwanted/abusive experience before the age of 16.

Contact abuse

Broadly, in Western societies including specifically the UK and the USA, any physical contact between the breasts and genitalia of a child or adult and a part of the other's body, with the exception of isolated accidental touch (e.g. in the bath or in bed), and for developmentally and age-appropriate cleaning or for applying medication or ointment, is considered to be sexual abuse. Abusive contact includes fondling, masturbation, oral-genital contact or penetration, attempted or actual digital and penile penetration, and the insertion of objects into the vagina or anus. Active abuse is often preceded by an insidious process of 'grooming' in which the abuser, having identified a particular child or children, finds ways of befriending the child or increasing the opportunities for being with the child unobserved. Given the addictive nature of much child sexual abuse, it is in the abuser's interest to be able to continue to abuse a child. There is therefore typically a gradual progression from touching to more penetrative abuse (Berliner & Conte 1990), so as to avoid causing initial pain or injury which would be more likely to lead the child to complain about or report the abuse. Anal abuse is understandably more common in boys, although younger girls are not infrequently anally abused (Hobbs & Wynne 1989). In a small proportion of cases, actual physical violence is used, either as a way of intimidating or coercing the child, or as an integral aspect of the abuse (30% in the study reported by Gomes-Schwartz *et al.* 1990).

In population studies of women, as opposed to victim samples, non-penetrative contact abuse is the form most commonly described (Haugaard & Reppucci 1988). Russell (1983), in her

urban community study of 930 women found that 38% had suffered contact abuse under the age of 18 years, and very serious sexual abuse (forced vaginal or anal intercourse and oral-genital abuse) in 27% of intrafamilial cases. In a British study of female and male students (Kelly *et al.* 1991), 27 and 11% of respondents, respectively, reported contact abuse. Four per cent of female, and 2% of male respondents, respectively, reported serious, penetrative or coercive abuse, with an age difference between abuser and victim of more than 5 years. Finkelhor (1979), in his questionnaire study of 796 college students, found that 4% had experienced abuse with full intercourse. By contrast, the rate for these serious forms of abuse in clinical samples rises to over 65% (Cupoli & Sewell 1988; Gomes-Schwartz *et al.* 1990).

Frequency and duration

Whereas population studies have shown a majority for whom sexual abuse is a single episode, in clinical samples the majority of children have been abused more than once by the same abuser. It appears that single episodes of abuse are less likely to be reported and subsequently referred to helping agencies. There is evidence that a child who has been sexually abused is vulnerable to further abuse by others: 14% in the Baker & Duncan (1985) study. This is likely to be a result of a combination of the original vulnerability of the child and the added vulnerability conferred by the experience of having been abused. A distinction needs to be made between repeat victimization by the same abuser and revictimization by different abusers (Hamilton & Browne 1999). Children subjected to organized abuse are often multiply abused. Repeated abuse often continues for several years (Gomes-Schwartz *et al.* 1990). Duration, frequency and severity, including penetration, are thus linked factors.

Age of victims

Children may be abused from infancy onwards. Children who experience intercourse tend to be older, with an average age of 11.4 years in the Gomes-Schwartz *et al.* (1990) study, compared with 9.1 years for other forms of significant contact abuse.

Gender of victims

Girl victims are about four times as common as boy victims (Adams-Tucker 1984; Badgley *et al.* 1984). There is a tendency for sexual abuse of boys to be underreported, in part because of shame and the fear of homosexuality. Adolescent boys are increasingly reluctant to talk about their abuse, even in therapy (Nasjleti 1980). This may explain some reports that boys are abused at a younger mean age than girls (Singer 1989). Younger boys are not infrequently abused alongside their sisters rather than in isolation (Vander Mey 1988). Extrafamilial abuse more commonly involves boys although there is no agreement about whether boys are more commonly abused by strangers (Watkins & Bentovim 1992).

Disability

National statistics on child abuse do not contain data on abused children's disabilities (Kelly 1992). However, in studies of children with disabilities the rate of sexual abuse is two or three times that in 'normal' children (Crosse *et al.* 1993; Sullivan & Knutson 2000). The reasons for this greater prevalence include: the children's difficulties in communicating abuse (Morris 1999); their dependency on intimate physical care; social isolation in institutional care (Utting *et al.* 1997); and care by staff rather than parents (Westcott & Jones 1999).

Abusers

The majority of abusers (85–95%) are male. Whereas male abusers who abuse prepubertal children may well target both boys and girls, there is some gender specificity in relation to adolescent girl victims. By the time a sexual abuser is identified, his pattern of abusing has often been well established. A small proportion of child sexual abuse is carried out by female abusers (Saradjian 1996), often in conjunction with a man. Women abusers on their own are more likely to abuse boys (Faller 1989).

Sexual abuse by adolescents, mostly boys, has become widely recognized (Abel *et al.* 1987) and is no longer considered an acceptable variant of adolescent sexual development. Many adult abusers report the onset of their abusive activities in adolescence and abuse by an adolescent cannot be considered safely to 'burn out' in adulthood (Vizard *et al.* 1995). A significant proportion of adolescent abusers are of low intellectual ability. Age is no bar to sexually abusive interactions and older men may well continue to abuse children.

There has been much debate about a possible psychological profile of abusers or about a commonality of childhood experiences that might have led them to abuse children. Whereas many will have experienced disruption and physical abuse in their formative years (Seghorn *et al.* 1987), their own sexual abuse is one predisposing, but not a prerequisite, factor for sexually abusing children (summarized in Watkins & Bentovim 1992). A study sought differences between the previous experiences of four comparison samples, each consisting of 15 boys aged 11–15 years who had, respectively,

- 1 been sexually abused;
- 2 abused other children;
- 3 been abused as well as abused other children; and
- 4 suffered from a conduct disorder (Skuse *et al.* 1998).

Factors predating the sexually abusive activity by the boys included discontinuity of care, exposure to or experience of physical violence and emotional abuse. Such findings help to explain why, in practice, sexual abusers constitute a heterogeneous group in terms of personal, social and demographic factors.

Abuser–child relationship

The majority of children knew their abuser before commencement of the abuse. This acquaintance may have been deliber-

ately fostered by the abuser as part of a grooming process, or the abuser and child may be part of the same family or social network. In community studies, the most common relationship is stepfather–stepdaughter (Finkelhor 1984). The same abuser may abuse children both within and outside the family, and include biological as well as stepchildren. Risk to other children in the family and in contact with the abuser is therefore difficult to predict and an assumption must be made that the proven capacity to actually abuse children renders all children in contact with that abuser at risk.

Organized abuse

Many abusers abuse in isolation. However, there are also organized forms of abuse involving more than one abuser and multiple children, some of whom are recruited in sex rings (Wild & Wynne 1986). Organized abuse may include formalized rituals (Frude 1996); debate continues about the extent to which sexual abuse is a part of sadistic or satanic practices. There are, in these cases, questions about the reliability, verifiability and credibility of the reports (Young *et al.* 1991). Organized abuse also includes the use of children and young persons for prostitution, and for the production of child pornography. Children in residential settings in particular may be subject to sexual abuse. These children, who are already vulnerable, are dependent on staff and often isolated from confiding contact with adults outside the residential setting (Utting *et al.* 1997).

Ethnicity, culture and socioeconomic status

Both in the UK and the USA, population-based studies have shown no ethnic differences in the rates of child sexual abuse (Korbin 1997). In the UK, Kelly *et al.* (1991) found no differences between white and black respondents. In the USA, studies have included African-American college students (Priest 1992); Latino, Asian, African-American and European-American women in Russell's (1986) study in San Francisco; and Wyatt's (1985) study which specifically sought equal representation of African- and European-American women respondents. Child sexual abuse has also been described in Filipino, Pacific Island, Cambodian and Asian communities living in the USA by Okamura *et al.* (1995), Rao *et al.* (1992) and Scully *et al.* (1995). However, data on the incidence of child sexual abuse in these communities are lacking, partly because of decisions on data collection criteria which do not classify racial/ethnic background sufficiently finely, and partly because shame and denial about sexual abuse within some cultures conspire against reporting (Okamura *et al.* 1995), particularly when the group has a minority status within a larger host culture. Accurate data on incidence within a particular ethnic group may reflect effects of that group's recent traumatic migration and experiences, rather than aspects of the particular culture, as exemplified by Cambodians living in the USA (Scully *et al.* 1995). Lastly, some societies continue to find difficulty in facilitating open acknowledgement of the existence of child abuse in general,

and sexual abuse in particular, within their countries (personal information).

Socioeconomic status is unrelated to the incidence of child sexual abuse in population studies (Berliner & Elliott 1996) but there is an overrepresentation of lower socioeconomic groups in clinic samples (Bentovim *et al.* 1987; Haugaard & Reppucci 1988). This may be because these groups are more likely to come to the attention of child protective agencies than middle class families who may find ways of hiding the abuse or avoiding its reporting (Gomes-Schwartz *et al.* 1990). Different forms of child abuse and neglect are not infrequently found in the same family and the same child (Mullen *et al.* 1994; Ney *et al.* 1994), especially among the socially disadvantaged. Child sexual abuse is associated with troubled family life including family disruption (Russell 1986), reconstituted families, intra-familial violence (Bifulco *et al.* 1991) and parents who are perceived as emotionally distant and uncaring (Alexander & Lupfer 1987).

Theories of risk and causation, and maintaining factors for child sexual abuse

There is no unitary theory of causation to explain child sexual abuse (Glaser & Frosh 1993). In 1896, Freud in his essay entitled 'The Aetiology of Hysteria' postulated that hysterical symptoms found in his patients were attributable to actual sexual experiences in early childhood. Later he changed his views and suggested instead that his patients' difficulties were based not on actual abuse but, rather, on incestuous fantasies or wishes for sexual contact and on young children's seductive capacities. The possible reasons for this change, which was to have a major influence on some later theories of child development, are discussed by Masson (1984). They include the consequent social isolation and pressure that Freud experienced, and the fact that by attributing experiential origins to his patients' difficulties, he was rejecting the prevalent explanations of mental illness in terms of heredity.

The current understanding of sexual abuse is that although, by definition, it is an interaction between the abuser and the child, or the perpetrator and the victim, intention and responsibility rest with the abuser. The abuser's wish for power and sexual gratification are the two main aspects. Sexual arousal to prepubertal children or paedophilia is likely to be a motivating force for abusers of prepubertal children.

Finkelhor (1984) has brought together several factors in a systemic model of four preconditions which, he postulates, are necessary for child sexual abuse to occur. They include both the necessary presence of motivating factors and the absence of inhibiting factors. They are:

- 1 motivation to sexually abuse children;
- 2 absence of internal inhibitors;
- 3 absence of external inhibitors; and
- 4 absence of child's resistance (or a child's vulnerability).

Preconditions for potential abusers

Motivations refer to the abuser's sexuality and sexual development and include paedophilia, fear/avoidance of peer sexual relationships and sadism. They also address interpersonal motivators, such as a need to overpower or gain mastery over more vulnerable persons, arising as a result of one's own past abuse and low self-esteem. It is noteworthy that in a survey of male undergraduates, 5–9% expressed sexual interest in children (Briere & Runtz 1989). This suggests that the predisposition to sexual abuse is far more common than the action, supporting the postulated need for other factors to exist before abuse will actually occur. Some of the motivations for women abusers are discussed by Welldon (1988) who described incestuous mothers as simultaneously attacking and emotionally engulfing or possessing their children.

Absence of internal inhibitors includes the effects of alcohol and stress. It also refers particularly to the cognitive distortions or rationalizations that abusers employ in continuing to perpetrate abuse and which have been studied by those treating sexual abusers. These cognitive distortions include minimization of the harmful effect of the abuse on the child; conceptualizing the abuse as 'love' or 'education'; and placing responsibility on the child or adolescent who is described as inviting or requesting the abuse.

Child risk factors

External inhibitors of sexual abuse include protective family structures and relationships surrounding the child, in particular a secure attachment to primary caregiver(s), good monitoring of the child's whereabouts and the existence of confiding relationships for the child. Their lack provides a risk for sexual abuse.

The child's vulnerability by virtue of age, disability, neglect or social isolation, all increase the likelihood of sexual abuse. Indeed, abusers recognize these factors as rendering a child suitable for abuse (Budín & Johnson 1989; Conte *et al.* 1989).

This explanatory schema does not remove the abuser's responsibility for the abuse, whatever the nature of contributory risk factors.

Maintaining factors

Summit (1983, 1992) hypothesized a child sexual abuse accommodation syndrome or pattern to explain how children progressively adjust to sexual abuse by a trusted person, by accommodating psychologically to the inherent contradictions, confusions and enforced secrecy accompanying the experience, and which also explains the way in which many children come to disclose sexual abuse. He postulated five stages:

- 1 secrecy;
- 2 helplessness;
- 3 entrapment and accommodation;
- 4 delayed, unconvincing disclosure; and
- 5 retraction.

This accommodation pattern enables some children to remain asymptomatic during the abuse, helping to maintain the secrecy and leaving the abuse undiscovered. The abuser's own pattern of denial of the abuse through cognitive distortions lessens his potential discomfort and enables him to continue the abuse. By the time sexual abuse is discovered in childhood, it has usually occurred many times.

Effects of child sexual abuse

The majority of children who have suffered sexual abuse experience a variety of problems (Beitchman *et al.* 1991; Kendall-Tackett *et al.* 1993), some of which extend into adulthood (Wyatt & Powell 1988); there is no specific post child sexual abuse syndrome (Kendall-Tackett *et al.* 1993). Some effects are direct consequences of the sexual experience, such as age-inappropriate sexualized behaviour. Others develop as a response to the abusive nature of what happened. The actual effects are shaped by the child's gender, age, family circumstances (Chaffin *et al.* 1997), ethnicity and social class. In non-clinical samples, adolescents report higher levels of depression and anxiety than younger children (Gidycz & Koss 1989), suggesting that with increasing maturity the adolescent more fully comprehends the implications of having been abused sexually. This is also supported by the finding that distress following child sexual abuse is greater in girls with higher cognitive functioning (Shapiro *et al.* 1992). This is despite the fact that, in general, higher innate ability and the capacity to understand are considered to be protective factors in overcoming adverse life experiences.

Effects in childhood

Sexual abuse may lead to unwanted pregnancy or sexually transmitted disease. Rarely, it may cause genital injuries. However, less than 50% of children with documented sexual abuse have physical findings (Muram 1989). Deleterious psychological effects constitute the starting points for suspecting sexual abuse but often they are only recognized retrospectively, because many are non-specific. About 1 in 3 young people show no outward indicators (Kendall-Tackett *et al.* 1993), allowing abuse to be undetected over prolonged periods. This is particularly likely with children as compared with adolescents (McLeer *et al.* 1998). Although most findings derive from clinical samples, studies of non-clinical adolescents also show raised rates of emotional/behavioural difficulties (Hibbard *et al.* 1990; McLeer *et al.* 1998).

Sexualized behaviour

Most children include in their activity and play some aspects of exploration of their body and its functions, including genitalia, pregnancy, 'mummies and daddies' and 'doctors and nurses'. Friedrich *et al.* (1991) developed the Child Sexual Behaviour Inventory (CSBI) based on parent report. Observations of

preschool-age children have also shown that masturbation in preschool-age children is a part of normal development; many preschool-age children touch women's breasts, look at or touch each other's genitalia and some simulate sexual intercourse while remaining fully clothed (Lindblad *et al.* 1995). A significant proportion add genitalia to their figure drawings at some point in their early years (Marjorie Smith, personal communication, 1998).

Age-inappropriate sexualized behaviour is found significantly more commonly in, although not in most, sexually abused children (Friedrich *et al.* 1992; Friedrich 1993; Cosentino *et al.* 1995) and is an important outcome of child sexual abuse (Gale *et al.* 1988). It refers to rarely seen behaviour and talk about genitalia and sexual activity, often involving another child, a doll or, sometimes, an adult. These inappropriate behaviours include inserting fingers, objects or a penis into the vagina or anus, and oral-genital contact (Lloyd Davies *et al.* 2000). It also includes more commonly seen genitally orientated behaviours, such as looking at, touching or drawing genitalia or simulating sexual intercourse fully clothed, when these are repeated, become a preoccupation for the child, or are accompanied by coercion of another child in the activity. This troubling behaviour is particularly likely to follow abuse at an early age (McClellan *et al.* 1996). In boys, it may be regarded as a way of reasserting their masculinity (Rogers & Terry 1984). It may also be a form of reexperiencing the abuse as part of a post-traumatic response (Kiser *et al.* 1988). It is often intractable, a challenge to treatment (see below) and leads to serious difficulties in finding alternative placements for these children, who are considered to pose a risk to other children and who may become socially excluded as a result (Hall *et al.* 1998). In some children, this behaviour comes to be regarded as actual sexual abuse of another child.

Unplanned pregnancy

In adolescence, there is an association between early pregnancy and a history of sexual abuse (Mullen *et al.* 1994). This reflects the sexual vulnerability of these girls to sexual abuse which is expressed in a number of ways including: low self-esteem which leads to a lowered threshold to, or welcoming of, sexual approaches; a confusion between affectionate approaches and sexual attention towards the girls; and actual behaviour which is perceived by others as inviting sexual approaches. A history of child sexual abuse is also frequently found in both boy and girl child prostitutes.

Guilt and self-blame

Clinical experience suggests that many children blame themselves for having been abused, for not stopping the abuse or for not disclosing it earlier. Interestingly, empirical studies do not support this impression (Hunter *et al.* 1992). Tremblay *et al.* (1999) found that a majority of 7–12-year-old children who had been sexually abused maintained a relatively high sense of global worth, and Cohen & Mannarino (1998) made similar

findings. By contrast, Mannarino *et al.* (1994) found that sexually abused children more commonly blame themselves for other negative events in their lives.

Post-traumatic stress disorder and dissociation

Post-traumatic stress disorder (PTSD) has been found as a sequel of child sexual abuse, the frequency varying from 44% in an abused group being evaluated for psychiatric disorders and treatment needs (McLeer *et al.* 1992) to 71% in a clinical symptomatic sample (Trowell *et al.* 1999). Moreover, many sexually abused children who do not meet the full diagnostic criteria of PTSD show symptoms of re-experiencing behaviours (McLeer *et al.* 1992), fear, anxiety and difficulty in sustaining concentration (Conte & Schuerman 1988).

Emotional problems

Depression is found more commonly among sexually abused than non-abused children (Wozencraft *et al.* 1991). Whereas depression is found in all age groups, suicidal ideation and self-injurious behaviour is mainly confined to adolescence (Lanktree *et al.* 1991). Low self-esteem (Wozencraft *et al.* 1991) is associated with a history of sexual abuse, and the association holds when family dysfunction is controlled for (Hotte & Rafman 1992). This continues into adolescence (Cavaiola & Schiff 1989). Anxiety is encountered in both sexually abused boys and girls, and in both clinical and non-clinically referred children post abuse. In children, these difficulties may become apparent only on direct questioning or when using specific measures that seek psychopathology (Berliner & Elliott 1996). However, adolescents more readily report higher levels of depression and anxiety than younger children (Gidycz & Koss 1989).

Disorders of behaviour

Aggression and disruptive behaviour may also follow sexual abuse (Kendall-Tackett *et al.* 1993). However, reporting also reflects parental difficulties (Everson *et al.* 1989) and behavioural problems are therefore more severe in clinical populations (Tong *et al.* 1986). Running away, substance abuse and vulnerability to HIV infection both through illicit drug usage and unprotected sex is found in both boy and girl adolescents following sexual abuse (Rotheram-Borus *et al.* 1996).

Peer relationship and school difficulties

Difficulties with peer relationships may arise because of sexualized behaviour, low self-esteem, shame and lack of trust (Mannarino *et al.* 1994). Educational underachievement is commonly encountered and can be explained by a combination of factors leading to poor attention. These include preoccupation with the abuse, fear of the abuser and post-traumatic phenomena. In addition, there is often considerable anxiety and disruption to daily life following the discovery of the abuse and

because of the events and responses that ensue. These include uncertainty about the child's future placement and nature of contact with the child's family, and possible change of school and disruption of friendships.

Patterns and continuities

Charting the 'natural history' of sexual abuse-related symptomatology is difficult, because prognosis depends not only on the child's coping and adaptation (Friedrich *et al.* 1988) but also on the nature of the response that the child encounters. This includes treatment which, if successful, will modify outcomes. Moreover, some difficulties are related to age and developmental stage so that new difficulties may arise with maturation. Some children become more symptomatic than when initially seen (Bentovim *et al.* 1987; Gomes-Schwartz *et al.* 1990; Kendall-Tackett *et al.* 1993). Some symptoms resolve more rapidly than others; dissociation, post-traumatic phenomena and sexualized behaviour all attenuate only slowly (Beitchman *et al.* 1991), even with treatment (Lanktree & Briere 1995). Improvement in family functioning, particularly in the domain of problem-solving, correlates with improvement in children's behaviour while maternal coping through avoidance strategies correlates with deterioration in behaviour (Oates *et al.* 1994). Family functioning post abuse is related to the closeness between the abuser, the child and the remaining family. If the abuser is a close family member, and especially if he is denying the fact of the abuse, the family will be more troubled. Whereas there is an overall trend towards improvement in children's functioning, the path is neither smooth nor is its direction straight or entirely predictable.

Effects in adulthood

Studies of male and female adult survivors of child sexual abuse show a clear pattern of interpersonal and intrapsychic difficulties, although this does not constitute a syndrome (Stein *et al.* 1988; Fontes 1995). Interestingly, in their community study from New Zealand, Mullen *et al.* (1996) found that sexually abused women tended not to attribute their mental health problems to their (serious) childhood sexual abuse.

The most commonly reported symptom is depression; deliberate self-harm is significantly higher in women abused in childhood than in non-abused women (e.g. 16 vs. 6%), even in community samples (Saunders *et al.* 1992). Anxiety is also reported but less commonly. Drug and alcohol abuse are important long-term sequelae (Mullen *et al.* 1993), found more commonly in male survivors (Stein *et al.* 1988).

Mullen *et al.* (1994) also found difficulties in the sexual functioning and intimate interpersonal relationships, and distrust of men in women who had been abused, and all the deleterious effects were exacerbated by abuse that had included intercourse. Less disturbance of sexual functioning has been found in men survivors (Stein *et al.* 1988). Only a minority of homosexual men had been sexually abused in childhood, and they

have no greater sexual interest in children than heterosexual men.

One study that tested the validity of Finkelhor and Browne's traumagenic model (see below) in a sample of 192 adult women survivors, found that stigma and self-blame, but not betrayal and powerlessness, mediated the effects of sexual abuse on adult psychological functioning (Coffey *et al.* 1996). Some of these difficulties, including low self-esteem, impact on the parenting functions of adult survivors and contribute to the explanation of intergenerational continuities of child abuse. Continuing low self-esteem is also reflected in higher rates of unskilled or semiskilled work among women sexually abused in childhood (Mullen *et al.* 1994).

Eating disorders have been reported as occurring more commonly in women survivors of childhood sexual abuse (Mullen *et al.* 1993).

Neurobiological responses to sexual abuse

There is accumulating evidence of neurobiological effects of child abuse and neglect, including sexual abuse, in both children and adults (Glaser 2000). They include the hypothalamic–pituitary–adrenal (HPA) axis and catecholamine responses, as well as changes in cerebral volume. In children, dysregulation of the HPA axis with blunting of the adrenocorticotrophic hormone (ACTH) response to ovine corticotrophin-releasing hormone, but without increased cortisol secretion, has been found in sexually abused girls at a mean of 5 years after the abuse, suggesting downregulation of the HPA axis following the stress of the abuse (De Bellis *et al.* 1994a). De Bellis *et al.* (1999a) found increased 24-h urinary cortisol secretion in children still suffering from PTSD following serious abuse including sexual abuse. Similarly, Kaufman *et al.* (1997) found an elevated ACTH response in children who had been abused and who were still living in adversity, experiencing active emotional abuse. Raised secretion of catecholamines has been found in sexually abused girls (De Bellis *et al.* 1994b). Finally, magnetic resonance imaging (MRI) brain scans of children suffering from PTSD following serious abuse (De Bellis *et al.* 1999b) showed 7% smaller cerebral volume and increased cortical cerebrospinal fluid volume in comparison to non-abused children. Unlike adults, the abused children did not show decreased hippocampal volume.

Golier & Yehuda's (1998) review suggested that some years after sexual abuse, lower cortisol levels are found, in conjunction with a possibly enhanced negative feedback in the HPA axis. Deficits in verbal, but not visual, short-term memory have been found in men and women who had experienced severe childhood physical, sexual and/or emotional abuse, often of early onset (Bremner *et al.* 1995). The severity of the verbal memory deficits correlated positively with the severity of the abuse, as measured on a specially developed instrument relying on past recall, the Early Trauma Inventory. The short-term verbal memory impairment shown in this study is not to be confused with memory for the past abuse which, as the methodology assumes, must be intact. It is suggested (Sapolsky 1996) that

excess cortisol secretion brought on by the stress of the abuse leads to hippocampal damage.

Factors contributing to the effects of sexual abuse

Tremblay *et al.* (1999) found that abuse variables, parental support and the child's coping strategies contributed independently to the psychological outcome for a group of 50 7–12-year-old children. Pre-abuse circumstances, child characteristics and post-abuse responses were also relevant.

Abuse variables

Abuse variables include the nature, duration, and severity of the abuse, and the relationship between the abuser and the child. Abuse factors that are associated with more severe psychological sequelae include prolonged duration and greater frequency of abuse (Caffaro-Rouget *et al.* 1989), penetration of mouth, anus or vagina and abuse accompanied by threats or force (Gomes-Schwartz *et al.* 1990).

Closeness in the relationship between the abuser and the child adversely affects prognosis. Clinical impression suggests a worse prognosis when there have been several abusers, although empirical findings are equivocal on this point (Kendall-Tackett *et al.* 1993). Abuse by mothers of their boy neonates, e.g. by sucking their penises, has shown a powerful sexualizing effect on the boys at a very young age (Chasnoff *et al.* 1986). There are few available data about the specific effects on girls of abuse by women.

Child variables

There is no consistent difference in the magnitude or severity of response between boys and girls. Contrary to expectations, there is no conclusive empirical evidence indicating that boys who have been sexually abused show more externalizing disorders than girls. However, boys experience more anxiety about becoming homosexual or about latent homosexuality within them that, they sometimes believe, had been detected by the abuser (Watkins & Bentovim 1992). The evidence on effects of age at onset of abuse is inconclusive when studied independently of duration of abuse. However, many studies indicate that older children are more symptomatic at the time of presentation. Early sexual abuse, before the age of 7 years, appears to be a risk factor for later inappropriate sexualized behaviour (Mian *et al.* 1996).

Interestingly, the child's coping strategies and cognitive evaluation of the abusive experiences have been shown to contribute less to the child's later functioning than severity of the abuse and the support of the non-abusing carer (Spaccarelli & Kim 1995).

Pre-abuse and family circumstances

The child's family and the nature of caregiving experienced by the child influence the outcome for the child (Waterman *et al.* 1993). Pre-existing adverse family relationships and circumstances may have increased the child's prior vulnerability to abuse as well as contributing to the adverse impact of the abuse on the child (Conte & Schuerman 1988). This includes neglect of supervision; lack of provision for basic needs which renders the child more vulnerable to predatory abusers; the formation of insecure attachments by the child which lessens the likelihood of the child talking about worrying experiences, such as sexual abuse; and social isolation. In some cases, sexual abuse can be regarded as a marker for other detrimental factors in the family which in themselves contribute significantly to later psychopathology (Mullen *et al.* 1993, 1996).

Post-abuse response

The post-abuse response includes the investigation, the response of the non-abusing caregiver(s) and the abuser, as well as protective steps taken to ensure the child's future safety. Denial of the allegation by the alleged abuser naturally leads to a stringent testing and even discrediting of the child's verbal descriptions (Summit 1992). Child protective steps, which may include removing the child from the home, are often necessary because of the denial of the abuse by the abuser (Glaser 1991).

Many mothers remain supportive of their child following discovery of sexual abuse (Sirls & Franke 1989). The non-abusing carer's belief, support and active protection of the child are significant determinants of a good outcome for the child, regardless of the nature of the sexual abuse (Everson *et al.* 1989; Runyan *et al.* 1992). Conversely, the mother's emotional distress adversely affects outcome for the child (Cohen & Mannarino 1998). This points to the need to ensure that at the time of discovery of sexual abuse, help and support are directed at the non-abusing caregiver(s) who are often faced with a conflict of interests, between the abuser and the child. The closer the relationship between the abuser and the non-abusing caregiver, the less supported will the child be by her family (Berliner & Elliott 1996) and the worse the adjustment of the child (Spaccarelli & Kim 1995). Abuse by a stepfather or a mother's current boyfriend is a particularly risky circumstance, compromising support of the child by the mother (Elliott & Briere 1994).

Belief in the child's account of abuse is the first step towards support for the child. It is not, however, synonymous with consistent protection of the child; this requires the primary carer(s) to distance themselves and the child from the abuser, both emotionally and physically. This is particularly difficult when the abuser is the mother's partner (Heriot 1996).

Model for the effects of child sexual abuse

Finkelhor & Browne (1985) developed a model to explain the effects of child sexual abuse. This eclectic and comprehensive

model reflects the complexity, and consequently the heterogeneous nature of the effects of child sexual abuse. It comprises the following: traumatic sexualization, betrayal, stigmatization and powerlessness.

Traumatic sexualization refers to the abuse experience and combines the trauma and the developmentally inappropriate sexual aspects of the abuse. Finkelhor (1988) postulated that the process of the abuse fetishises children's genitalia in a developmentally inappropriate way, rewards children for, and confuses children about the meaning and involvement of their sexual behaviour, and leads to an association of sexuality with trauma. These aspects are considered to be unique to child sexual abuse.

A sense of betrayal refers to aspects of the child-abuser and child-caregiver relationships. It reflects the fact that abusers have usually been trusted by the child, either inherently by the nature of the relationship, or by the relationship that has been created by the abuser, sometimes deliberately, prior to the abuse. The sense of betrayal also extends to the experience of not being believed by their non-abusing caregivers, especially mothers (Herman 1981). Young children, who believe in the power of their parents to protect them from harm, lose this sense of safety and protection when they become abused.

Stigmatization concerns the child's emotional response and self-view. It includes the sense of shame, blame/guilt and worthlessness which are both communicated to the child in the process of the abuse and by the way sexual abuse is regarded. Children often seek to 'explain' why they were targeted and ascribe self-denigrating meanings. Boys sometimes believe that they must have been recognized as homosexual in order to have been 'chosen'. Many girls express feelings of having become 'spoilt goods' (Rogers & Terry 1984).

Powerlessness refers to the child's experience of threat or overwhelming fear sometimes associated with sexual abuse and the origin of post-traumatic stress responses. Less traumatically, it also encompasses the child's experience of being overruled and their body invaded and spoiled.

Shapiro (1989) discussed a reciprocal relationship between self-blame and helplessness or powerlessness in sexually abused children. If the child's perception of helplessness is confined to the abuse situation, this may mitigate against self-blame for the abuse. Conversely, if the child blames herself, this may help to overcome her perception of herself as powerless.

Role of child and adolescent mental health services in child sexual abuse

Child sexual abuse is sometimes part of the referral presentations and sometimes its occurrence is discovered incidentally during assessment or treatment. Also, some troubled parents will have been sexually abused in childhood. The possibility of abuse in family members therefore always needs to be considered; familiarity with its effects as well as with its investigation, and with protection and legal aspects, is important. Sexual abuse needs to be considered especially in children showing age-

inappropriate sexualized behaviour and in depressed or suicidal adolescents. At times, an unsolicited disclosure is made by a child during therapeutic work. Child psychologists, psychiatrists and psychotherapists may contribute to investigations of child sexual abuse, particularly in assessment interviews of young or very traumatized children, or in children with communication difficulties. Consultation to social services in case management and to carers of children who have been sexually abused is often requested. A particular role is the provision of individually appropriate treatment for abused children and their families.

Child sexual abuse may also call for forensic work. This includes assessments for Children Act 1989 proceedings, providing expert reports and oral evidence (Wall 2000). Comments are usually requested on the presence or absence of Significant Harm and on the nature of the Care Plan, which includes the future care and residence of the child, contact with family members including the abuser, and the child's and family's therapeutic needs. Risk assessments on adolescent abusers may also be required. Children who have been sexually abused are eligible for Criminal Injury Compensation Authority awards, and child mental health professionals may be requested to provide reports about the nature and extent of the harm to the child and their treatment needs.

Initial professional encounters with child sexual abuse

Principles

Whenever sexual abuse is suspected or presented explicitly to a professional, including child mental health practitioners, multidisciplinary professional involvement follows inevitably. Its broad aims are to ascertain what, if anything, has happened to the child and to gain an understanding of the child's development and family context and needs. If the child has been abused, the child's needs will include the following.

- 1 The immediate and long-term protection of the child from sexual abuse.
- 2 The amelioration of the effects of the abuse including:
 - reduction of distress and the resolution of internal conflicts for the child;
 - resolution of interpersonal conflicts surrounding the child; and
 - treating physical consequences of the abuse.
- 3 Ensuring optimal development for the child following cessation of abuse.

Although these aims are clear, their achievement in practice is fraught with difficulties. Suspicions need to be verified and a child's account tested, because protection comes at a cost and therapy can only follow protection. As there are rarely witnesses to the abuse, establishing whether it has occurred will rest heavily on the child's verbal description, which may be retracted even if it was true. Discovery of abuse is often accompanied by

denial by the alleged abuser, and some doubt or disbelief, and usually constitutes a crisis for the family and a challenge to the professional system. The child's ultimate well-being will, to a significant extent, be determined by the support given by the family. The nature of the early intervention by professionals and their consideration of the position and needs of the mother or non-abusing caregivers, will have long-lasting effects on the child's and the family's subsequent expectations and attitudes towards professionals with whom they may need to continue to work (Sharland *et al.* 1996).

In some countries, including the UK, the responsibility for child protection rests with social services to whom suspicions or actual abuse are reported. The subsequent multidisciplinary and multiagency process involves, in addition, the police, health and education and the courts. In other countries, the responsibility for child protection remains with the courts. A number of well-established steps in the process have been identified (Jones 1997; Department of Health *et al.* 1999), each step depending on the outcome of the previous one.

- 1 Suspicion or recognition leading to referral to (child protection) social services.
- 2 Establishing whether there is a need for immediate protection.
- 3 Planning the investigation including:
 - interagency discussion;
 - interviewing the child;
 - medical examination of the child; and
 - initial assessment of the family.
- 4 Validation and initial child protection meeting (conference).
- 5 Protection plan and a more comprehensive assessment.
- 6 Implementation of plans and review.
- 7 Prosecution.
- 8 Therapy.

Different combinations of agencies are involved in the many stages.

Suspicion, recognition and disclosure

Suspicion is based on one or more indicators, both specific and non-specific (Glaser & Frosh 1993). Specific indicators include: inappropriate sexualized behaviour (see above); genital physical signs (Hobbs & Wynne 1989) including sexually transmitted diseases and pregnancy in a young girl or when the identity of the father is unclear; running away and deliberate self-harm in adolescence; sexual abuse of other children in the family; and known contact with a sexual abuser. Non-specific indicators include a variety of behavioural, emotional and educational difficulties. Sexual abuse needs to be considered especially when there is a sudden onset of difficulties in a previously untroubled child and when no other obvious explanations are available. These difficulties include inability to sustain attention, deterioration in educational progress, social isolation or aggressiveness, indicators of low self-esteem, marked unhappiness or depression, disturbed sleep and nightmares, fearfulness and separation anxiety, and eating disorders.

In child and adolescent psychiatric practice, it is important to consider the possibility of sexual abuse as one explanation for those difficulties that are recognized as effects of sexual abuse. Rather than an initial direct enquiry about sexual abuse, it is preferable to enquire about upsetting and unwanted experiences and previous contact with social services. With adolescents, a direct enquiry could be made, especially following deliberate self-harm. Careful notes should be made of such assessment interviews (Jones *et al.* 1993) and it is always advisable to discuss one's concerns and suspicions with a colleague. It is also possible to request an 'anonymous consultation' with a social worker, in which the child's identity is not divulged. As a result of such assessments, sexual abuse may come to light which may or may not already be known about by child protection agencies. If it is a new disclosure, the child needs to be listened to, avoiding interruptions and questions, and the conversation needs to be carefully recorded in writing.

Although in the UK, unlike in the USA, there is no *mandatory* reporting of seriously suspected or actual sexual abuse, it is considered to be good professional practice to report serious suspicions or disclosures to child protective agencies or social services (Department of Health *et al.* 1999). This overrides the usual rules of confidentiality. A child may not wish for their disclosure to be divulged to another agency. When it is not possible to accede to the child's wishes, the child's misgivings need to be explored, the reasons given for the need to report the abuse, and the child needs to be involved in the process of notifying social services. Referral is usually made with the knowledge of the family, unless there are indicators that this will place the child at increased risk, including pressure on the child to retract an allegation.

Abuse more usually comes to light when a child talks about it to a relative, friend or teacher (Bradley & Wood 1996). Children who spontaneously describe sexual abuse and who make an intentional disclosure are likely to be accurate in their account.

The need for immediate protection is a decision of social services in consultation with other professionals and agencies and might require an emergency protection order in respect of the child (Children Act 1989).

Investigation and formal interview

The next step in the investigative and protection process is a professional (or strategy) meeting, which is convened by the statutory agencies — police and social services. It will also include any professionals with immediate relevant knowledge about the concerns and about the child and the family, including a professional to whom an allegation or disclosure has been made. This could therefore be a child psychiatrist or other mental health professional.

The purpose of the strategy discussion is to plan the investigation, the approach to the family, the formal interview with the child and the medical examination (Heger & Emans 2000). Children will be interviewed formally if there are clear suspi-

cions of abuse or if the child has already disclosed the abuse informally. Both clinical experience and empirical evidence (Keary & Fitzpatrick 1994) show that children (especially younger ones) will not usually describe sexual abuse during a formal interview, unless they have previously spoken about it. (The converse is not, however, true.) Consideration therefore needs to be given to the relative merits of enabling a child to talk informally, with the attendant risk of this being later construed as suggestive, against submitting a child who is not ready to talk to a formal interview which may not yield a description of abuse which had, nevertheless, occurred.

Talking about an event either at the time or afterwards, enables a child to organize the experience in a more coherent way and enhances the laying down of a more coherent account and memory of the experience (Haden *et al.* 1997). Although the fact of a conversation will distort the memory to some extent, talking continues to improve the capacity to recall an experience as well as to make sense of it, especially when the experience is stressful or traumatic (Goodman & Quas 1997).

The formal interview is video recorded and may be used both as prosecution evidence in a subsequent criminal trial, and in civil child protection legal proceedings. It is therefore carried out by police and social services according to strictly specified guidelines. Rarely, children are encountered whose distressed or traumatized mental state, or whose difficulties in communication indicate the need for interviewing skills of a child mental health professional. Some people have used facilitated communication with autistic children who are suspected of having been abused, but systematic studies have made it clear that what is communicated usually does *not* derive from the child (see Rutter & Yule, Chapter 7). This is an unsafe procedure.

Ceci *et al.* (Chapter 8) discuss what is known about children's memory and their reliability as witnesses. Among many other factors not associated with memory but which may, nevertheless, be misinterpreted as poor recall, is the extent to which the child is motivated to talk about past events. The child may well continue to be cared for, or be in close contact with an abuser, and may therefore consider disclosure of the abuse to be a betrayal of the abuser. Silence may be one way of dealing with this dilemma (Freyd 1996). Children who are interviewed some time after the abuse, and who may be suffering from PTSD, may find difficulty in talking about the abuse.

The child's responses are by no means related only to the strength of memories or the power of recall. As well as challenging the child's capacity to recall, the child's truthfulness, clarity of thought as opposed to confusion, and the child's capacity to withstand misleading suggestions, are all often questioned. There is now much research evidence to show that the circumstances in which the child's account is sought and obtained, and the power differential in the relationship between the interviewer and the child, have a significant bearing on the child's 'performance' (for a review see Lamb *et al.* 1997). Interviewing styles and forms of questioning are capable of significantly distorting children's accounts which do not then reflect what the child had previously recalled. For instance, when the rapport-

building stage of the interview consists of open questions, children's response to the first open question regarding a past experience yields 2.5 more details and words than following a closed question. Moreover, this initial pattern continues in response to open questions throughout the interview. Repeated occasions *per se*, in which the child is simply invited to describe past experiences, without pressure or suggestion, do not compromise accuracy of recall (Fivush & Schwarzmüller 1995). By contrast, closed questions requiring a forced choice, yes/no answers (and not infrequently used by advocates in court) yield far less accurate information. However, in order to obtain optimal information and verify certain facts, closed questions can be alternated with open ones.

There has been much debate about the use of anatomically correct dolls in the interviewing of children. There is little evidence that young non-abused children proceed beyond exploration of the dolls' genitalia to enact sexualized behaviour (Glaser & Collins 1989). Nevertheless, the dolls should not be used as a screening tool (Boat & Everson 1994) or cue (Everson & Boat 1994), but rather to enable young children to illustrate what they have conveyed verbally.

Validation

Validation of child sexual abuse requires assessment of the evolution of suspicions, and the circumstances as well as the content of the child's first description or disclosure of abuse. The outcome of a formal interview and the findings in a medical examination receive obvious scrutiny, particularly in legal proceedings, both civil and criminal. Other factors include family circumstances; the child's relationship with the alleged abuser; the responses to the allegation by the mother or the non-abusing caregivers, and by the alleged abuser. In a retrospective review of 551 case notes of reported concerns about possible child sexual abuse, 43% were substantiated, 21% were inconclusive, and 34% were not considered to be abuse cases. Only 2.5% were erroneous concerns emanating from children, and included only eight (1.5%) of false allegations originating from the child, and three made in collusion with a parent (Oates *et al.* 2000). In other studies, false allegations were most commonly made under the influence of a parent in the context of disputed contact or residence disputes between warring parents.

The nature of protection

A child who is believed to have been abused is deemed to be protected providing all contact with the alleged abuser is either fully supervised or stopped. A child can only be protected in a context in which there is belief in the child's allegations, without explicit blame of the child, and where there is a commitment by the child's non-abusing caregiver to protect the child. Children abused by persons outside the family tend to be excluded from child protective services on the, sometimes erroneous (Tebbutt *et al.* 1997), assumption that they will be protected by their families. If protection is achieved, and if no legal proceedings ensue,

there may never be a formal record of the validated fact of the abuse.

Child protection conference and planning

A multidisciplinary child protection conference is convened if there is a reasonable likelihood that a child has been abused and remains unprotected. The purpose of a conference is to determine, on the basis of information gathered, whether the child continues to be at risk of Significant Harm and, if so, the nature of the protection plan which will ensure the child's safety. This plan will include a comprehensive assessment of the child and the family's needs and commencement of therapeutic work, to both of which child mental health services are often required to contribute.

Legal proceedings

There are both civil and criminal proceedings in which the question of child sexual abuse is at issue. Civil proceedings concern the future safety of the child. In England under the Children Act (1989) the child's welfare is paramount. The child does not attend court or give evidence; hearsay and expert evidence are allowed. Civil proceedings include the following.

- 1 Public law care proceedings in which Significant Harm is determined and a finding may be made about sexual abuse having occurred. The court may grant an order (care or supervision) to ensure the child's well-being and a care plan is required, for which the local authority is responsible.
- 2 Private law family proceedings in which residence and contact disputes between parents are sometimes based on allegations of sexual abuse of the child while in the care of one of the parents.

In criminal proceedings, the child is an accessory to the court process, whose interest is the determination of the guilt or innocence of the alleged abuser. Unless the alleged abuser pleads guilty, both the child's account of the abuse (which may have previously been video-recorded) and cross-examination of the child, are required. Expert evidence and opinion regarding the child's credibility is not permitted in English courts, that being an issue for the jury and the judge to decide.

Therapeutic work

A systemic treatment approach to the effects of child sexual abuse requires consideration of the child's needs, both individually and in the context of the family. Just as there is no post abuse syndrome, so is the application of a programmatic universal treatment not appropriate. It is more useful to consider in each case which likely issues might require treatment. A starting point is consideration of the individual needs, and relationships between the three participants in the 'abuse triangle': the abuser, the child and the non-abusive caregiver (Glaser 1991).

The fulfilment of the child's and family members' needs often requires social work support as well as more formal psychological therapy and psychiatric treatment. An integrated multi-disciplinary and multiagency approach is required (Furniss 1991) in which therapy both deals with needs as they arise and according to their severity, and is offered at appropriate points in the post-abuse process (Jones 1996). For instance, it is not appropriate for a child to receive group or individual therapy for the effects of the abuse while the child remains unprotected; children in transition from one family to a new permanent home are often more preoccupied with their impermanence and their family's response than with the sexual abuse. It may be inadvisable for a child to join a therapeutic group before testifying in impending criminal proceedings; therapy might need to await outcome of criminal proceedings if a child has retracted allegations or the alleged abuser denies the abuse (Home Office *et al.* 2001). Furthermore, work with the child is most beneficial when undertaken in parallel with work with the parent(s) or carers and family (Monck *et al.* 1996). Some of the child's needs can only be addressed by work with the non-abusing carers alone or with the child and mother/parents together (Celano *et al.* 1996). For other difficulties, it is appropriate to work with the child alone or in a peer-group setting.

Children's therapeutic needs

Not all children who have been sexually abused require prolonged or even systematic therapy. However, as a minimum requirement it is important to ascertain that the child is able to talk about their experiences to a parent or other identified person, who believes the child and is able to listen to the child supportively and uncritically. Children who have been sexually abused also require age-appropriate education about sexuality and the nature and risks of sexual abuse. As stated earlier, many children are symptomatic and therefore require treatment. Whereas some symptoms, such as sexualized behaviour, are readily apparent, others, such as PTSD or depression, may need to be actively sought. Specific instruments, such as the Children's Impact of Traumatic Events Scale-Revised (CITES-R) (Wolfe *et al.* 1991), the Trauma Symptom Checklist for Children (Briere 2001) and measures of depression such as the Childhood Depression Inventory (Kovacs 1983) are of particular help. It is important to include children who have been abused by strangers or by someone outside the family (Van Scoyk *et al.* 1988; Grosz *et al.* 2000), whose therapeutic needs may be overlooked when protection from re-abuse is not considered to be an issue (Sharland *et al.* 1996).

Overall, treatments that are directed at specific difficulties have been shown to be more effective than no treatment (Finkelhor & Berliner 1995) or the mere passage of time (Deblinger *et al.* 1996) and length of treatment has been found to be predictive of outcome for depression (Lanktree & Briere 1995). There are some findings of no effect (Oates *et al.* 1994; Tebbutt *et al.* 1997) or some deterioration for a minority of children during therapy (Jones & Ramchandani 1999). It is not clear what the relative

contribution of intercurrent developments in the child's life or the therapy itself made to the reported deterioration. In the light of the mostly positive outcome for therapy, it would not be appropriate to withhold treatment from symptomatic children. However, these findings point to the importance of monitoring the child's psychological state during treatment and a preparedness to halt therapy if necessary.

There are several ways by which treatment approaches for children can be categorized. Children may be treated individually or in groups; treatment may be directed at specific symptoms; and specific therapeutic approaches, such as psychodynamic or cognitive behavioural therapy (Cohen & Mannarino 1993; Deblinger & Heflin 1996), may be selected.

Group and individual therapy

The shared membership of a group offers an alternative to the secretiveness, isolation and shame experienced by most sexually abused children; this may explain findings from a small sample of children who expressed a preference for group over individual therapy (Prior *et al.* 1994). The group setting is appropriate for learning about sexuality and for developing a socially appropriate 'story' about one's own abuse. The observation of children in groups enables professionals to assess children's further therapeutic needs, which may include longer term individual psychotherapy.

It is preferable for a group to have more than one child with a particular attribute, such as minority ethnicity, abuse by a stranger or living away from home. Groups for children aged over 7 years are more appropriately offered separately for boys and girls and broadly age-banded (Nelki & Watters 1989). Groups require two therapists, of whom one should be a woman. Groups for pre-adolescent children are usually activity-based and follow a programme which addresses issues commonly encountered by children who have been abused. These include a range of distressing feelings, such as shame, guilt, anger and low self-esteem; sexuality; confiding and secrets (Berliner 1997). Adolescents are able to use groups for a more reflective exploration of their feelings (Furniss *et al.* 1988).

Children's attendance in therapy, whether group or individual, is dependent on their parents' psychological and physical support. The provision of support or therapy for the accompanying parent or carer in conjunction with the child's therapy is therefore useful in addressing both emotional and practical issues of the parents (Damon & Waterman 1986). This can be offered individually or in a group. It also enables the parents to remain involved in, and informed about relevant aspects of the child's therapy, in order to support that process (Rushton & Miles 2000).

Whereas groups are widely used and their process well documented (Berman 1990), a recent review of published outcome studies of therapy for sexually abused children (Jones & Ramchandani 1999) found overall little difference in effect between group and individual treatments in improving children's symptoms. In one of the studies reviewed (Trowell *et al.* 1995),

the outcome for very troubled girls randomly assigned to individual psychodynamic psychotherapy or group therapy showed significant improvement of a comparable extent at 1- and 2-year follow-up after both forms of therapy. The only significant difference was a greater decrease in PTSD re-experiencing of trauma, and persistent avoidance of stimuli dimensions, for girls receiving individual therapy.

Specific symptoms and therapeutic modalities

Sexualized behaviour (Trowell *et al.* 1999) and PTSD have been found to be particularly difficult to alleviate. However, cognitive behavioural therapy directed at particular difficulties has been shown to be significantly more efficacious than non-directive supportive therapy in improving outcome for young sexually abused children, including a significant decrease in sexualized behaviour (Cohen & Mannarino 1997). Interestingly, both psychodynamic therapy (see above) and cognitive behavioural therapy which was directed specifically at symptoms of PTSD (Deblinger *et al.* 1996) have been shown to be effective in reducing PTSD.

Therapeutic work with caregivers and family

Mothers and non-abusing caregivers

The mental health of the non-abusing mother or caregiver, as well as her belief in and support of the child are important factors determining the outcome for a sexually abused child. In the absence of parental support, children may not remain living with their biological family, because of both blame and lack of protection. There are many obstacles to maternal or parental support following discovery of abuse, which are amenable to change through specific therapeutic work, either individually or in a group. The obstacles include the nature of the relationship between the carer and the abuser, and the need for an imposed distance or termination of that relationship; the mother or carer's guilt about not protecting the child; anger towards the child; and memories of some mothers' own abuse. The discovery of sexual abuse and its aftermath also offer opportunities for helping parents with parenting issues (Celano *et al.* 1996).

Siblings and the family

Siblings are sometimes the silent witnesses of abuse and their needs and feelings may be overlooked in the process of attending to the sexually abused child and the mother. Meetings with the whole family can redress this balance, also enabling the family to talk openly about the fact of the abuse, whose mention is often avoided despite the fact that family members are acutely aware of it. However, family meetings would not include the abuser unless he has taken responsibility for the abuse and is receiving treatment. Family work is important when there are indications of blaming or scapegoating of the

abused child. Other dysfunctional aspects of family interactions that are associated with child sexual abuse include, in particular, inappropriate intergenerational boundaries, disorganization, parental neglect and unavailability (Madonna *et al.* 1991; Bentovim 1992). They require more formal family therapy (Elton 1988).

Work with abusers

Adolescent abusers

The treatment of adolescent abusers is important in order to prevent progression of abuse into adulthood. The prognosis may be more encouraging than with adult abusers because the adolescent may be less defensive and at a developmental stage when he is emotionally vulnerable and responsive to change. Moreover, the child protective and youth justice systems can be instrumental in encouraging attendance at therapy. A particularly important factor is the support, by the young abuser's parents, for the adolescent to own up to the abuse. Without this, it is difficult to offer therapy. A dual approach is required, which encompasses both the young abuser's responsibility for the abuse and his likely past emotional, physical or sexual victimization. Therapy may be offered individually (Woods 1997) or in groups (Smets & Cebula 1987). Using activities as well as words, a group can offer the following:

- peer support;
- challenging denial and minimization of the abuse and responsibility for it;
- sex education;
- development of social skills;
- victim awareness;
- recognition of cognitive distortions concerning the abuse; and
- mapping the abuse cycle (Hawkes 1999) and learning to halt its progression.

Adult abusers

The issue of treatment for adult abusers is important for those children who are closely related to their abuser and who wish to resume a meaningful relationship with him. Central to treatment, often carried out in group settings, is reduction of denial by the abuser (Salter 1988). Initial denial of their involvement is encountered in the majority of abusers. There is commonly also denial of the extent of the abuse, responsibility for the abuse, the harm caused to the child or the inappropriate nature of the sexual contact. Therapy needs to recognize the emotional comfort which denial offers and to acknowledge the cost of assuming responsibility. The issues described above in adolescent abuser groups also apply to adult abusers. Common to both is the recognition that the risk for returning to child sexual abuse remains a possibility.

Conclusions

Child sexual abuse is a discrete, definable and often repeated event that is embedded in a complex web of contextual factors, both historical and relational. Its antecedents and consequences are manifold and not necessarily specific. For these reasons, specific prevention is particularly difficult and alertness to the possibility and early recognition offer the best hope for damage limitation. Children cannot be relied upon to protect themselves. Secrecy, denial and disbelief are integrally related to sexual abuse and exert a very significant influence on the professional response and outcome for the children and their families.

Introduction

'In the home for abandoned children, they are sad and sometimes die of sadness.' From the Diary of a Spanish Bishop, 1725 (Spitz 1945)

It has been known for centuries that a loving reciprocal early relationship is essential for healthy development. Most families provide this. However, when birth parents have psychological or health problems, learning or physical disability, and/or live under adverse conditions, such as poverty or overcrowding, parenting capacity may be compromised and the child may become vulnerable. Short-term substitute care to deal with a crisis will sometimes follow, or the family may be investigated by the child protection services and the child removed. Some children may not return home because they remain at risk or because the parents have rejected them.

We are concerned, in this chapter, with children placed in foster family or residential care and with factors related to this placement including: the children's emotional and behavioural functioning; the characteristics of the care environments; abuse in care; children's relationships within and outside the setting; the perspectives of the children; the longer term outcomes and treatment interventions. The approach we have taken is to make direct comparisons between the effects of two environments—foster family care (mostly longer term) and residential care—on the children placed there. The chapter will not address forms of residential care such as inpatient psychiatric units (see Green, Chapter 61), hospital wards, young offender institutions (see S. Bailey, Chapter 60) or, the largest group of all, boarding schools in the independent sector. However, some of the issues discussed will be equally relevant to these groups. Nor will we attempt to deal with the specialized problems of children with significant learning or physical disabilities in residential care (see Bernard, Chapter 67).

The placement of healthy infants in adoptive homes seems to be achievable with no worse long-term outcome than for children never separated from their birth families (Maughan & Pickles 1990; Bohman 1997). A more pertinent question for the current child welfare system is whether children who have had a history of broken attachments, abuse, neglect and other adversities make adequate developmental recoveries in a new environment and, where appropriate, form sufficiently strong psychological ties to their new carers. A crucial question is whether the substitute care provided is of sufficient quality and stability to avoid further harm and serves a remedial purpose (Rutter 2000).

Nearly 50 children in every 10 000 are being 'looked after' by the local authority in England and Wales (Department of Health 1999), but these rates vary widely across the world (e.g. 75 in 10 000 in the USA). In the UK, after a steady fall, the proportion of children under 18 'in care' may have been rising again (from 80 in 10 000 in 1987, to 45 in 1995 and to 49 in 1999). Of the two major placement categories, most children (65%) are looked after in foster placements and 12% in children's homes. The remaining children include those placed under supervision with birth parents and those placed for adoption. The number of children in residential care in England and Wales fell by almost 80% from the late 1970s to the 1990s, but for the past 5 years the foster:residential care ratio has been constant. In Europe, Australasia and North America, a general trend exists towards reducing numbers and lengths of stay in residential care. However, this has not been evident in other parts of the world (Hill 2000).

The move towards briefer stays in residential care is not wholly positive; some children experience both foster and residential care and, with greater emphasis on family preservation, it is not unusual for children to spend short periods in foster or residential placements interspersed with periods in a less than optimal family environment. This is a particularly difficult area to research, but it is important to track the effects of numerous changes of environment and of such complex care careers. Current knowledge of the likely consequences of maltreatment has recently been summarized (Cicchetti & Toth 1995; Glaser 2000) and the stresses involved in living in adverse preplacement environments put children at risk for health, developmental and academic problems.

Historical background

The social arrangement called family foster care has had a longer history than residential placement, in the sense that the care of children in need has always been provided by other families (Werner 1984). Fortunately, humans are sometimes driven by acts of generosity and community spirit and parentless children can be successfully brought up by others. In the modern more formally organized fostering system, alternative care is provided by unrelated families who are recruited, assessed, regulated and paid for their services.

The history of residential care in the UK can be traced to the first Poor Law of 1531 when there was a need to take over the

functions of the dissolved monasteries. However, the growth of institution building three centuries later, which saw the arrival of the orphanage and the workhouse, has had the most powerful influence on its character. Attempts to document and analyse the history of residential care (Parker 1990; Frost *et al.* 1999) have considered the ill effects of industrialization and urbanization on family life on the one hand and the part played by religion and philanthropy in ‘rescuing’ children from poverty and crime on the other.

Fostering and residential care have run in parallel as alternative arrangements for children since the nineteenth century, often competing for status and resources. The introduction, in 1857, by the Foundling Hospital in London of a new system in which children were boarded out with families may have been the origin of rivalry between residential and foster care (Frost *et al.* 1999).

Theoretical developments have contributed to the preference for family rather than institutional care, including Bowlby’s (1951) emphasis on preserving attachment with an adult caregiver, Goffman’s (1961) critique of institutions in general and Maluccio *et al.*’s (1986) theories on the importance of ‘permanence’. Influenced by these ideas, a hierarchy of out-of-home placement choices is now often advocated with adoption first, foster family care second and residential care as the least desirable option.

International comparisons

It is instructive when exploring evidence on placement alternatives to embrace international comparisons of fostering and residential care. Although now absent from the Western world, horrifying examples of poor child care in large insanitary institutions with inadequate nutrition and lack of personal warmth are still to be found (Chisholm *et al.* 1995). Within Europe wide variations exist in the total number of children in public care, the proportion living in children’s homes, opportunities for training for carers and levels of remuneration (Gottesman 1991; Madge 1994; Sellick 1998). Colton & Hellinkx (1994) identified a number of common developments across Europe, such as the reduction in the size of homes, the professionalization of carers and a preference for placements that are inclusive rather than exclusive of the family and community. Although we are aware of important practice advances in various parts of the world (e.g. Australasia and Scandinavia), little has reached the academic literature other than work from the UK and the USA. We hope that a more genuinely international perspective will emerge in the near future.

What characterizes the foster family and residential care environment?

Child and adolescent mental health professionals may be asked for opinions about appropriate placements for children in diffi-

culty who need to be placed away from their biological family or they may be providing a therapeutic service. The type of setting will have an important impact on whether or not these difficulties are resolved.

Since the 1940s, researchers have observed the effects of institutions on children. Spitz (1945) concluded that adequate stimulation and presence of the child’s mother were crucial in preventing physical and intellectual delay. This and later research, demonstrating that the effects of institutionalization on children’s behaviour include the ‘indiscriminate’ giving of affection and a tendency to go easily to strangers, has transformed social care (Goldfarb 1945; Dennis & Najarian 1957; Tizard & Hodges 1978; Chisholm *et al.* 1995; Vorria *et al.* 1998). In the developed world, many of the remaining residential institutions attempt to address these findings by providing smaller units with better family and community links.

Systematic research on fostering has developed since the 1960s with attempts to investigate the stability of foster family placements and to establish predictors of successful outcome (Trasler 1960; Parker 1966; George 1970; Fanshel & Shinn 1978; Berridge & Cleaver 1987). Despite attempts to reduce the extent of serial placements, fostering can still be an unstable arrangement for many children.

Foster care clearly differs in many ways from residential care and there may be different expectations about what each environment can offer a child. Fresh attachments may be more likely to develop where the caregiver is available most of the time, as in foster family care, as opposed to various carers operating on a shift basis as in residential care. In addition, relationships between children and their foster carers, who tend to be older than parents of similar aged children in the general population (Triseliotis *et al.* 2000), will undoubtedly differ from relationships that residential care staff, who may be only a few years older, have with the teenagers they look after. This has important implications for limit setting and for the maintenance of emotional and sexual boundaries. In a small but influential study, Colton (1988) gathered both qualitative and quantitative data from 12 foster carers and the senior member of staff of 12 children’s homes in England. Data from structured interviews suggested that foster placements were more child-orientated, had better physical amenities and children had more community contacts than those in residential care. Direct observation of care practices showed that foster carers used fewer ineffective and inappropriate techniques of control and used warmer, more approving, informative (as opposed to controlling) speech than residential care staff. Children received more adult attention in foster homes and their perceptions of their environments compared favourably with those in residential care. Berridge & Brodie (1998) confirmed these findings and also found that, in the residential homes they visited, virtually no specialist educational input or professional help was available to enable the young people to deal with psychological problems.

However, Sinclair & Gibbs (1998) found that children who had experienced painful foster care breakdowns sometimes preferred the residential environment and that child outcomes can

be improved where a set of coherent goals promotes a healthy staff culture (Brown *et al.* 1998). A significant proportion of foster placements 'break down'; that is, the child has to leave the placement, in a manner that is not in accord with the plans of the social work department. Rates of breakdown as high as 35% have been quoted for what were planned as long-term placements (Strathclyde Regional Council Social Work Department 1991) and 10% for short-term placements (Berridge & Cleaver 1987). Many see this high rate of breakdown as one of the major flaws of foster care. For all concerned, a precipitous placement ending is traumatic, not least for the child who is left with an uncertain future. When a child has experienced a series of placement breakdowns, residential care may be seen as the 'end of the road' or, alternatively, as a relief from the pain of forming relationships that may fail again.

Table 22.1 sets out some of the similarities and differences between foster family and residential care in the UK, although it offers only broad comparisons. The information has been taken from UK studies and national statistics (Colton 1988; Knapp 1997; Sinclair & Gibbs 1998; Triseliotis *et al.* 2000).

Some evidence exists of important differences between the population of children in residential care and that in foster care (see Table 22.1; Sinclair & Gibbs 1998; Triseliotis *et al.* 2000). While children of all ages are in foster care, residential care accommodates mainly teenagers. The length of stay in foster care ranges from a few days to a whole childhood, whereas in residential care the length of stay is now much reduced to an average of 6 months. In the UK, the collection of data on ethnicity for children in local authority care is now mandatory, but accurate statistics do not yet exist. UK research suggests that between 8 and 22% of looked-after children are 'black' (Barn 1993; Mehra 1996), but differences in definitions of ethnic groups make interpretation difficult and the ethnic mix in different care environments is as yet unknown.

Abuse in care

The experience of children in public care cannot now be discussed without reference to scandals over extensive physical and sexual abuse by residential workers which have resulted in highly publicized inquiries in the UK. For example, a study of Welsh children's homes described extensive abuse of residents by staff (Welsh Office 2000). The protection of children who have been sexually abused may be inadequate in both foster and residential care, with vulnerable children sharing rooms with children with a known abuse history (Farmer & Pollock 1998). Residential care has been so much vilified that many have questioned whether there remains a place for such provision at all. Scandals sometimes alert public attention dramatically and can trigger reform, better training, more inspection, stricter quality control and quality assurance. Foster care has also been criticized, although the discussion of these forms of alternative care is best undertaken in comparison with the outcome for children who had not been removed from home.

Table 22.1 A comparison between foster family care and residential care in the UK

Foster family care	Residential care
Carers live in own home	Carers live away from setting
Paid an allowance	Paid a wage
On average 1.7 children present	On average 7 children present
4 out of 10 children over 10 years old	9 out of 10 children over 10 years old
Age range 0–18	Age range usually 5–18
Roughly equal sex ratio	6 out of 10 boys
Individualized care	Group care by a sequence of carers
More child orientated, e.g. child generally has access to all areas of the family home	More institution orientated, e.g. child usually excluded from the office
Better physical amenities (e.g. higher ratio of baths/locking toilets to residents, more personal effects such as photos, posters, etc., in bedrooms)	Poorer physical amenities
Emphasis on good family and community contacts	Traditionally more isolated from family and community, but improving in this respect
Long-term placement common	Long-term placement now rare
Direct costs low	Direct costs high (staff and building)
Indirect costs high (social work support, carer recruitment and training)	Indirect costs low
Pre-placement training almost universal but variable in quality. Qualifications rare	In-service training common, but variable in quality. 1 in 5 staff have a residential social work qualification
Composition of the family group generally more consistent	Permanent peer group unlikely
Balance of care and control	Frequently more control than care
Often more children than adults	More staff than residents

A British study (Hobbs *et al.* 1999) has compared reported abuse in foster and residential care with that in a general urban population. Children in foster care were 7–8 times, and children in residential care were 6 times more likely to be reported as physically or sexually abused compared with children in the general population. The study points out that in addition to abuse by carers, abuse could be perpetrated by, amongst others, birth family during contact or by other looked-after children. This highlights the risks of placing vulnerable children together in the same home, where victims may become perpetrators. A Scottish study found that 91% of residential placements caring for children who had sexually abused others also cared for children who had been sexually abused (Lindsay 1999). Farmer & Pollock (1998) found that one in five sexually abused children in care had sexually abused other residents in children's homes, or

foster homes. Little therapeutic help was being directed specifically at the abusing behaviour and carers had great uncertainty about managing the sexually indiscriminate behaviour of adolescent girls.

Does the reported increase in abuse in foster family care reflect the real prevalence? Foster families in Baltimore had over a threefold increase in the frequency of maltreatment reports, particularly physical abuse, as compared to non-foster families, although a smaller proportion were substantiated. There are various possible reasons for this finding. First, increased vigilance over children in foster care may increase *reports* of abuse. For example, in Baltimore, no corporal punishment at all is allowed by foster carers, whereas some of the local schools still allow corporal punishment, so a lower threshold for reports undoubtedly exists for foster families (Benedict *et al.* 1994). Secondly, children in foster care tend to have more of the risk factors for child abuse, such as physical and learning disabilities and behavioural problems. A study comparing 78 children who had been abused or neglected while in foster care with 229 who had not, showed that those abused while in foster care were significantly more likely to have mental health and development problems (Benedict *et al.* 1996a). Thirdly, some biological families may make reports of abuse in foster care in the hope of making a return home more likely (Benedict *et al.* 1994). It is possible that foster carers may be more likely to abuse children who are not biologically their own, but this is unproven.

There has been increasing recognition that certain adults may actively seek out opportunities to abuse vulnerable children. This, plus the past experiences of looked-after children and those children with whom they are placed, put this group at heightened risk of abuse in the very settings designed to protect and care for them (Gallagher 1999).

What is known about the emotional and behavioural functioning in each environment during childhood?

Knowledge of the clinical status of children and young people in the care system has often relied upon research enquiries conducted in specific child welfare organizations or in selected areas of the country without the benefit of not-in-care controls. Until information in child care agencies is routinely collected, processed and analysed—a promise held out by the Looking After Children materials promoted by the UK Department of Health (Parker *et al.* 1991; Ward 1996)—the following findings are the best information on children in care. Studies have consistently shown elevated rates of problems compared with children never in public care. The range of findings suggest real variations in the prevalence of mental health problems in foster care because of location, placement length and characteristics of children, but no decrease in prevalence with time.

Early studies (Parker 1966; Lambert *et al.* 1977) showed between one-third and one-half of children to have problems of clinical significance. The study by Rowe *et al.* (1984) on long-

term foster care was one of the first in the UK to use an established measure: the Rutter A Scale. The study concluded that 29% of children in long-term foster care between the ages of 5 and 15 years scored at or above the cut-off for disturbance. Common problems were temper tantrums and lack of concentration. Although this rate was many times higher than found in general population data, it was not as high as other studies of similar populations. This may have been because the children were a fairly stable group. Thorpe (1980), in contrast, found that 39% of her sample were disturbed.

St. Claire & Osborn (1987) found that children in foster care, and more so in residential care, had substantial cognitive deficits and problem behaviour even after allowing for possible confounding variables. Although those who had spent time in residential care showed more antisocial behaviour, it is possible that behaviour problems were present before admission to the residential placement. Problems were thought to be caused by pre-care experiences and pre-existing behavioural difficulties rather than aspects of the current placement environment.

More recent studies have also shown a high rate of mental health problems. Quinton *et al.* (1998) found high levels in a neglected and abused sample immediately after being placed from care into new intended permanent family placement: 54% of boys and 58% of girls were beyond the cut-off for psychopathology. That the mean scores for the group did not differ significantly across the first year of placement shows this was not a momentary phenomenon as a result of the transition to a new family. A two-stage cross-sectional study of all adolescents in care in Oxfordshire, with a comparison group matched for age and sex, used the Achenbach Child Behaviour Checklist (CBCL) as a screening instrument, then interviewed high-scorers using the semistructured Kiddie Schedule for Affective Disorders and Schizophrenia (K-SADS; Chambers *et al.* 1985). The prevalence of psychiatric disorder was 67%: 57% for adolescents in foster care and 98% in residential care. This contrasted with only 15% in the comparison group (McCann *et al.* 1996). A replication of the McCann study, based in a small local authority in Scotland (A. Addo, A. Blower, L. Lamington & K. Towilson, personal communication 2000), has found lower rates (54%) of psychopathology in looked-after children.

Dumaret *et al.* (1997) have examined psychological problems in fostered children of below-average IQ. A cross-sectional case note review was made of all children with IQs of 60–90 who were in foster care ($n=127$) in seven areas in France. All were adopted from foster care after the age of 4 years and had had a full assessment in the year before adoption. At the pre-adoption assessment, nearly half had emotional/psychological problems—nearly four times the French average. Factors associated with mental health status included maternal learning disability, late age at first adoption and a history of abuse and neglect.

Few studies have focused solely on residential care, but a UK study examined the psychological status of the residents (Sinclair & Gibbs 1998) using an interview-based well-being measure (Angold *et al.* 1987) on their sample ($n=216$) and

found the following problems were present for more than half the group: 'worried', 'unhappy', 'nervous', 'easily upset' and 'poor self-opinion'. Forty per cent had thought about killing themselves. This was clearly a very troubled population.

Prevalence studies such as these beg the question 'to what extent were these problems present prior to entering local authority care?' A case-control study compared 50 children who were in foster care as a result of abuse or neglect for at least 3 months with 50 children eligible for Medicaid (from low-income families). Mean CBCL scores were higher for the foster care sample, but differences were no longer significant when controlled for family structure and stability, suggesting that the experience of foster care itself was not contributing to the children's problems (Hulsey & White 1989). At entry to an episode of care, children appear to have approximately twice the prevalence of emotional and behavioural problems expected in the general population (Dimigen *et al.* 1999).

Although not definitive, the research suggests that residential care is detrimental to children's mental health, whereas foster care may improve it. A Finnish longitudinal study of 53 children in residential care found that emotional and behavioural problems worsened over 2.5 years, while a UK study of 141 children in 48 children's homes reported little change in mood or adjustment over 6–9 months follow-up (Gibbs & Sinclair 1998). In contrast, prospective studies of children in permanent family placements have shown that emotional and behavioural problems are improved or unchanged 9 months–1 year into placement (Rushton *et al.* 1995; Quinton *et al.* 1998; Minnis 1999).

One of the most direct pieces of evidence that foster care can, of itself, be therapeutic compared to other forms of care, comes from Iraqi Kurdistan. Fifty-four orphans (24 in orphanages and 30 in foster families) were assessed using the CBCL and a checklist for post-traumatic stress disorder (PTSD). Total problems on the CBCL increased in the orphanage group while significantly decreasing in the fostered group. The orphanage sample reported a higher incidence of PTSD than the fostered group (Ahmad & Mohamad 1996). This suggests that mental health may improve in foster care and deteriorate in residential care, but the story is unlikely to be that simple. Children may be placed in residential care because their problems are considered too severe for a family to deal with, therefore these children may be a more disturbed group when first accommodated. A paper reporting on a study carried out in the 1970s has helped to tease out the effects of prior problems from the effects of the care environment by studying children from similar social environments who experienced either residential or family foster care. Both groups were compared with classroom controls and although both were more prone to hyperactivity/inattention, such a problem was substantially more marked in the group who had experienced residential care (Roy *et al.* 2000).

Several points need to be made about the higher levels of problems frequently found in residential care samples.

1 These differences are likely to be most evident when the placement environments are very distinctly dissimilar, for example, when comparing lack of individualized care in a children's home

with stable life in a foster family. However, if the comparison were to be drawn between similar children, one group in a small stable children's home with a family atmosphere and the other in a large foster family, the differences might reduce or disappear.

2 The differences could result from the fact that populations entering these environments are different, particularly in age, background and abuse histories, and comparisons can be misleading without employing matched controls.

3 The means of assessment may have a biasing effect. Interviews with children may detect emotional problems better than child self-reports and biases may be inherent in using the carer as the informant. For example, it is possible that foster carers and residential workers may underrate problems, as they are used to living with children with a high rate of difficulty and so minimize the difference from the general population.

Perspectives of the children

Information about in-care populations has tended to be gathered via carers, social workers and teachers. A recent research development has been to elicit information from the children more directly. This has so far produced softer data, but developments in appropriate techniques for conducting research interviews with children may add an important dimension to knowledge about substitute care. Several investigations have asked the children themselves about their experiences as foster children or children's home residents. In a study by Kufeldt *et al.* (1995), 40 foster children were asked to complete a structured assessment both on their own family and on their foster family. They regarded their foster family as significantly more 'healthy' than their birth family. McAuley's (1996) small-scale study used semistructured questionnaires to elicit responses from foster children about their lives, feelings and wishes. Sinclair & Gibbs (1998) used structured interviews with over 200 children, asking especially about their experience of the children's home and its 'social climate', their families and their social workers. Not surprisingly, the young people wanted a good physical environment and friendly staff. They found their sense of subjective well-being was strongly related to the extent of current bullying and harassment by other residents. These direct interviews may help to bring out features of the children's world to which adult assessors may be less attuned. For example, one boy described to Biehal & Wade (1996) his feeling of alienation from family life:

'It were just a family I saw in the park once. Christmas day. So I went out for a ride on me bike, sat on a park bench watching these kids play. They were flying a kite so I went up to them and says 'what's it like having Christmas with your family?'

Physical health

This chapter is concerned mostly with psychological problems but we briefly mention physical health because of the obvious links between the two areas. It is not unusual for physical health

problems to fall through the net, often because of difficulties with tracking medical notes and poor communication between services. A US study of children in kinship care, showed that approximately half the children had not clearly received all their immunizations and the level of undetected health problems suggested inadequate primary care (Dubowitz *et al.* 1994). In the UK, all children entering an episode of care are meant to have a routine medical, but Polnay *et al.* (1996) have concluded that the system of assessment and treatment of physical and mental health problems of children in residential care is often unsuccessful because the routine medical examination is frequently avoided by young people. They recommend the use of self-completion health questionnaires and improved training of residential care staff in health promotion to further the goal of optimum health.

Education

Education is known to protect the mental health of high-risk children (Rutter 1985), yet many looked-after adolescents attend school only intermittently and are at considerably higher risk of exclusion than others (Blyth & Milner 1996; Fletcher-Campbell 1997). In England and Wales, over 75% of care leavers have no educational qualifications at all and only 3% attain five GCSEs compared with 60% in the general population. Educational expectations have been found to be low and academic success limited in both residential and foster care (Jackson 1989; Cheung & Heath 1994; Heath *et al.* 1994) and school absence of children in residential care is particularly high (Sinclair & Gibbs 1998).

A study comparing ex-care adults who had been particularly successful in educational terms with their less successful peers has emphasized the importance of school for children in care. Educational success was associated with better mental health and greater life satisfaction, whereas children who had not achieved educationally were many times more likely to be unemployed, single parents or homeless. Factors associated with educational success in care included experiencing at least one stable placement, having a parent or carer who valued education, having out-of-care friends and interests, learning to read early and attending school regularly. High educational achievers were no more likely to have had educated birth parents. Residential care seemed to be a particularly discouraging environment. Ex-residents described a lack of interest in school by staff and poor facilities for homework. In contrast, carers who read to children and encourage the use of books and libraries may be providing them with some of the most important protective factors for their psychosocial development (Jackson & Martin 1998).

Relationships within and outside the placement

Relationships in any family are complex, but children looked

after in foster or residential care are expected to negotiate a network of relationships of a different order of magnitude. Children in foster care may have attachments with foster carers, the carers' biological children, their own siblings (either in the same placement, living in a different placement or with the birth family), other foster children from different birth families, and with their own biological parents. Children in residential care may have attachments to a range of residential social workers, with their own biological family and with other children in the residential placement.

Attachment relationships assume great importance for children in foster or residential care who have inevitably suffered separation and loss and are likely to have had insecure attachments with primary caregivers. Insecure attachment is known to be an important risk factor for later psychosocial functioning (Crowell & Feldman 1988; Goldberg 1991; Lyons-Ruth 1996; Warren *et al.* 1997), and there is limited evidence that relationship styles with birth parents may predict the formation of fresh attachments with foster carers. A US study measured internal representations of self and primary attachment figures in 32 children entering foster care for the first time from a birth family in which they had suffered abuse. These representations significantly predicted children's subsequent views of their relationships with their foster mothers and their behaviour in the new placement (Milan & Pinderhughes 2000). Stovall & Dozier (2000) investigated the development of attachment between young children and foster carers by asking carers to complete a daily diary of attachment behaviours over the first 2 months, and by using more traditional methods to measure carer-child attachment and the foster mother's state of mind regarding attachment with her own parents. For infants placed below 12 months of age, the attachment style with the carer tended to reflect that of the foster mother with her own parents. However, those placed after 12 months tended to have persistently insecure attachment styles with the foster carer.

The question of whether or not a 'blood bond' is important for the formation of secure attachment is obviously pertinent to foster family and residential care, but most of the evidence in this area relates to adoption. The attachment styles of adoptive mother-infant pairs and controls appear to be similar (Singer *et al.* 1985) and no differences are found in middle childhood between the adjustment of biological children and those children adopted in infancy. This suggests that a blood bond is not fundamental for secure attachment. Late adopted children have more problems (Triseliotis *et al.* 1995). Emotional and behavioural problems themselves do not appear to be associated with placement breakdown but, when attachment problems are also present, the balance may be tipped towards placement instability (Rushton *et al.* 2000). Satisfying relationships do develop within the first few years of placement, even with older children placed with the intention of permanence (Rushton & Mayes 1997). Whether 'permanency' in terms of adoption helps attachment with new caregivers remains controversial, although a review of the literature on permanency planning and its effects on foster children found no difference in the psychosocial

adjustment of children where permanency planning had taken place and those where it had not (Seltzer & Bloksberg 1987).

Contact with the birth family

Which relationships are most important for looked-after children? Interviews with children in residential care on the subject of contact have given perhaps surprising results. Around half wanted more contact with siblings, one-third more contact with their mother and a significant minority wanted more contact with former foster carers. However, 25% of the children wanted *less* contact with their mother (Sinclair & Gibbs 1998). Qualitative research with foster families suggests that, within the foster family itself, children feel most able to confide in the foster mother. However, they tend to love and to think that they are loved by their birth families ‘most in the world’, despite usually being admitted to care because of abuse or neglect by the birth family. One year into placement, they still think and dream about birth parents frequently (McAuley 1996), but tend to rate their emotional involvement with both birth parents and carers as low (Kufeldt *et al.* 1995). These studies paint a picture of children lacking in warm trusting reciprocal relationships whose yearnings for closeness and support from their birth parents are unfulfilled.

Where the plan for a child in a family placement is not to return home, the degree of contact with birth parents that is beneficial remains controversial (Quinton *et al.* 1997). It has been found that the less contact a child has with the birth mother, the less secure they feel in the foster home (Fanshel *et al.* 1990) and that children who visit their birth parents more frequently are more likely to rate their parents as healthy/normal (Kufeldt *et al.* 1995). This has been seen as evidence that contact with birth parents is good. However, children coming from better functioning birth families may be more able to maintain relationships in general—both with the birth and the foster family. Also, better functioning birth parents may be more able to maintain contact with their children. It may be unwise therefore to assume that relationships with birth parents should be maintained regardless of the nature of that relationship. Where co-operative working between foster and birth families can be maintained, however, there is evidence that contact may benefit the child. Foster placements appear to be more stable where birth parents have prepared children for placement (Palmer 1996) and foster carers’ anxiety about young children’s contact with birth parents is associated with poorer child adjustment (Gean *et al.* 1985).

A child’s entry to care can be traumatic for all the family, and parents are often left confused about their rights and obligations, making visiting difficult (Millham *et al.* 1986). Around one-third of children in UK residential care see one or more of their birth parents more than once a week compared with around two-fifths of children in medium to long-term foster care, while around one-fifth of children in both settings have no contact with parents (Sinclair & Gibbs 1998; Minnis 1999). A Scottish survey of 835 foster carers found that, while the

majority of foster carers were well disposed towards birth parents, negative reactions were also common. Most carers preferred contact to take place outside their home. Just over half had experienced difficulties with contact, including verbal and physical attacks, seeing children being let down by parents who keep inconsistent contact and having the family routine disrupted by parents coming late or staying too long. Such difficult relationships between adults who have significant roles in a child’s life are likely to place additional stresses on children (Triseliotis *et al.* 2000). Until recently, children in residential care have tended to be relatively isolated in institutions, and there has been little focus on building relationships with their families, whose relationship difficulties may often be very entrenched. The nature of institutions may prove more of a barrier for visiting for some families, while others may find it more difficult to enter another family home, but practitioners are being urged to remove barriers and to work more in partnership with families (Hill 2000).

For the majority of children, placement in foster or residential care leads to separation from siblings, and looked-after children may have siblings living in a variety of situations, both in and out of the care system (Kosonen 1996a). Siblings can provide much care and support for each other (Cicirelli 1995; Kosonen 1996b) and the inclusion of siblings in planning for looked-after children has been a relatively neglected area of research and practice.

A new initiative of ‘concurrent planning’ (Katz 1999) is an attempt ‘to work towards family reunification while, at the same time, developing an alternative permanent placement’. Foster carers recruited to these schemes are expected to work towards family reunification, but to accept the child on a permanent basis if this is not successful. This will clearly require a different attitude on the part of biological parents and foster carers towards one another, plus a great deal of training and resources for it to be a success. The effect on the mental health of children in care of having to negotiate new relationships, separations and losses is an area requiring research. Whether or not concurrent planning can make these transitions easier for children remains to be seen. Until this information is available, practitioners must continue to work with individual cases while attempting to balance the full complexity of the child’s situation.

How does kinship foster care compare with traditional foster care?

Kinship foster care can be defined as the placement of children in public care into the homes of extended family members who have been formally approved in a similar way to traditional foster parents. This relatively new development is the fastest growing placement practice in the USA, particularly for African-American families, and is more developed than in Europe. A major aim is to reduce dislocation for children placed in care and to retain them in the extended families and communities familiar to them, thereby maintaining their cultural and ethnic

identity. Many questions remain as to whether this practice genuinely benefits the children and the focus here will be on findings from outcome research.

A comprehensive review of research reports (Scannapieco 1999) has compared findings and concluded that kinship foster care research is still in its infancy, being frequently compromised by small samples and problems with representativeness, lack of equivalence in the samples and differing outcome measures. Berrick *et al.* (1994) and Iglehart (1994) have reported that children in kinship care have fewer developmental and behavioural problems than those in foster care, but it is possible that children with more serious maltreatment histories are generally placed away from their relatives. Maternal grandmothers are the most frequent carers and kinship carers in general are likely to be older, less educated, have lower incomes and be in poorer health than foster carers (Dubowitz *et al.* 1994). This suggests that although the children remain in a familiar environment, it is also a materially poor environment, similar to that of the birth families. Research on the intergenerational transmission of attachment styles (Fonagy *et al.* 1991) implies caution in placing children with grandparents. Parents who provided inadequate parenting may have themselves been brought up by parents who did not provide adequate care.

The Benedict *et al.* (1996b) study has produced some of the most valuable follow-up data. Former foster children were between 25 and 35 years old when interviewed to assess their adult functioning. Comparisons were made between the total sample of former foster children ($n=71$), comprising kinship foster care children ($n=31$) and non-relative foster children ($n=40$) and groups of children matched for age, gender and ethnicity who were never separated from their birth families. Both fostered groups fared less well than never-placed comparisons. Differences in social support, behavioural adjustment and mental health status were not very pronounced, but those placed in non-relative foster homes were more likely to have experienced homelessness, to have been unemployed and to have a lower standard of living. This reinforces the argument for helping foster children leaving care to find and maintain adequate accommodation and to enhance their educational achievements. However, it is not possible to establish from research based on a cross-sectional follow-up whether the differences the researchers found resulted from the types of placement in themselves or from other mediating variables, such as preplacement experiences.

What is the longer term outcome for foster family and residential care?

Considering the levels of emotional and behavioural problems noted in childhood, studies of ex-foster care adults, as a whole, give a surprisingly positive picture. However, inherent difficulties exist in evaluating longitudinal studies of this group. The type of care provided in various settings may have changed radically in the years since the subjects were in foster care, so the

findings may have limited relevance for today's practice. It is also hard to compare residential with foster care on these outcomes as the populations entering different kinds of care may differ. Notwithstanding these differences various studies are worthy of comment. Buchanan (1999), in a recent analysis of the National Child Development Study data, showed that children who had been in care (types of placement cannot be distinguished in this cohort) were less satisfied with their lives at age 16 and significantly more at risk of depression at age 33. Despite this, three-quarters of 16-year-olds and four-fifths of 33-year-olds did not have psychological problems. Life satisfaction was associated with qualifications, jobs and partners.

Fanshel *et al.* (1990), in a retrospective cohort study of 'special needs' children in foster care, showed that 66% of respondents were wage-earners, with only 10% receiving public assistance. Thirteen per cent had serious drug problems, with one-third having had such problems in the past. One-quarter had had alcohol problems, 13% currently. In a later cross-sectional survey of 'alumni' of the same programme, most saw their experiences in foster care as positive and only 6% were unemployed, although there was no control group with which to compare (Wedeven *et al.* 1997).

A French retrospective cohort study of 63 adults reared in long-term foster care (for at least 5 years) found that the social class spread was similar to France as a whole and similar proportions of 'alumni' to the French national averages were married, were home owners and were employed. More were divorced (9 vs. 3.9%) and had no high school diploma (67 vs. 21.8%), one-third had used drugs, one-quarter had had charges or arrests for criminal activity and 13% described themselves as having health problems. Participants had better educational achievement the longer they had been in foster care and a poor educational outcome was associated with learning difficulties *before* going into care. Poor adult outcome was associated with social or psychiatric disorder in the birth parents and with problems such as abuse before going into care (Dumaret *et al.* 1997). A retrospective cohort study from the USA of adults who had been in long-term foster care gave a less rosy picture. Forty-two per cent had not completed high school, 31% were unemployed, 27% had been homeless, 54% had used drugs, 20% had been arrested, 45% had been violent to their partner and 35% had been victims of their partner's violence (Benedict *et al.* 1996b). The reasons for these geographical differences in outcomes are unknown, but they may indicate different levels of difficulty in children being fostered, different fostering environments, or different levels of psychosocial problems in the base populations in the USA as opposed to France. Little is known about outcomes for adults who spent a shorter time in foster care.

Studies of adult outcome from residential care are probably even more difficult to relate to the present day as the nature of residential care, and the kinds of children placed there, have changed a great deal in recent decades. One notable prospective study examined the long-term consequences for a sample of boys and girls raised in group homes in the 1960s (Quinton & Rutter 1984; Rutter *et al.* 1990). The adult follow-up of this

ex-care sample showed different outcomes for men and women. Outcomes for women, when compared with controls, showed an increased rate of psychiatric disorder and parenting problems. One-third were faring poorly at follow-up and predictors of poor outcome were found to be disrupted early years and having multiple caregivers. Predictors of positive outcome were good school experiences, the capacity to plan ahead, avoidance of relationships with men with problems and not having babies in adolescence. For both men and women, adult outcomes were, to some extent, dependent on the quality of relationships made after leaving care.

Almost all children in residential and foster family care in the UK eventually return to their families. For a young person still to be in care or enter care in late adolescence tends to indicate particularly poor family relationships. A UK study showed that only 8% of 16–18-year-olds leaving care returned to live with a parent, suggesting that those still in care in their late teens are those for whom a return home has not been negotiable. Only a minority of this age group had positive supportive relationships with a parent, although contact with extended family or older siblings could provide important sources of support for a significant minority. This was also true of foster families. However, many young people did not receive ongoing support from foster carers and voiced a great sense of loss after leaving care. Almost one-quarter of the young women had their own children on discharge from care (compared with only 5% of women of the same age in the general population; Biehal & Wade 1996).

Young people who leave care at 16–18 years may, in fact, have spent most of their lives with birth families, having been placed in adolescence. The successful placement of adolescents in foster family care is generally hard to achieve because of the difficulties recruiting families, the fact that these young people may have been exposed to adversity for longer and because of the severity of their emotional and behavioural problems. Residential care is therefore a common placement option (Department of Health 1999) but may fail to contain their difficult behaviour (Berridge & Brodie 1998). Specialist foster care has been considered as an alternative, but the rate of breakdown can be as high as 40% (Fratter *et al.* 1991; Strathclyde Regional Council Social Work Department 1991). An evaluation of one specialist fostering scheme for adolescents has identified possible predictors of placement breakdown (Fenyo *et al.* 2000). This confirmed the findings of placement research on younger children: the presence of a teenager near in age to a child in the foster home is a strong predictor of breakdown, as is previous placement breakdown and behavioural difficulties, specifically delinquency and truancy. Teenage fostering schemes are being subjected to local audit, but a prospective study which controls for preplacement adversities and which compares foster with residential care outcomes is still lacking.

To what extent does the environment a young person enters upon leaving care have an impact upon their later functioning? The years immediately after leaving the care system are likely to be crucial for adult adjustment. A UK study surveyed 75% of the Leaving Care Projects in England and Wales in 1996 and com-

pared the results with a similar study from 1992. Only 11% of care leavers between the ages of 16 and 21 were in full-time employment in 1996 while over half were unemployed, with a decline since 1992 in benefits and in financial assistance for further education and training. No doubt the economic and social climate into which a young person is ‘discharged’ from care will have an impact on his or her psychosocial adjustment. The study points out that 65% of 19-year-olds in the UK still live at home yet young people leaving care, who as a group have considerably greater difficulties than the general population, receive substantially less support in the crucial years of early adult life (Broad 1998). Young people from the general population go through a number of transitions in their late teens to early twenties, including leaving school, leaving home, setting up a home of their own and perhaps becoming a parent. For young people leaving care, these transitions are accelerated.

Young people leaving residential care may be doubly disadvantaged in their transition to independence compared to those leaving foster care. First, because of the greater likelihood of psychosocial problems in the birth family, residential care leavers may be less able to re-establish family links than those leaving foster care. Secondly, it is almost certainly harder to maintain relationships with members of a rotating staff group than with a foster carer. These young people may leave care with no one to confide in or who can offer them support. A large proportion of homeless youth and prison inmates have been in local authority care, evidencing a common transition from care into social exclusion (Jackson & Martin 1998). More research is urgently needed on this most vulnerable of groups.

Research on risk and protective factors helps explain why some children do well after local authority care while others do not. Earlier admission to long-term foster care and later discharge are associated with better outcomes for children, as is the absence of conduct problems. Recent policies emphasizing short-term placements may have allowed children to go in and out of care and caused delays in settling children who would benefit from long-term placements. The possibility exists of behavioural improvement for children placed under the age of 10, but this is much less likely for those exposed to longer periods of neglect and/or abuse (Minty 1999). Studies in the general population have shown that the most important predictor for good long-term outcome is a child’s ability to form one good relationship, not necessarily with a parent or relative (Rosenfeld *et al.* 1997). Helping a child form and maintain that one crucial relationship within the complexity of a life in care would be a useful ‘gold standard’ towards which services could aim.

Treatment in residential and foster care

Delivering treatment to children in the care system is notoriously difficult: partly because of the problem of continuity for children who may move placement (Bondy *et al.* 1990) and partly because of lack of recognition of children’s problems. A notable proportion of those diagnosed as suffering from major mental

illness in McCann *et al.*'s (1996) study had hitherto unrecognized problems and this was particularly true of major depression. Those who work exclusively with looked-after children may have particular difficulty in recognizing problems warranting referral because they have become accustomed to working with disturbed children. This suggests that more systematic screening for looked-after children is essential and the new Looking After Children materials may go some way towards achieving this in the UK (Polnay & Ward 2000).

Undertreatment may not be the rule in all countries. A US study of medication use by looked-after children suggested that children in foster care were prescribed medication three times more frequently than similar children from the general population, while being approximately twice as likely to have a diagnosis of attention deficit hyperactivity disorder (ADHD) or major depression (Zima *et al.* 1999). There was no mention, in this study, of psychological treatments, and prescribing in isolation from other therapies would be a cause for concern.

Accounts of treatment of children in foster care are rare and evaluation unsatisfactory (Bondy *et al.* 1990; Barrows 1996), but received wisdom states that psychotherapists are often reluctant to begin treatment because of the difficulties that arise when children, who may have made an attachment to carers, peers and a therapist, have to move placement, school and clinic, breaking all of these bonds at once (Bondy *et al.* 1990). Research on treatment in residential care has been equally sparse. Some residential placements, particularly in the USA, are seen as treatment *per se* but studies of residential treatment have rarely been randomized. Comparisons of different residential treatment modalities (e.g. behaviour therapy vs. transactional analysis) suggest that, regardless of the content of the programme, a proportion of children show behavioural improvement while in the placement, but these improvements tend not to be sustained on leaving care, depending on the family and social circumstances into which the child is discharged. Carefully selected children, however, may respond well to a period of residential treatment within a continuum of care which includes family placement (Curry 1991).

One innovative US model for improving the emotional and behavioural functioning of children in foster care was the Fostering Individualized Assistance Programme (FIAP) in which children aged 7–15, deemed 'at risk' of behaviour problems after screening, were assigned a specialist caseworker who coordinated and/or delivered such services as individual and family therapy, advocacy, educational assistance and financial help. This was assessed by randomized single-blind controlled trial and showed that, after 18 months, the FIAP group were doing better as measured by the CBCL than controls and there were fewer runaways in this group (Clark *et al.* 1994). Presumably a children's social worker could perform this task, but success would require ease of access to, and good ongoing communication with, a range of services.

Whatever specific mental health problems a child in foster or residential care displays, children in this group are united in having suffered separation and loss. The vast majority pro-

bably also had grossly distorted attachment relationships prior to coming into care. The social and relationship difficulties displayed by children who have either been maltreated or have never had the opportunity to form selective attachments are well documented (Tizard & Hodges 1978; Gaensbauer & Sands 1979; George & Main 1979; Chisholm *et al.* 1995) and include indiscriminate friendliness, restless inattentive behaviour, aggression and unpredictable social responses. These problems may not precipitate referral to mental health services, yet may make it difficult for new relationships to develop between foster carers or residential workers and the children they look after. Rushton *et al.* (1998) have shown that children with restless inattentive behaviour may not benefit even from concerted attempts to help them settle into new placements.

The development of methods for treating children with serious attachment difficulties is one of the major challenges to child psychiatry. A large body of research has demonstrated the association between reciprocal communication between parent and infant in early childhood and the quality of attachment (Ainsworth 1979; Denham 1994; Freitag *et al.* 1996; Klann-Delius & Hofmeister 1997; Reddy *et al.* 1997). Interventions that help carers to communicate sensitively with children and to understand behaviour as communication—a basic tenet of parental behaviour management training programmes (Webster-Stratten & Herbert 1994)—may prove to be beneficial for looked-after children. A randomized trial using a communication training programme for foster carers showed trends towards improvement in general mental health and attachment disorders in children (Minnis 1999). The training was based on 'Communicating with Children: Helping Children in Distress' (Richman 1993) and was delivered by a social worker using an adult education model (Minnis *et al.* 1999). The implementation of such programmes on a larger scale could perhaps be achieved by effective joint working between health and social services.

How can child and adolescent psychiatry best serve this group within the current structure of services? An English study of health provision showed that child and adolescent psychiatry provided patchy provision for children in care across the country (Kurtz *et al.* 1994). The needs of this group are now being recognized more widely, but service evaluations are still rare. Arcelus *et al.* (1999), in an account of a mental health service for children in care, found that more than two-thirds of referrals were for children with aggressive behaviour, but there was a striking absence of adult carers and informants present in the assessment. This presents a major treatment challenge because the therapies indicated for such difficulties usually involve parents or families. Where children engaged in treatment, and when there was enough stability in the child's life for treatment to be supported, both psychodynamic and cognitive-behavioural therapeutic techniques appeared to enhance children's coping skills. Family therapy in foster care is an area that appears to have been neglected by research. Newer treatments based on 'holding therapy' designed for children with attachment difficulties are being used in some centres (Hughes 1997), but no

formal trials have been carried out and such intervention remains controversial.

The only interventions with demonstrated effectiveness in reducing the emotional and behavioural problems of looked-after children are those delivered either in close liaison with foster carers, or directly through foster carers. A randomized controlled trial of a specialized fostering programme in the USA has shown benefits to children's mental health for those with the most severe emotional and behavioural problems. This scheme offered, on a weekly basis, 2-h group sessions for foster carers, 3–5 h of face-to-face plus frequent telephone contact with staff each week, therapy for child and family where appropriate and a significantly improved fostering allowance. While such interventions are clearly expensive, this trial also demonstrated cost effectiveness with an estimated \$10000 reduction in hospitalization costs per child (Chamberlain & Weinrott 1990).

If such benefits can emerge using highly trained and supported foster carers, could similar results be achieved in residential care? Residential staff may have little contact with child and adolescent mental health services and lack support in dealing with difficult emotional and behavioural problems (Hatfield *et al.* 1996), therefore interventions designed to support staff in dealing with such problems would be expected to benefit residents. However, Gibbs & Sinclair (1998) have pointed out that virtually all the therapies possible in residential care (including group and individual work) are also possible in foster care, without the same dangers of bullying and sexual harassment from other residents, or involvement in a delinquent culture. If lack of secure attachment is a fundamental difficulty for many looked-after children, placement with expertly supported foster carers who can provide this may be the most therapeutic option. Many child and adolescent mental health services in the UK provide one-off consultation for social workers or foster carers working with looked-after children with emotional and behavioural problems. While this model has merit in that it assumes foster families to be the main agents of change in children they look after, there is no evidence for its effectiveness. Ongoing partnership between mental health professionals and foster carers has, however, been shown to be successful. The work of the Clark and Chamberlain groups suggest that even children and young people with the most severe emotional and behavioural problems can be contained and successfully treated in foster care if the carers are well trained, supported and remunerated (Chamberlain & Weinrott 1990; Clark *et al.* 1994).

Conclusions

We now have good epidemiological data on the emotional and behavioural problems of looked-after children, but information is still lacking on the efficacy of interventions with these children and their carers. The rare attempts that have been made to conduct experimental trials of such interventions require replication and expansion. The extant literature shows a very high

prevalence of emotional and behavioural problems both in children going into residential or foster care, and in children already being looked after. The prevalence of problems is particularly high among children in residential care, and while some studies suggest that problems may diminish in foster care and worsen in residential care, a direct comparison is difficult because the types of child entering the two environments are probably very different. The concept of an adoption–foster care–residential care hierarchy becomes even more pronounced in the context of revelations of appalling abuse by child care staff. This argues for a smaller number of high-quality safe residential places for those who need and prefer them. A complementary need would then be recruitment and support of foster families and/or more emphasis on family preservation. Foster care appears to be more child-centred and has not suffered from the blanket adverse publicity directed at residential care. On the other hand, placement breakdown and indeterminate placements remains a problem in foster care. At the policy level, every country must scrutinize potential carers, maintain high standards of staff conduct, strengthen children's rights, listen to children's allegations and provide them with advocates. Recruitment of foster carers must be maintained in order to provide a pool of high-quality placements.

Improved channels of referral to existing Child and Adolescent Mental Health Services (CAMHS) would be one model for tackling the children's problems. However, the historical origins and culture of the child mental health and social services differ and it will be a major challenge to achieve genuinely joint working between these agencies. It may be that the structure of CAMHS, in which diagnosis depends in part on adult informants who know the child well, may not be entirely appropriate for delivering treatment to children in care. An alternative model of service provision is specialist CAMHS services for looked-after children and some of these are currently being evaluated. Specialist foster care, in which carers receive significantly improved stipends and training plus close and ongoing liaison with CAMHS, aims to help the child gain a secure base from which development and treatment can take place. This third model is the only one which has been shown to be cost-effective. Excellent 'joined-up working' between social services, health and education will be essential in achieving such a service and a positive change in this direction will take research, money and political will.

Contemporary trends in adoption policy and practice

Creating a family through adoption has changed considerably over the past four decades. Historically, adoption was a service for childless couples. Selection was based on finding a match between children, most typically healthy white infants, and prospective parents. Over time, adoption has become focused on the needs of children and on adoptive parents' actual aptitude for parenting. Further, the number of infants available for adoption has declined because of increases in effective contraception, available abortion and social acceptability for young single women keeping their babies. As a consequence, the criteria for adoption in Western countries have changed. Ethnic origins, age, and the physical and emotional health of the child, once limiting factors when the goal was to match infant and parents, are now less of an issue. Adoption of children who are older and have other special needs as well as interracial and intercountry adoptions are more common. In the last two decades the definition of parents' suitability to adopt also has changed to embrace single parents, gay and lesbian parents, older individuals, and families who are less economically advantaged. Finally, there is greater concern for all members of the adoption triad with some form of open adoption and the option to search for a birth child or birth parent becoming more common.

Drawing on an international literature base, this chapter reviews the outcomes of multiple forms of adoption and considers related conceptual, clinical and social issues. Risks for socio-emotional disturbance are examined in the light of developmental tasks and transitions for adopted children and their families. Implications of research findings are discussed in relation to mental health and prevention service needs of adopted children and their families.

Best interests of children in care

Children need a sensitive, caring and secure environment and individualized care. These needs provide the basis for serving the best interests of children when removal from their birth families is inevitable. When one considers the socioemotional or educational outcomes of children in care, adoption is preferable to being raised in foster care or in a residential setting (Bohman & Sigvardsson 1990; Maughan & Pickles 1990). Long-term foster care is the second best option in so far as it pro-

vides continuous individual caregiving (Minty 1999; Roy *et al.* 2000) and, in that sense, mirrors the situation for adopted children. This is also an important option because older children may refuse adoption, choosing returning to birth parents as their long-term goal. As is the case for adoption, older children placed in foster or residential care are more likely to have special needs and this affects the choice for placement (see Rushton & Minnis, Chapter 22).

While change is possible at many developmental points, the potential for change may be constrained by prior adaptations, highlighting the need for early decisions (Rutter 1999). Although delays should be avoided in deciding whether a child in care should be released for adoption or returned to their birth family, there is no consensus regarding the point at which delay becomes deleterious to child adjustment. Much is dependent on the child's age, experiences and, for older children, readiness for adoption. Unfortunately, decisions regarding children in care are often made in an adversarial environment where one camp is working toward removal of the child and the other toward maintaining the integrity of the birth family. To terminate parental rights, it must be proven that birth parents, usually the mother, has not acted responsibly in caring for and protecting her child, is erratic or errant in visiting and showing interest in her child's activities and well-being, and does not co-operate with child welfare and mental health systems to demonstrate convincingly that rehabilitation or life style change is likely. Birth mothers often love their children but cannot care for them. Removal of the child is another blow to their self-esteem, salvaged only by winning back the child or getting pregnant again. In some instances the adversarial process may be averted by including the birth mother and other family members in the planning process with arrangements made simultaneously for the birth mother and the child (Triseliotis *et al.* 1997). Providing empathy, options and resources (e.g. education, therapy or support), and access to some ongoing information about the child may facilitate a mutually beneficial decision. This approach may also increase opportunities for obtaining information about the birth family's biological and psychosocial history which is important for both adopted children and their adoptive families.

Delay may be caused in placement because keeping a sibling group together is the preferred option. The benefit of this remains controversial and results tend to be mixed (Triseliotis *et al.* 1997). On the positive side, harmonious sibling groups provide continuity and support for one another and an effort

should be made to keep such groups together (Barth & Berry 1988). However, limitations in adoptive family financial and personal resources may reduce the feasibility of this option.

Outcomes of adoption

Studies of community samples show a heightened risk for learning difficulties (Brodzinsky & Steiger 1991) and adjustment problems, particularly disruptive behaviour, in middle childhood and early adolescence (Wierzbicki 1993). This pattern applies to children adopted as infants as well as to those adopted later (Smyer *et al.* 1998). Recent criticisms of research methodology—related to use of convenience samples, lack of adequate comparison groups, small sample size, retrospective methods and subjective measurement—have renewed debate over whether or not adopted children exhibit more psychopathology (Haugaard 1998; Brand & Brinich 1999; Peters *et al.* 1999). Results of controlled epidemiological and longitudinal studies (Lipman *et al.* 1992) conclude that only a small subset of adopted children have socioemotional problems; thus, most adopted children adjust well. It is also notable that, with rare exceptions (Smith & Brodzinsky 1994; Sobol *et al.* 1994), children's perceptions of their own problems have not been solicited.

Conclusions regarding adjustment apply to heterogeneous samples. In the next sections, the risks for different forms of adoptions will be considered.

Children with special needs

Adoption policy supports a commitment to finding homes for all children, including children with special needs. The term 'special needs' applies to children who are adopted later (usually over the age of 5), are members of a sibling group, have medical conditions, physical and developmental disabilities, or mental health problems. Despite concerns to the contrary, most of these placements are successful (Barth & Needell 1995). Characteristics of adoptive mothers predicting positive adjustment at 5-year follow-up include having fewer initial reservations, more experience, strong religious beliefs and not being depressed (Glidden 1994). Low maternal education, child functioning and family income are unrelated to outcome. Vulnerability to adjustment problems and disruption is greatest in late adopted children, particularly when there has been an accumulation of adverse experiences (e.g. abuse, privation and rejection) and serious behaviour problems prior to adoption (Verhulst *et al.* 1992; Rushton *et al.* 1995; Howe 1998).

Interracial adoption

Discussions of interracial adoption focus on within-country adoption of non-white minority status children, typically adoption of black children by white parents in the USA (McRoy *et al.* 1997) and African-Caribbean children in the UK (Rushton & Minnis 1997). Some members of the black community maintain

that this trend reflects a bias against black families because of lower income status. Historically, black families have had more difficulty being approved for adoption. While there have been more assertive attempts to enlist black adoptive families, there is still a disproportionate number of black children in care (McRoy *et al.* 1997). Political issues aside, the outcomes for interracial adoptions have been positive and similar to that of intraracial adoptions (Rushton & Minnis 1997).

Interracial adoption also concerns native North American children. The history of adoption of native Indian children is rooted in violation of native rights and culture in the nineteenth and twentieth century when children were forcibly taken from parents and community and taught to depreciate their ethnic roots. Adoption into non-native families also violated the native practice of caring for children within the extended family. Moreover, the cultural distinctiveness, limited assimilation of native peoples, and paucity of models within the larger society may make it more difficult for native than for black children (Griffith & Duby 1991). In addition, native children have experienced poor relationships with adoptive parents and low self-esteem (Bagley 1990). As a result, adoption of native Indian children has decreased markedly.

Although society has moved toward greater acceptance of interracial adoption, the fact that the social context remains racist suggests that, when given an option, children should be placed in ethnically matched households (Rushton & Minnis 1997). When children are placed interracially, careful attention should be given to ensuring that adoptive parents have the understanding and sensitivity to support their children's ethnic identity.

Intercountry adoption

Intercountry adoption originated with efforts to rescue children victimized by war, epidemics and other calamities, or abandoned because of poverty and population control policies. Along with these humanitarian concerns, in some cases, intercountry adoption is motivated by preference of white parents for adopting infants and children who are not observably racially different or have special needs. Reports from a number of countries attest to the success of this form of adoption from parents' perspectives (Hoksbergen 1997; Cederblad *et al.* 1999). Moreover, children fare well with respect to ethnic identity and self-esteem (Cohen & Westhues 1995).

Intercountry adoptions do include children with special needs. Some children are in poor health, have neurological and developmental disabilities that are initially unknown or undisclosed (Johnson *et al.* 1992; Miller & Hendrie 2000), and have been exposed to prolonged privation. Such was the case for children adopted from Romania in the early 1990s, who have been the most comprehensively studied international adoptees. Although length of institutionalization of these children was related to cognitive deficits, even those exposed to extreme privation made medical, physical and cognitive gains, functioning within normal limits within 2 years on average (Marcovitch *et al.* 1997; Rutter *et al.* 2000). Moreover, cognitive gains were

retained when followed at 4 and 6 years of age (Castle *et al.* 1999; O'Connor *et al.* 2000b). Nevertheless, late adopted children continued to exhibit significantly lower cognitive test scores relative to earlier adopted Romanian and within-country adopted children.

Socioemotional outcomes are less positive. High rates of insecure and unusual attachment patterns, behaviour problems, inattention/hyperactivity (O'Connor *et al.* 1999, 2000a), and autistic symptoms (Rutter *et al.* 1999a) have been observed, particularly among late adopted children (Chisholm *et al.* 1995; Fisher *et al.* 1997; Marcovitch *et al.* 1997; O'Connor *et al.* 1999). Although some of these symptoms abate, insecure attachments were stable over at least 3 years (Chisholm 1998; O'Connor *et al.* 2000a). Relationship problems with peers also persisted even when family attachments were formed (Fisher *et al.* 1997; O'Connor *et al.* 1999). It must be recognized that indices of attachment developed from normative Western samples may not have the same meaning. For instance, behaviour such as indiscriminate approach was associated with being a favourite in the institution, an adaptive behaviour in an environment with limited caregiving resources (Chisholm 1998). It must also be recognized that although parents were not concerned at first, family relations and stress may worsen if time proves that children's initial interpersonal problems do not abate (Chisholm 1998).

Adoption by non-traditional families

Past prejudices against single-parent adoption have given way to acceptance with good result (Glidden 1994). When followed into adolescence, children adopted by single parents continue to do well (Groze & Rosenthal 1991). Single parents are usually older non-white and lower income women willing to adopt children with special needs. Although it would appear that the most difficult children are placed with those with the fewest resources, children in single-parent homes experience fewer emotional and behavioural problems than children in two-parent adoptive homes (Rosenthal & Groze 1991). There are some strengths in single parenthood, including commitment to both the child and adoption, capacity to handle crises, relatively simple family structure, independence, self-confidence, and ability to develop and use supportive networks (Shireman 1995). However, encouraging single parents to adopt means that financial subsidies, counselling, education concerning child development, and help with planning for the child's future are critical.

Adoption by gay and lesbian parents has also increased (Hersov 1994). Systematic studies of outcome are not available. There are probably more adoptions by gay and lesbian couples than is known to adoption agencies, as some single-parent adoptions fall into this category. Supports are provided within the gay and lesbian community but fuller acceptance would open access to a broader service system.

Open adoption

Traditionally, members of the adoption triad were protected

from the perceived stigma of adoption by confidentiality, with the intention of creating a situation in which all members of the adoption triad could get on with their lives. The reality was otherwise. In the 1970s, concerns with human rights and freedom of information coalesced with the human need to know and open adoption increased, as has search for birth parents by adopted children and adopted children by birth parents (Grotevant & McRoy 1997).

The term 'open adoption' refers to a continuum of arrangements ranging from confidential adoption, time-limited meetings with information relayed by the caseworker, ongoing information sharing mediated by the caseworker, to fully open adoption with direct meetings. The findings to date have applied to same-race infant private or independent adoptions. Grotevant and McRoy (1997) found that for 4–11-year-old children, outcomes of openness could be beneficial. Moreover, adoptive parents felt satisfied and birth mothers with ongoing contact showed better grief resolution than those without (Christian *et al.* 1997). It is also apparent that initial choices are not always permanent. Although most birth parents were interested in having information about their child, many did not want to interfere with their child's life or make the long-term commitment to a contact agreement (Hughes 1995). Contacts have been shown to decrease or stop after 5 years (Berry *et al.* 1998). Further, adoptive parents who chose open adoption for fear that they would not be able to adopt otherwise, tended to reduce frequency of contact over time. At this point it appears that adoptive and birth parents must negotiate arrangements regarding openness to fit their unique situations. Of prime importance is the impact of contact on the child and whether reduction in contact is perceived as a loss. Many issues regarding openness remain, such as how to deal with differing access to birth families for multiple children within a family and the fact that for some children contact is impossible.

With older children, the terminology is 'adoption with contact'. Triseliotis (1991) made a strong case for this, drawing a parallel with literature indicating that children's adjustment following divorce is related to consistent ongoing relationships with both parents. Opposing arguments claim that continuing contact will interfere with the children's bonding to their new family. Contact is adversely affected when the birth family opposes adoption (Parker 1999). However, lack of contact can also interfere if children continue to worry about their birth families and this can precede adoption disruption (Cohen & Duvall 1996). Some benefit accrues when a foster family, who have a relationship with the birth parent, are the adoptive family (Howe 1998). Clearly, empirical studies are required to show the conditions under which contact does or does not ease adjustment to the adoptive home.

Search for birth parents and birth children

The majority of adopted adults think about obtaining information or reuniting with birth relatives (Howe & Feast 2000).

Adoptees who search are usually female and relatively young. Although those who search are more likely to be ambivalent or dissatisfied about their adoption, this is not the sole reason for searching. Concerns regarding identity and understanding reasons for relinquishment are primary and a relationship with the birth parent only secondary (Howe & Feast 2000). Various types of relationships evolve following reunion, and early contact usually diminishes over time with approximately half of reunited individuals continuing to have contact after 5 years (Howe & Feast 2000). While feelings of emotional closeness are important, outcome is also mediated by geography, perceived response of birth relatives, or adoptive family members, sexual attraction, and expectations each party had of the other.

There are few social guidelines for how these family members should behave towards one another and clinicians may be able to help in negotiating the relationship. Consequently, they need to become knowledgeable about the search process (Gladstone & Westhues 1998). For instance, it may be necessary for the adoptee to deal with feelings regarding disloyalty towards their adoptive family. In addition, aspects of the reunion experience may underlie other issues that an adopted person presents within therapy. Also, help may be needed to resolve conflicts associated with expectations, inappropriate behaviour, role ambiguity, and differences in attitudes or values. Finally, help may be sought in dealing with the reality of post-reunion relationships and their outcomes.

Determinants of adjustment

Determinants of adjustment go beyond a specific type of adoption arrangement and entail an interdependent transaction between child characteristics, experiences prior to adoption and adoptive family characteristics.

There is now strong evidence of the importance that genetically determined traits bring to relationships. Evidence is strongest for a genetic basis for cognitive outcomes. Although adopted children's IQ scores correlate significantly with those of birth parents, children raised in adoptive homes score higher than those who remain with birth parents in disadvantaged social environments (Dumaret 1985). With respect to socioemotional characteristics, certain conditions—e.g. bipolar disorder, attention deficit hyperactivity syndrome (ADHD) and autism—appear to be more heritable than others (Rutter *et al.* 1999b). However, inheritance of other traits—e.g. temperament, criminality, other mental illnesses and substance abuse—is not so clear. Children born to parents with psychiatric disorder and antisocial behaviour are at higher risk for those problems but the risks are greater when the problems are also present in the adoptive family (Peters *et al.* 1999). The way genetics influences socioemotional functioning is probably indirect. There is a bidirectional transactional process between genetic and environmental influences, such that genetic factors contribute to children's experiences, making them susceptible to or protecting them from environmental influence and shaping the way that

others act toward them (Ge *et al.* 1996; Rutter 2000). For instance, adopted children at genetic risk for antisocial behaviour have been shown to receive more negative control from parents than children who were not at risk (O'Connor *et al.* 1998).

As well as genetic risks, clinical samples often include children adopted late who have been exposed to adverse experiences including abuse and neglect, multiple moves into care, early hospitalizations, admission to care after the age of 2 years, prolonged institutional experiences, lack of satisfactory parenting and birth parent rejection. Outcomes for children with adverse early histories are improved by being placed in cohesive families who are flexible decision-makers (Groze 1994), can tolerate differences in the child in relation to other family members, have realistic expectations (Barth & Berry 1988), and where fathers are actively involved in parenting (Westhues & Cohen 1990).

Developmental issues in adoptive family adjustment

Changes in family structure and relationships created by having a child bring stresses to all families. Becoming an adoptive family, however, involves additional features. Common to all adoptions, parents are required to go through an intrusive investigation for suitability to parent and readiness to adopt, and live with the uncertainties of the timing of placement and legal finalization of the adoption. Once placed, the child must be integrated into the immediate and extended family and social network.

For families adopting infants, the transition process is relatively non-stressful (Levy-Shiff *et al.* 1990) and the mother-infant attachment relationship is as likely to be secure as in non-adoptive samples (Juffer & Rosenboom 1997). Adjustment problems, if they occur, emerge in middle childhood and early adolescence when children have the cognitive maturity to understand that to be adopted necessarily means that they were relinquished by another family. Some adopted children subsequently become ambivalent about their adoption, experience feelings of loss and grief, and emotional or behavioural problems ensue. Another developmental milestone occurs when adopted adolescents grapple with the unknowns in their biological and personal histories which complicates normal developmental preoccupations. Although adjustment problems peak in middle childhood and early adolescence, they tend to dissipate in later adolescence and adulthood (Bohman & Sigvardsson 1990; Sobol *et al.* 1994). Therefore, it would appear that long-term adjustment for infant adoptees is related to normal developmental processes (Brodzinsky 1987) and individual coping styles (Smith & Brodzinsky 1994).

The transition to adoptive family life in older and other special needs children is more complex and the adjustment period lengthier. Not surprisingly, children who have experienced inadequate caregiving have difficulty putting trust in adults for love and protection and may be less adaptive in a new setting. While adoptive parents can usually understand the implications of

trauma, abuse and rejection that their adopted child experienced in the past, actually making accommodations can be difficult. Following placement, symptoms such as lying, stealing, challenges to family rules and lack of empathy may appear in adopted children (Pinderhughes 1996). When an adoption disrupts it is frequently attributed to children's attachment problems reflected in these symptoms. When at their most disruptive, adopted children may actually be testing the security of the placement, but these are not the signs of attachment formation that parents expect (Cohen & Duvall 1996). Restabilizing as a new family involves tasks for both adults and children, such as forming attachments and establishing rituals and rules. For adoptive parents, providing a secure environment while managing and setting limits on child behavioural problems without rejection by the child can be a challenge (Reitz & Watson 1992; Rushton *et al.* 2000). The restabilization process depends on family resources, supports and coping strategies (Groze 1994). Factors that interfere with this process include adoptive parents' inflexibility and difficulties in dealing with the adopted child's emotional needs, unresolved grief associated with infertility, unrealistic expectations and perceiving the child as incompatible with the family (Grotevant & Kohler 1999). Problems also arise when a child is placed in a family with a birth infant or child close to his or her age (Beckett *et al.* 1998). Step-parents who adopt older children may have difficulties in the transition process in tolerating their child's attachment to the absent birth parent. This is an important issue because step-parent adoption comprises the largest proportion of older child adoptions.

Although successful restabilization is the norm, ambivalence about the adoption may ensue and the child be returned to care during the probation period (Festinger 1990). All of this suggests that for families adopting older children and children who have experienced early severe adversity, selection and preparation of families and post-adoption services and supports have special importance.

Selection and preparation of children and families for adoption

Child welfare services and private adoption agencies are responsible for determining eligibility, evaluating tolerance for the risks of older and other special needs adoptions, and supporting and assisting parents in the adoption process (Triseliotis *et al.* 1997). Available information on children's genetic, medical and psychosocial history is described to parents and the implications for physical, cognitive and socioemotional functioning are discussed. For parents adopting children with special needs, meetings with experienced adoptive parents are arranged where they can talk about challenges and rewards of adopting these children. Adopting parents also are helped to reflect on the individual and family strengths and weaknesses they bring to adoption (Parker 1999). Despite these efforts, prospective parents have reported that there is insufficient discussion of the impact of adoption on birth children, inadequate targeted information for

subgroups of adopting parents (e.g. single parents), and that challenging behaviour is not always accurately presented. The need for both adopted and birth children's involvement in the adoption process has also been emphasized (Parker 1999).

Because it is not possible to know how parents will actually respond to their adopted child's emotional needs and behavioural characteristics, post-placement services should become a routine part of the adoption process for families adopting children with special needs. These must be health focused and aimed at helping adopted children and their families negotiate an important transition period. Such services could also permit timely intervention if difficulties arise. In fact, behavioural problems sometimes can be capitalized upon during the post-placement period to promote secure attachment; secure attachment is not threatened by children's emotional pain but how it is handled. Post-placement programmes can also help parents and adopted children when a return to care seems inevitable. These tasks cannot be accomplished by post-adoption support groups organized by the adoption agencies or by parent-run organizations. Such groups are important but cannot address struggles of individual families in developing relationships and usually do not involve children directly.

Some programmes have been developed specifically for use with adoptive families in the post-placement transition period. The Family Attachment Programme applies principles from both attachment theory and brief interactional family therapy in a series of exercises with the whole family (Cohen & Duvall 1996). The goal is to assist parents to understand and empathize with their child's pre-adoption experiences, explore losses the child and family have had and move into the future by punctuating new family roles, rituals and rules, establishing realistic expectations, facilitating effective communication, and encouraging risk-taking in self-disclosure in the service of building trusting relationships. To help children to situate themselves in terms of time, place and relationships with important people in their histories, tools such as the Life Story Book, Life Story Map, and genealogical diagrams are used. These help children express feelings, put confusing events into order, and create a more coherent narrative of the child's life that can be shared with their new family (Cohen & Duvall 1996; Triseliotis *et al.* 1997). Creation of a coherent narrative is recognized as an especially important component of an integrative sense of identity throughout the life cycle of adopted children (Grotevant 1997). Including all family members is critical in the post-placement period, when the primary task is family formation. Therefore, family focused programmes should take precedence over individual therapy for the child.

For infants, toddlers and preschool-age children, less verbally based services are most appropriate. With healthy international infant adoptees, Juffer *et al.* (1997) found a positive effect on attachment security, maternal sensitivity and infant exploration using a brief intervention involving a book concerning sensitive parenting coupled with an intervenor commenting on videotaped mother-infant interactions that illustrated sensitive responses. This was more effective than giving parents the book

alone. Infant-led approaches (Muir *et al.* 1999) also have been used in the post-placement period although systematic studies have not been carried out on adoptive families specifically (Cohen *et al.* 1999).

Post-adoption services should not be provided by the adoption worker responsible for placement whom parents may perceive as having the power to remove the child if problems emerge in the transitional probationary period. An arms's length arrangement whereby the family is seen by a mental health practitioner who maintains contact with the adoption agency is likely to facilitate a positive outcome.

Adopted children and their families in the clinic

Adopted children and adolescents have been shown to be over-represented in both outpatient and inpatient services, especially for disruptive behaviour problems such as conduct disorder and ADHD (Wierzbicki 1993; Moore & Fombonne 1999). In one study, although parents of adopted adolescents were more likely to make a mental health referral than parents of non-adopted adolescents with problems of similar severity, for children with more severe problems the referral rates did not differ (Warren 1992). Potential reasons for the increased mental health referrals of children with moderate problems include adoptive parents' greater comfort accessing services, hypervigilance about difficulties coupled with perception of their children as more susceptible to adjustment problems, and the fragility and consequent reactivity of adoptive families to even low level problems (Warren 1992).

Most families who seek clinical service receive the same service as non-adoptive families and often feel their problems are overly pathologized (Cohen *et al.* 1993). Mental health professionals typically do not have specialized training and may not understand the adoption process, characteristics of adoptive parents, the issues with which adopted children and their families struggle, the fact that the child's problems preceded adoption (Nickman & Lewis 1994), and that some difficulties arise as part of normative developmental transitions and crises in the adopted child or adoptive family life cycle (Brodzinsky 1987). In fact, it has been shown that adoptive families in treatment have greater psychosocial resources and better familial and marital functioning than non-adoptive families in treatment (Cohen *et al.* 1993). This suggests that strengths of adoptive parents can be utilized to bring about rapid changes. Treatment of non-adoptive families may be lengthier and more complex because marital and family problems contribute to and maintain child problems. Practitioners also may erroneously believe that some issues are specific to adoption and this could colour intervention. For instance, descriptive reports have indicated that adoptive families may not feel entitled to be parents and, as a consequence, have difficulty setting limits on child behaviour for fear of being rejected (Reitz & Watson 1992). However, when adoptive and non-adoptive families who were and were not re-

ceiving mental health services were studied, these traits were found to apply to families seeking service regardless of adoption status (Cohen *et al.* 1996). As suggested above, the difference may be that, given adoptive families strengths, they have greater potential for change. Finally, clinicians are not always aware of the patterns of recovery for children exposed to adverse pre-adoption experiences when placed in a positive family environment so that accurate information can be given (Rutter *et al.* 2000).

Unfortunately, the research literature has not examined outcomes of interventions with adoptive families. As discussed above, research findings suggest that adoptive families do well with less complicated brief interventions that help them to provide structure and limits for their child's behaviour (Schaffer & Lindstrom 1990; Cohen *et al.* 1993). For children who exhibit attachment disorders, interventions with a relational focus appear to be helpful (Jernberg 1989; Juffer *et al.* 1997; Muir *et al.* 1999). Children also may benefit from environmental manipulations, such as gradual exposure to stimulation, directing selective social approach and display of affection, and facilitating social pragmatic skills (Rutter *et al.* 2000). Cline (1990) has suggested a more extreme measure, holding therapy, which has gained attention from parents desperate for help with their severely attachment disordered children. However, the reputation of holding therapy is based on its extreme methods and extravagant claims and not on empirical evidence. There is an urgent need to test empirically all of these possible avenues of treatment.

An alternate solution to treatment of severe child behaviour problems is to remove the child from the adoptive family. Cohen *et al.* (1993) found that among adoptive families presenting for clinical service 5 or more years after adoption, 25% considered removal of the child whose behaviour they perceived as unmanageable as a solution to problems and 9% ultimately did so. Although in most cases removal could be averted with treatment, therapists must be sensitive to clues that removal of the child is the preferred solution so that this can be addressed directly. In other situations, a different kind of living arrangement that involves living away while maintaining contact can be an option. The intimacy of family life may be too threatening for children with significant attachment problems, although they do not want to sever connection. Unfortunately, in some cases a child has been removed from the adoptive home when the family only wanted respite care. It is important that clinicians have the flexibility to weigh a range of possible solutions.

Conclusions and future challenges

This chapter has reviewed advances in understanding the various forms of adoption. In the last decade, many of the prejudices and dire predictions of the past have given way either to acceptance or to serious systematic consideration. Although more is known about the process of adoption and its outcomes,

challenges remain for both researchers and practitioners. Specifically, the literature consistently supports the strengths of adoptive parenthood and the resilience of children, even those who have experienced adversity. There is a subgroup of children with special needs, however, who pose challenges to their families and to practitioners. Some of the challenges to practitioners arise because of lack of specialized training regarding adoption. It must be acknowledged that training can only go so far because we are lacking essential empirical information on the treatment of adoptive families. The need for information extends beyond special needs adoption and encompasses understanding the many forms of open adoption and adoption with contact, the critical time frame for making placement decisions and the exact criteria on which they should be based, and the long-term consequences of opening adoption records. Challenges also remain regarding intercountry adoption in terms of regulation of adoption procedures and working collaboratively with countries offering children for adoption to ensure that pre-placement care serves children's best interests. There does not appear to be evidence of the kind of political heat with respect to intercountry interracial adoption that is associated with within-country interracial adoption. Nevertheless, given the increase of intercountry adoptions, some of which are also interracial, it is important to track the experiences of the children with attention paid to issues of racism and identity.

Clearly, complex questions remain in the field of adoption for which there are no easy answers. They must continue to be explored systematically in order to create policies and practices that will protect children while being flexible enough to accommodate a variety of arrangements.

Introduction

The importance of a historical account of the development of child and adolescent psychiatry is threefold. First, the history displayed is one that illustrates change, disagreement and innovation in attitudes to childhood (Stone 1979) and then within the specialism itself, showing how nothing is constant through time and very few apparent truths are independent of historical circumstance and limitation. Even definitions of what constitutes a child and when adulthood begins remain in constant flux.

Secondly, history makes abundantly clear how psychiatry is fashioned within social and familial ideas of childhood and adolescence (Walvin 1984; Parry-Jones 1989, 1992). A world where children were put to work changed, in the late nineteenth century, into a world where children were sent to school. There they were inspected and tested and urged to embody social and legal values which had serious implications for their futures and for their mental and physical health. No longer hidden in the mines and back alleys, they generated a diverse psychoeducational enterprise, part of which was the child psychiatrist and the child psychotherapist.

Thirdly, history is the story of progress and assists in the task of estimating the future. More importantly, it seeks to avoid simple ideas of progress or prophecy and, instead, to show how all medical practices have their rationality and their purpose, even when seeming outdated to the modern mind. The most modern of therapies and the most sophisticated of disease entities will share in that fate, and history can both teach the need for modesty as well as describing how modern psychiatry came into being (Jones 1972) and helped fashion the present state of affairs (Collingwood 1946; Carr 1961; Evans 1997). This perspective also has the advantage of summoning a world where interest in children and adolescents as psychiatric subjects was at a minimum.

‘Until about a generation ago most psychiatrists knew little about children from first-hand experience’, wrote Leo Kanner (1935) in his seminal textbook. The history of the asylum and the growth of the psychiatric profession in the nineteenth and early twentieth centuries is paralleled by a history of marginality for the investigating of insanity in children. Unusual or difficult behaviour was enmeshed in conventional, often Christian, accounts of early social life, family experience and innate dispositions to evil doing. The language of morality and good conduct dominated both parents and children, and medicalized accounts of the life of the child made small—if any—inroads into that

established vocabulary (Pollock 1983; Steedman 1995). Some clinicians (Clouston 1880, 1891) attempted a psychiatry of adolescence, seeing it as the developmental stage wherein semiadult notions of will and responsibility might be invoked. In this enterprise they hoped to display how genuine forms of mental illness might be separable from whole clusters of moral judgments and moral accusations (Kett 1977). A true childhood psychology was also a late starter within the often contested growth of psychiatry as a whole and, in the twentieth century, had to face challenges from related but essentially adult-centred practices such as psychoanalysis (Walk 1964; Bynum *et al.* 1985/1988; Von Gontard 1988; Scull 1993; Shorter 1997). Even the specific developmental theories of the modern era, the psychosexual (Freud 1905), the social/generational (Erikson 1959), or the cognitive (Piaget 1926), can be seen to be overarching, to lack empirical evidence and to ignore key biological details.

There is also the historical need to distinguish childhood insanity from mental deficiency. The entry under ‘insanity in children’ in Daniel Hack Tuke’s (1892) *Dictionary of Psychological Medicine* sets a useful historical precedent, stating that insanity in prepubescent, non-imbecilic children was a subject of importance ‘*but not commonly observed*’. They might be managed at home and avoid the asylum, would not go to idiot schools and thereby would escape notice. The child, as imagined by the author of the entry, T. Clifford Allbutt, Regius Professor of Physic at Cambridge, lived in a world of fantasy and simplicity and imitation—suicide in children was for example an ‘imitative act’. The child’s internal world of simple and primary forms indicated a lack of reflection and yet was full of affect. Insanity in children was apparently almost always hereditary, although it might be brought on by bad upbringing and excessive study and was the ‘vestibule of the insanity of adults’. Allbutt even affirmed that: ‘There is as it were a veil between the mind of earlier and the mind of later life’ (Allbutt 1892), and his approach gives a sense of the late Victorian dilemma in dealing with the reality of ‘childhood insanity’, a dilemma matched only in its uncertainty by the elusive nature of the condition itself.

Early accounts

Early accounts of the development of child psychiatry (Walk 1964; Stone 1973; Brandon 1986; Von Gontard 1988) tended to focus on clinical anecdotes beginning in late Enlightenment

England. Walk began with one of the cases most repeated in the subsequent literature, that of a child born ‘raving mad’ and mentioned by Alexander Crichton in his *Inquiry into the Nature and Origin of Mental Derangement* (1798). When 4 days old it took four women to hold the child down, and he was also prone to uncontrollable fits of laughter. Walk also described a case in William Perfect’s *Annals of Insanity* (1787) and three in John Haslam’s *Observations on Madness* (1809). A notable aspect of the latter was his somewhat dismissive telling of stories about patients for whom nothing could be done, and one case being a ‘convincing description of simple schizophrenia’ in a boy of 10 (Walk 1964). The distinguished ethnologist and doctor, J. C. Prichard (1835), also used a case of moral insanity in a girl of 7 to illustrate the proximity of a psychiatric diagnosis to common Christian notions of foul and immoral behaviour.

Other important contributions can be found in the work of W.A.F. Browne (1805–1885) and his son James Crichton-Browne (1840–1938), and in the phrenological writings of Andrew Combe (1797–1847), all of whom admired the French psychiatrists J.E.D. Esquirol (1772–1840) and Felix Voisin (1794–1872). Esquirol actually wrote that infancy is ‘secure from insanity’, while then going on to discuss a manic child aged 8, another aged 9 and a melancholic aged 11. He stated that mental alienation can only begin at puberty, and that it is only ‘dementia’ that is sometimes observed among the young. Suicide could appear in schoolchildren but usually after a ‘vicious’ education. None the less, for those believing in the notion of infantile insanity, Esquirol was the champion. He gave enough authoritative, although exceptional, examples for later writers to highlight and amplify: a 3-year-old girl behaving obscenely in church was mentioned by Henry Maudsley (1867), for example.

Charles West and the origins of Great Ormond Street can at first sight seem important but the strict concern for insanity in children was not highly developed in his early writings (West 1848), and the hospital made no initial provision for mentally ill children. West wrote of hypochondriasis and night terrors but had little to say on brain disorders (West 1854). However, his work from the 1860s increasingly concentrated on moral insanity and mental illness, acting as an index of the growth of a paediatric specialism from the mid-nineteenth century (West 1860, 1871). The British situation was wholly altered in the 1860s by James Crichton-Browne who, among other things, stated a full case for the ‘psychical diseases of early life’ (Neve & Turner 1995).

A number of philosophical obstacles to the concept of childhood madness were strong in the early nineteenth century. Children were seen to reside in the world of *unreason* and were thus exempted from disorders of *reason*. The exceptions to this were monstrous, aberrant or occurring at an age close to precocious adulthood and always rare. Private madhouses did not generally admit children, for financial reasons, and very few children were admitted to public institutions—about 0.15% of asylum admissions in the first half of the century were in the 0–10 age group. Between 1796 and 1840 at the York Retreat, the percent-

age of patients aged between 0 and 10 admitted was 0.96 compared to 12.77 in the age group 10–20 (Bucknill & Tuke 1858). Between 1815 and 1899, some 1000 children and adolescents were admitted to Bethlem (Wilkins 1993), while only two or three children under 14 years were likely to be admitted annually to other lunatic asylums. Textbooks from the 1870s onwards, in both Europe and the USA, found room, however, for sophisticated discussion separating juvenile insanity from idiocy, epilepsy and neurological disorders and concentrating on adolescence as the developmental moment where both hereditary legacies and future dangers were made manifest (Clouston 1892, 1898; Maudsley 1895; Kraepelin 1919; Bleuler 1950).

There is an important relationship between this growing medicalization of childhood diseases and the wider context of family life and family fortunes. Examining a wide range of evidence, especially letters and diaries, Pollock (1983) contested the claim that good mothering is a modern invention, or that children were seen as evil or unimportant, or even went unmourned, prior to some eighteenth century discovery of ‘sentiment’ or notions of ‘primitive innocence’. She looked at the case for construing ideas of childhood via the history of child labour or the rise of various educational systems—and schooling was a key influence in generating a demand for a child psychiatry—but stressed that, if there is one thing that might have taught a cruel lesson before the late nineteenth century, it would be the high infant mortality rate. However, despite this general uniformity in the parent–child relationship between 1500 and 1900, Pollock did admit that in the early nineteenth century there was evidence for a growth in expressions of both ambivalence and nostalgia for the world of childhood, suggesting that punishment was on the increase especially in schools, and that both home and school were crueller. Pollock’s work is historically significant in that, at the same time as psychiatry was becoming professionally organized (Scull 1993), there was a social and moral conservatism at work. The difficulty of advancing psychiatric views of behaviour—famously in criminal insanity cases—might equally have applied to the early life of children, an ascendant moral language insisting on goodness and badness rather than trying to formulate imprecise notions of mental illness.

A Haslam case history

John Haslam (1764–1844) was apothecary to Bethlem between 1795 and 1816, and in his *Observations on Madness and Melancholy* (1809) he included three cases of insane children. In 1803 he was asked to see a 10-year-old ‘young gentleman’, whose history had been well established by another ‘learned and respectable’ physician. Despite having parents of sound mind, at the age of 2 this child had been sent away from home to an aunt’s house because he had become so ‘mischievous and uncontrollable’. At his parents’ request he was indulged in every wish, becoming thereby ‘the creature of volition and the terror of the family’. Subsequent attempts at limiting his behaviour failed, hence the referral to Haslam.

Although of healthy appearance, the boy’s countenance was

‘decidedly maniacal’. There was some ‘deficiency of the skin’s sensibility’ (he did not complain at the painful removal of a dressing for a boil), and he showed normal physical functions, apart from seeming to sleep more than usual. Haslam also described his memory as ‘very retentive’, but noted that he had a limited attention span, being only attracted ‘by fits and starts’. ‘He had been several times to school and was the hopeless pupil of many masters, distinguished for their patience and rigid discipline . . . it may therefore be concluded that . . . he had derived all the benefits which could result from privations to his stomach, and from the application of the rod to the more delicate parts of his skin.’

At the physician’s first interview, this boy managed to ‘break a window and tear the frill of my shirt’. He was gratified regularly by other destructive acts (china, windows, tearing lace), and he tended to abuse cats and dogs, throwing them on the fire or tearing out their whiskers. When spoken to, apparently he usually said, ‘I do not choose to answer.’ He formed no friendships with other children and ‘would as readily kick or bite a girl as a boy’. Although attached to the keeper who looked after him, the keeper himself was of a different opinion, being persuaded that the boy would ‘destroy him, whenever he found the means and opportunity’ when he grew older. The boy also showed some insight, suggesting that ‘God had not made him like other children’, and regularly threatened suicide. Haslam’s final comments are informative:

‘During the time he [the boy] remained here, I conducted him to the hospital, and pointed out to him several patients who were chained in their cells; he discovered no fear or alarm; and when I showed him a mischievous maniac who was more strictly confined than the rest, he said, with great exultation “this would be the right place for me”.

Considering the duration of his insanity, and being ignorant of any means by which he was likely to recover, he returned to his friends.’

In other words, for Haslam he was not a suitable case for treatment. Theoretical diagnoses were not even mentioned (although hinted at in the term ‘maniacal’) but the modern child psychiatrist may find many parallels to the clinical dilemmas of today. The combination of parental and educational despair, the troubling prognosis, the uncertain diagnostic framework and the therapeutic impotence are not artefacts of history. Troubled twenty-first century children may be better delineated in terms of developmental psychology and family systems but reviewing these historical stories is a useful antidote to complacency. A number of them can be found in the work of Burrows (1828), Morison (1828, 1848), Combe (1831, 1835, 1841), Browne (1837) and Conolly (1862), as well as the standard continental authors.

The nineteenth century

In *Psychical Diseases of Early Life*, read before the Royal Medical Society of Edinburgh in the winter of 1859, James Crichton-

Browne (1860) insisted that insanity did occur *in utero*, in infancy and in childhood, other writings notwithstanding. Esquirol was quoted approvingly on the power of hereditary taint. Those parents who had violated natural laws through self-abuse, lust and intemperance could expect punishment. The transmission of syphilis, measles and smallpox could occur *in utero*; idiocy could result from a blow to the abdomen. The results of fear were there—Browne quoted the famous case of the effect of a mother’s fear of Spanish invasion on the birth of that philosopher of fear, Thomas Hobbes. Illegitimate children carried the marks of their mother’s anxiety, although some natural children were the product of ‘ardent passion’ and thus close to genius. Dementia was a fact in early life, although not the same thing as idiocy, because in dementia ‘the mind has existed but is veiled and diseased’. ‘Acute dementia is frequently met with in this country between 10 and 16’, and (in Scottish fashion) Crichton-Browne deemed it curable, in many cases, by generous diet. Drawing on cases from the Crichton Royal Hospital at Dumfries and other sources (including that of Samuel Taylor Coleridge’s son, Hartley), he also cited theomania, demonomania, kleptomania, pyromania and cases of night terrors from Charles West. He also discussed suicidal impulse and choreomania, and the need to attend to early training, mental culture and physical education, but the point of his paper was expressed in a sentence near the end: ‘Those influences that are productive of psychical disease are coextensive with existence.’

This founding text in British child psychiatry made a developmental, phrenological and ambitious claim for the rectitude of breaking ranks from the standard authorities who declared infantile insanity impossible. The importance of this for Crichton-Browne’s own career was that it became part of a sustained ideal of the crucial importance of early experience, of early nurturing of the brain, so as to lower the rate of admissions to lunatic asylums (Neve & Turner 1995). He called for practical paediatrics based on social and moral hygiene because his own clinical experience had taught him that, for too many patients, the arrival in the asylum was too late. The psychical diseases of early life had to become objects of concern for parents and for teachers because it was then that the damage would be done. Children’s sleep, children’s breakfasts, children’s avoidance from destructive examinations at primary school (‘over-pressure’) and morally upright parents whose brains were healthily matched, these were the ‘weapons’—as he called them in 1859—with which to resist the advance of mental disease. His later time as an influential Lord Chancellor’s Visitor in lunacy and society doctor continued this crusade, with a re-emphasis of all these themes.

Crichton-Browne’s various concerns can also be felt in the work of the Yorkshireman Henry Maudsley (motherless from the age of 7) and the Scotsman Thomas Clouston (1840–1915). The most useful works of Maudsley’s are *The Physiology and Pathology of Mind* (1867) and his revised third edition published as *The Pathology of Mind* (1895), the latter having two sections on ‘The insanities of children’ (22 pages), and ‘Pubescent or adolescent insanities’ (also 22 pages). Between

these two editions was passed (in Great Britain) the groundbreaking Education Act of 1870 (children had to go to school), and in about 1875 the birth rate started to decline. Thus, in 1870, some 40% of 10-year-olds (and 2% of 14-year-olds) were in full-time education, but by 1902 this was officially 100% (Marsh 1958).

Contributions from T. Clifford Allbutt (1892), Fletcher Beach (1898) and William Ireland (1898) on psychological problems in children were published in the last decade of the century, the latter suggesting that children experienced an 'involuntary analysis of sensations'. Maudsley, however, while his hereditarian approach represented the degenerationist fears of the time, saw his key purpose in outlining the insanities of early life as being to confirm 'the principles of the study of the development of mind'. Thus, a child cannot have an hallucination until it has acquired 'a definite sensation', because 'children like brutes live in the present'. He acknowledged the eidetic imagination of children and discussed the 'phantasms' that are visible representations of their thoughts. In other words, 'what they think they actually see'. Such precocious imagination he regarded as something not to be fostered 'as a wonderful evidence of talent' (he cited William Blake as a warning), but preferred that 'the child should be solicited to regular intercourse with the realities of nature'. Damping down playful fantasizing was essential (Maudsley 1867). The child-led elaborations and creative play (Klein 1950; Winnicott 1958, 1971) encouraged by the twentieth century child guidance clinic would have been anathema to Maudsley and his contemporaries. Their concern was for diagnostic dilemmas, such as moral insanity, its causes, course and treatment, and the dawning awareness that as often as not such conditions were recognizable in childhood, as seen in the new schools, the courts and in their own private 'nervous clinics'.

Moral insanity

Illustrative of a late-nineteenth century trend towards considering moral defects in children as a disorder of brain function was the work of George Still, assistant physician for diseases of children at King's College Hospital and at Great Ormond Street. In three Goulstonian Lectures, entitled 'Some abnormal psychological conditions in children', Still (1902) discussed 'an abnormal defect of moral control', defined as 'control of action in conformity with the idea of the good of all'. He was dealing with an issue that he felt had a 'far-reaching' importance 'for the welfare of these unfortunate children and for the good of society'. In particular he stressed the problem of education, the method of providing supervision, how far one should resort to 'confinement in special institutions', and how far 'these children are to be held responsible for their misdoings'.

In Still's analysis, moral control required, as an essential factor, normal intellectual capacity. Impaired intellect was often the basis for moral defect, and many examples were given in the lectures. He also suggested that there could still be a primary failure to develop moral control, or there could be a morbid loss (permanent or temporary) of an already acquired moral control,

brought about by physical illness. While such conditions accounted for most cases, Still accepted that there was a residual group of children who suffered from 'a defect of moral consciousness which cannot be accounted for by a fault of environment'. He asserted that this had an evolutionary basis, quoting Darwin's phrase, 'so-called moral sense is aboriginally derived from the social instincts'. In a reflection of the psychophysiology of Henry Maudsley, he felt that this 'psychical defect' not only represented a 'perversion of function in the higher nervous centres' but was 'an actual physical abnormality underlying the moral defect'. Some cases might be temporary, some could be improved by careful training, but all should be *protected*, and all should be seen as a potential danger.

Elaborating on this socioneurological approach, Still also suggested that this defect could be caused by the same conditions as those that created idiocy or imbecility in other children. He listed family histories, degenerative stigmata and 'associated mental and nervous disorders' as being especially prevalent in his case sample (some 20 cases). Although acknowledging that 'a moral sense' was difficult to define, he could still conceive of it as the most recent and therefore most unstable product of mental evolution. His version can be seen as a contemporary, and perhaps logical, extension of that put forward by James Crichton-Browne, as a newer neurological account of phenomena once seen as immoral, while still using the older language of morality (e.g. 'vicious', 'depraved') to describe abnormal psychological function.

This version of disorderly children was an understandable attempt to discover order in the fitful debate around 'moral insanity' in the latter part of the nineteenth century. The influential co-editors of the *Journal of Mental Science*, Daniel Hack Tuke (1885) and George Savage (1891), published significant contributions and the topic was also raised by Robert Steen (1913). There was a general unanimity on typical cases and potential causes, with childhood onset accepted as a key principle. Savage felt that no one was 'capable of being intellectually complete and yet morally defective' and high moral control equated to high intellectual control, and often moral insanity was a stage of a progressing mental disease. He stressed the health of the parents and wrote of 'children saturated with insanity while still in the womb'. He defined most cases as coming on between the ages of 5 and 10 years, with behaviours such as lying, stealing, disruption in school, and non-response to punishment as indicative of the limited therapeutic options. These were the results apparently of 'badly built minds', and he coined the phrase 'a kind of partial moral dementia'.

Tuke, who also provided the entry for 'moral insanity' in the *Dictionary of Psychological Medicine* (1892) wrote of 'moral or emotional insanity', collected case material and even suggested that such individuals might be 'a reversion to an old savage type . . . born by accident in the wrong century'. While agreeing that moral influences might modify such tendencies, he quoted a Dr Kerlin who would have had these pupils banned from the school room to 'lifelong detention', because 'early detection' was not difficult. However, Tuke had to admit that diagnosis required

individual case assessment, because there was no absolute rule to distinguishing moral insanity from moral depravity.

The most interesting aspect of Steen's paper (1913) was its acknowledged purpose, to persuade parliament to include moral insanity in the Mental Deficiency Bill then being considered. Steen gave figures of 3.5 in 1000 private cases, and 1 in 1000 pauper cases, to indicate the relative rarity of the condition and its likely congenital origin, but recognized the similarity with Kraepelin's 'psychopathic personality' concept. He concluded that the term 'moral insanity' had come to him through 'many different types of cases'; that moral defectives were a distinct class within the broader category; and that confinement in an asylum could be beneficial. Any 'display of temper' could be 'met with a few days rest in bed', and 'after a few weeks they adapt themselves to the institutional routine and have an excellent time, as they are usually proficient in games and amusements'. While this therapeutic approach, based on social structure and control, may seem somewhat amateur, it is striking that these brief comments remain one of the few articulated treatment outlines within the moral insanity literature. It is also striking that Steen stressed early recognition, based on the history rather than the 'present state', emphasizing the central role of the moral insanity question within the wider understanding of the elusive nature of 'childhood insanity'.

Maudsley's contribution to this complex debate is noteworthy because, although his language is full of apparent Victorian disgust (e.g. 'vice', 'defect', 'perverted'), even describing children as having a 'hideous and uncontrollable propensity to acts of cruelty', his explicit object was to provide a scientific basis to morality. Children, to him, were of necessity 'extremely selfish' because they operated by the two basic instincts of self-conservation and propagation. He described a boy being 'the most vicious of all wild beasts', yet insisted on the 'purity and innocence of a child's mind', testifying to 'an absence of mind'. He asserted forcefully the reality of child sexuality, with 'frequent manifestations of its existence throughout early life', thus, 'whosoever avers otherwise . . . must be strangely or hypocritically oblivious of the events of his own early life.' Nevertheless, children were 'little more than an organic machine automatically impelled by disordered nerve centres'. It has been suggested that in some sense Maudsley hated children, with the insane child as the original Morelian degenerate, but he could still look for love 'or a congenial pursuit' to 'divert self devastating feelings to channels of outward activity'. This apparently worked 'by increasing and strengthening their relations, with the outside world of not-self, and therewith its hold on them'.

The work of Thomas Clouston introduced the notion of adolescent insanity to British psychiatry. It should be stressed that Clouston's version of adolescence is a discovery (just as hebephrenia, first described by Kahlbaum, is also a late asylum invention) and aimed at describing the age between 18 and 25 years (Clouston 1880, 1891, 1892). He emphasized the distinction, pointing out that: 'The boy enjoys Ballantyne and Captain Marryat; at puberty the adolescent takes to Scott and Dickens and only the man enjoys and understands Shakespeare, George

Eliot and Thackeray.' Thus, 'the adolescent feels instinctively that he has now entered a new country, the face of which he does not know.' He also noted that the period between 21 and 25 years of age showed the highest incidence of uncomplicated insanity, to him the most hereditary of all forms of mental disease, although curable in terms of discharge. He felt that 'psychologically and physiologically they emerged from the attack as men and women'.

In other words, Clouston was partaking in a physiological analysis of 'growing-up'. Eschewing quotes from the old cases, he outlined a highly structured version of normal developmental psychology; in particular, its dangerous sexuality. Careful education (not 'over-pressure'), mental hygiene, diet and exercise were central to his therapeutic regime, nurturing the brain (and soul—he was a committed Christian) through the stormy currents of puberty and adolescence, and breaking down the neurological fixations (or deviations) that might develop. His work represented the apogee of the established belief outlined by Crichton-Browne (1860), and elaborated by Froebel (1893), Maudsley (1895), Beach (1898), Keay (1888) and Allbutt (1892), that 'early training, mental culture, and physical education act, not merely in modelling disposition and laying the foundation of character, but in the rearing up of barriers opposed to the incursion of disease' (Clouston 1892).

Clouston also contributed to a new specialism within British and Continental psychiatry—the study of child suicide (Bartmann 1994). A number of authors included cases of young people killing themselves, discussing whether such acts were voluntary or partly imitative and whether new pressures in modern life—especially schooling and examination—were contributing to the statistical increase in such behaviour (Morselli 1881; Westcott 1885; Strahan 1893). The socially well-connected novelist, Thomas Hardy, who knew both Crichton-Browne and Allbutt, tapped into the anxieties of the age by portraying a child suicide (who first murders two infants as an act of compassion) in his 1895 novel, *Jude the Obscure*. The scandal the novel caused should not detract from the way that Hardy reflected growing concerns about the range and early appearance of psychiatric illness in children.

Conclusions

The collective view of the psychiatry of the child before the twentieth century—as summarized by Allbutt (1892)—agreed the following 'scientific' facts. Insane children were not defective enough to be sent to idiot schools and could be managed at home. The insanity of children was 'the vestibule' of insanity in adults, signifying an 'unstable nervous system'. The child's insanity was the insanity of the senses, of simpler impressions and of the instincts, of the lower and earlier organized centres. Suicide or homicide in children was imitative and unreflective, thus 'the child hangs himself or drowns himself to escape a lesson for which he is not prepared'. 'If man lives in a vain show, far more so does the child', and the normal child's mind was deemed 'fantastic', with 'daydreams as the only realities'.

Disturbances therefore occurred in the world of the affective and the imitative rather than in the world of thought. Insanity in the baby presented as kicking and biting. Insanity in children was often hereditary, or a gift from syphilitic parents. Prognosis was variable but melancholy, timidity and mild mania could be dealt with over 2–3 years under ‘judicious management’ and by following hygienic modes of life. However, such management was very difficult to obtain because the number of properly trained governesses was low, and Allbutt ‘earnestly hoped that the number of ladies having the mental and moral endowments necessary for such difficult duties . . . will increase’ (Allbutt 1892). He feared that otherwise adolescence would be reached in a state of greater or less imbecility and concluded by reporting several recent cases of ‘degenerative cerebral disease’, with his core references being Moreau de Tours (1888), Maudsley (1879) and Down (1887).

The patchwork nineteenth century psychiatric construction of the reality of childhood insanity, e.g. Wilmarth (1894) generated an unsystematic variety of medical accounts, but all placed great importance on family, school and society. In the next century, this conjunction of the medical, the educational, the legal and the social, e.g. Hall (1904) would receive formal recognition in the development of specialist units, psychological theories (Claparède 1911), juvenile courts and dedicated child therapists and social workers. Fuelled by advances in nutrition, public health acts (e.g. against child labour), world wars and education for all (Dwork 1987; Hendrick 1994, 1997), the bringing up of children in both Europe and the USA became a matter of municipal and, to some extent, state responsibility (Burke & Miller 1929; Cooter 1992). By 1914, Mott, a leading psychiatrist, wrote (in a monograph on *Nature and Nurture in Mental Development*) that the ‘medical inspection of school children and health visiting’ was of essential importance in ‘the development of body and mind’. He even allowed a chapter of his book to be specially written by a lady sanitary inspector and school nurse (Mott 1914).

History of child psychiatry in the twentieth century

‘When the twentieth century made its appearance, there was not—and there could not be—anything that might in any sense be regarded as child psychiatry. It took a series of definite steps in the development of cultural attitudes to make possible the inclusion of children in the domain of psychiatry.’ (Kanner 1935)

Any review of the developments in child psychiatry over the last 100 years has to acknowledge the range of studies already available. These include broader surveys such as by Lowrey (1944), Nissen (1974, 1991), Howells & Osborn (1981), Wardle (1991a,b), Rydelius (1995), Stone (1997) and Geissman & Geissman (1998). Further reviews by Heywood (1959), Eisenberg (1969), Horn (1984), Clarke & Clarke (1986), Hersov (1986), Cless (1988) and Duché (1990) are more specific, but there is also

a large secondary literature (Staples 1995; Kern 1973; Donaldson 1996, Levy 1968) dealing especially with developments in the field of child psychoanalysis. According to Parry-Jones (1994), Kanner (1960) attributed the origin of the term ‘child psychiatry’ to its use at a Swiss psychiatric society meeting in 1933. In essence, the difference from the nineteenth century and its anecdotal accounts of ‘insane’ offspring and their bad behaviour, lies in the emergence of near-universal schooling. Once most children came under the eye of institutions and professionals, their more subtle forms of disturbance could be noted. Instead of idiots, epileptics and grossly disordered psychotics (requiring asylum care), society felt the need to deal with ‘troubled’ or ‘delinquent’ children (Sullivan 1915), Healy 1917), and to formulate a range of social and clinical terms so as to comprehend them.

Although the rise of eugenics and child-rearing concerns (Beers 1908), the development of child guidance units (Crutcher 1943; Wardle 1991a), the influence of Freudian psychoanalysis (Freud 1905, 1953–74), and the advances in educational psychology (Binet & Simon 1905; Burt 1925; Gesell 1925; Piaget 1926) are seen as the essential strands, in the preceding century there was already a considerable specialist literature (Emminghaus 1887; Hurd 1895; Harms 1960). Hysteria was of particular importance (Kern 1973), with school pressures, concerns about child labour, heredity (e.g. the mother transmitting her dispositions to the child), and poverty in general, providing possible explanations for disturbed childhood behaviour. In 1896, there appeared a yearly periodical devoted to the study of character disorders in children (*Die Kinderfehler*), and in 1905 Sigmund Freud took on Little Hans. In fact Freud himself never saw a child in his consulting room (using parents as go-betweens instead) but the work of his daughter, Anna, in considerable and notorious competition with Melanie Klein, became a landmark cultural debate in the psychoanalytic, educational and child guidance worlds (Zaretsky 1999), a debate linked to the increasing acceptance of a welfare state and the professionalization of child care procedures.

Influence of Leo Kanner

Kanner’s textbook, *Child Psychiatry*, was first published in 1935 with the second edition appearing in 1948. The preface to the former was by Adolf Meyer who considered that ‘the personality of the child’ had been given ‘vital status’, and that child psychiatry was now ‘more and more on a safe and broad middle of the road course between the extremes of reluctance and of excessive zeal’. An additional preface insisted on the paediatrician understanding also ‘parents, teachers, and all those surrounding the child’. The second edition (1948) recalled the ‘somewhat strident notes of conflicting and doctrinaire claims agitating this field in the 1930s’ and suggested they have now been largely ‘quieted by sobering responsible work’. The author suggested that there had been advances in projective methods, somatic approaches and an understanding of attitudes and relationships in early childhood deriving from experience during the Second World War.

To Kanner, the important factors giving impetus to ‘the century of the child’ included the introduction of psychometry (Binet & Simon 1905, 1914), the element of dynamic psychiatry (looking for the origins of mental problems in one’s upbringing), the setting up of juvenile courts (the first in 1895 in South Australia and then in 1899 in Illinois and Colorado), and the mental hygiene movement (Beers 1908). The discovery that ‘any amount of tutoring, drilling, admonitions, punitive measures, promises or bribes’ did not actually work, and that magistrates and judges wanted to know just why children were misbehaving, led to changes of some significance before 1920. This included the ‘environmental cushioning of the decidedly delinquent, the noticeably retarded, the woefully neglected and mistreated, foster home placements, special education, removal from parental mismanagement or gang associations’, and the preference for ‘wholesome recreational facilities’. Kanner was particularly impressed by the Heilpädagogik movement in Europe and the subsequent development in the 1920s and 1930s of dealing with ‘the everyday problems of the everyday child’.

He defined the Boston Habit Clinic of 1921 as the first child guidance clinic, and by 1930 some 500 clinics had opened when the first International Congress of Mental Hygiene was held in Washington D.C. Other work (Wickman 1928) called for a shift towards ‘the psychology of the social development of children’, whereas August Aichhorn (1878–1949) in his 1925 book *Wayward Youth* outlined an approach to caring for delinquent children.

The 1930s and 1940s led to developments in working psychologically with children (e.g. play therapy as outlined by Anna Freud), and liaison paediatric/psychiatric clinics, but the paediatric perception of childhood conditions remained doggedly organic. Kanner quoted a popular 1928 textbook giving eight possible causes of enuresis, only one of which was ‘neurotic’, and which baldly stated that children with ‘unstable nervous equilibrium from chorea, epilepsy and similar conditions are prone to incontinence of urine’. Under ‘psychical influences, especially in dreams, the child imagines a convenient place for urination and the reflexes act’. That was the full section. By contrast, Kanner saw the work of Cameron (1919) as exceptional, including as it did a detailed section that began with a thoughtful recognition of ‘the apprehensions of the grown-up people who have charge of the (enuretic) children’ and their ‘unwise suggestions’.

Kanner’s textbook continues to have a modern feel. It is divided into four parts: ‘history of child psychiatry’; ‘basic orientation’; ‘clinical considerations’; and ‘phenomenology’, the latter being divided into three sections: ‘personality problems arising from physical illness’; ‘psychosomatic problems’; and ‘problems with behaviour’. The clinical section deals with the symptom ‘as an admission ticket, or signal, or safety valve, or as a means of solving problems, or as a nuisance’. It includes practical details of dealing with the initial contact, the case history, projective methods in psychotherapy, and prevention. Physical aspects concentrate on brain disease, epilepsies and endocrinopathies,

while psychosomatic problems are dealt with under the various orders and groups (e.g. digestive system).

By far the longest section, some 300 pages, deals with behavioural presentations, such as eating, sleeping, speech and language, scholastic performance or even anger. Treatment approaches are based on psychotherapy, particularly using rapport, transference and the relationship. With regard to rapport, Kanner advises the child, ‘I’ll tell you what it is all about and what I want you to do.’ In terms of transference, he suggests that one should say something like, ‘I’ll tell you what has been going on in your unconscious. See for yourself what you can do with it.’ As for the relationship, the line is ‘You go ahead and be yourself. Thereby you tell yourself and me about the way you feel about yourself and your status in the world. Let us see together what you can do with your resources.’ Warning about parents and jealousies between parent and child, Kanner advises the use of a referee in arguments, the dangers of being invited to dinner (‘noodle soup psychiatry’), and the usefulness of minor psychotherapy by general paediatricians. Social factors, in terms of casework and looking at what was going on in the classroom, are never forgotten or minimized.

Service developments

Sources generally agree that the pioneering child-focused clinic set up by Witmer in 1896, in Pennsylvania, was a core model of service development. In 1909, Healy founded the Chicago Juvenile Psychopathic Institute (aimed essentially at delinquency treatment), and in 1922 a number of demonstration clinics were set up (e.g. Klopp 1932; Witmer 1940) in the USA via the Commonwealth Fund (Stevenson & Smith 1934). The subsequent developments in England (Wardle 1991a) included interested visitors to the USA (e.g. Mrs Strachey, a London magistrate, whose husband was the editor of the *Spectator*), and the sending of some social workers to train in child guidance methods. In 1927, Emanuel Miller set up the East London Child Guidance Clinic; in 1929, the London Child Guidance Clinic, in Canonbury, was established using US methods. By 1930, in the USA there were some 500 clinics (Kanner 1935), while in England there were some 95 clinics by 1944 (Howells 1965), and 367 by 1970 (Wardle 1991a). According to Parry-Jones (1984), ‘an entirely new model of interdisciplinary collaboration by psychologist, psychiatric social workers and psychiatrists was created which shaped child psychiatrists’ working relationships and service delivery patterns for half a century’. Such developments occurred together with outpatient clinics in hospital departments, the increasing employment of child psychiatrists (in the UK 68 consultants in 1953, 365 in 1986), academic and professorial posts, and the increasing expansion of the speciality in terms of training places and speciality status (Kanner 1959; Wardle 1991a). Unfortunately, services became distant from asylum psychiatry, a particular problem for the more difficult adolescents, such units only being established in Britain in the 1950s and 1960s, although earlier in the USA (Curran 1939). Formal research into the impact and effectiveness of these child guid-

ance centres and inpatient units tended to lag behind, not least because of the difficulties in establishing an agreed diagnostic classification system (Rutter *et al.* 1975).

A useful summary of developments can be found in Warren's historical survey of the Maudsley Hospital Child Psychiatry Unit ('Child psychiatry and the Maudsley Hospital: an historical survey', unpublished Third Kenneth Cameron Memorial Lecture, Institute of Psychiatry Library, 1974). Harking back to the establishment of the Child Guidance Council (set up in 1926), Warren acknowledged the role of 'aments' (those with learning disabilities) in providing the first child patients. By the late 1920s there were three psychiatric clinics looking after child patients, but in 1930 a playgroup was set up (to look after bored children within an indefinite appointment system), and possibilities for observation were developed. By 1930, there were weekly conferences on child problems, and eventually a full children's department was established in 1939, with formal treatment. The inpatient unit had to wait until after the war (1947); however, its design was still more appropriate to physically sick children than those with psychological problems. In 1947, a full-time occupational therapist was appointed, a teacher and a school were set up in 1950 and by the late 1940s most trainee psychiatrists were spending some time rotating through the children's departments (Cameron 1949). The actual publishing and development of research was limited until the appointment of the first senior lecturer in child psychiatry (James Anthony) in 1952.

Reviewing child psychiatry in general in 1968, Rutter was moved to state that 'the history of research in child psychiatry is a short one'. The most important insights came from Kanner (1943) in his description of infantile autism, and Levy (1941) in his study of maternal overprotection. Further studies during the 1950s on encopresis, psychosis in childhood, sleep disturbances and manic depressive psychosis began to establish clearer diagnostic entities and developmental and behavioural norms. A focus of work at the Maudsley Hospital related to links between disorders in childhood and adult life, in particular the diagnostic development of those suffering from neurosis in childhood. Such patients were demonstrated to have continuing problems of depression, anxiety or other neurotic disorders, although a number showed problems with immature/inadequate personalities. Delinquent children tended to move towards antisocial disorders, while children with conduct disorders had milder disorders of personality (Rutter 1968). In essence, the core studies of the post-war period, between about 1950 and 1975, were aimed at establishing the epidemiology, diagnostic boundaries, specificities and relationship factors (particularly within the family) germane to child psychiatric problems. This very much reflected the dominant epidemiological and social bias of the Maudsley Hospital under the influence of Aubrey Lewis and Michael Shepherd.

Mid-century developments

In a more general sense, and variably attached to the highly in-

fluent child psychoanalytic movement (see below), routine child psychiatry in the 1940s and 1950s could not avoid the impact of the Second World War. The most outstanding document deriving from this, *Maternal Care and Mental Health* (Bowlby 1951), has probably been the most influential piece of writing of the century. Later expanded into *Child Care and the Growth of Love* (1953), this widely read and neopopulist piece of work combined a psychoanalytic perspective with a careful clinical approach. Bowlby's most striking contribution was an understanding of maternal deprivation which has continued to inform services, education, populist understanding and political approaches (Van Dijken 1998).

By the 1970s further research had shown the need for 'a more precise delineation of the different aspects of "badness" . . . and the reasons why children differ in their responses' (Rutter 1972b) to bad care in early life, but the stimulus to research has been immense. Thus, Bowlby's opening statement can be considered as true today as it was then: 'The quality of the parental care which a child receives in his earliest years is of vital importance for his future mental health.' His conclusion remains equally accepted: 'The proper care of children deprived of a normal home life can now be seen to be not really an act of common humanity, but to be essential for the mental and social welfare of a community.' His expressed hope, that 'all over the world men and women in public life will recognize the relation of mental health to maternal care, and will seize their opportunities for promoting courageous and far-reaching reforms', remains to be put into practice. In fact, the increasing recognition of child physical and sexual abuse (e.g. the National Family Violence survey in the USA, in 1973), the rise of the single-parent family and the continued widespread impoverishment of children globally, all represent a significant failure of the influence of the psychiatric establishment.

Yet it is not as if there has been a lack of other texts popularizing the importance of the process of childhood development. Eric Erikson's *Childhood and Society* (1951) and Donald Winnicott's *The Child, the Family and the Outside World* (1964) are just two among many. The link between childhood misbehaviour and broken homes had been well understood earlier in the century. A study of head injuries (Fabian & Bender 1947) showed that 83% of children attending with significant head injuries had 'mental abnormality more than their parents', and that the 'home atmosphere in these cases was one of hate, rejection and violence'. The problem of 'identification with a sadistic father was marked in boys', and the healthy influence of police officers and the youth club movement, in a 1947 report of the Commissioner of Metropolitan Police (Scott 1947), showed a marked drop in juvenile crime when such projects were developed. A survey from the Cambridge Child Guidance Clinic (Banister & Ravden 1944) correlated nervous symptoms with broken homes and commented on well-adjusted children having more strongly developed interest in hobbies and 'much less frequent attendance at cinemas'. The Chief Clerk to the London Juvenile Courts (Giles 1946) considered that problem parents much exceeded problem children.

In the 1950s, apart from the insights of John Bowlby, with respect to maternal deprivation, the influence of the films made by James and Joyce Robertson (1971) about children's admission to hospital, and a residential nursery, cannot be exaggerated (Freud A. 1953). This led to a completely altered attitude towards mothers visiting their children in hospital, allowing virtually open access in an attempt to combat the problems of separation. Equally influential were the large-scale studies of Spitz (1951) on 'pathological mothering', and Lewis (1954) on deprived children who reviewed 500 cases, with over 100 being followed-up directly. The traumatizing effects of separation before the age of 5 were established, but the circumstances, the quality of mothering and the subsequent care were seen as determining an outcome.

The problems of adolescents, in the increasing economic well-being of the 1950s, also came to the fore (Underwood 1955). As with the original developments in child psychiatry, social influences were the Education Act of 1944 and the National Health Act of 1948 (in the UK), placing specific responsibilities on child psychiatric services. Particular confusions developed around the notions of childhood and/or adolescent psychosis, and there was considerable debate as to its reality, causation and key symptoms. Cameron outlined these confusions, suggesting that the psychopathological concepts deriving from Kleinian psychoanalysis did not really fit with the manifest clinical syndromes, and that at times it was difficult to be clear as to whether 'a manifest clinical entity or a psychopathological postulate was under consideration'. Cameron's (1956) article 'Past and present trends in child psychiatry' summarized a number of these issues.

However, perhaps most important in practical terms were the continuing 'developments' in the range of treatments used. Essentially, from the 1950s, family and group approaches were offered, with a flourishing of family therapy in the 1960s and 1970s. Alongside this, the work of a number of behavioural psychologists (Bandura 1969; Yule 1984) has shown effectiveness in relevant diagnostic cases but, as Wardle (1991a) pointed out, there has been a tendency for different approaches to denigrate each other. Likewise, the difficulties of co-ordinating multidisciplinary teams have been lambasted (e.g. the 1987 Butler-Sloss Inquiry into child abuse in Cleveland, UK), and the persisting interdisciplinary rivals within the broad child care movement (education, psychiatry, psychoanalysis, social work, home support, educational psychology) have never been fully resolved. Certain practical advances, in terms of causation, development, psychopathology and treatment, do have a general importance in illustrating post-war trends. Dyslexia, once an intrapsychic conflict of 'streptosymbolia' (Rosen 1947) is now an established neurological disorder, while studies of the offspring of psychotic parents have demonstrated the genetic and biological bases of conditions such as schizophrenia (Mednick *et al.* 1984; Stone 1997). The pharmacological treatment of hyperactivity, using methylphenidate or similar stimulants (Gittelman-Klein & Klein 1976), the recognition and classification of depression in childhood (Rutter *et al.* 1986; Carlson &

Cantwell 1979), and the clear separation between infantile autism and early onset schizophrenia in childhood (Rutter 1972a) are other significant clarifications. Not only have these findings demonstrated an increasingly biological perspective, they have also enabled a more realistic understanding of developmental psychopathology and reflect the improved nutrition and infant mortality figures of the period. Nevertheless, compared with adults, the use of medication has been significantly inhibited by ethical issues, differential age responses and the limited reliability of diagnoses.

Psychoanalytic approaches

To many lay observers, child psychiatry has been seen to be coterminous with child psychoanalysis. The influence of Freudian theory, psychotherapeutically orientated child guidance clinics (Freud 1946), and the Tavistock Institute (in the UK) have led to some marginalization of the routine services. These include multidisciplinary teams, inpatient units, medication approaches (e.g. the use of stimulants for ADHD or antidepressants for significant depressive illnesses) or the practicalities of educational psychology in schools. Childhood loss (real or imagined), play therapy, systems theory in the context of family dynamics, and the clear diagnostic differences between childhood disorders and those of adulthood have enhanced a predominantly psychotherapeutic culture within the speciality. In terms of journals, for example, *The Psychoanalytic Study of the Child* was first published in 1945, and *The Journal of Child Psychotherapy* in December 1963. More eclectic journals, such as *The Journal of Child Psychology and Psychiatry* (first published in 1960) or *The Journal of the American Academy of Child and Adolescent Psychiatry* (first published in 1961) also include considerable amounts of psychoanalytic and psychotherapeutic material. In a review of *The Psychoanalytic Study of the Child* (between 1945 and 1975), it was seen as providing the 'major repository of the science of psychoanalysis, centred on the child', and as 'a scholarly forum in which psychoanalysis as a developmental psychology in general theory could be systematically reviewed and elaborated'. Some 500 papers of both US and European origin were published in that 30-year period, with three leading editors (Anna Freud, Henry Hartmann and Ernst Kris) contributing significantly, especially the first.

In terms of the celebrated debate during the late 1920s and early 1930s between Anna Freud (1895–1982) and Melanie Klein (1882–1960), detailed biographies of the two protagonists provide fascinating background material on their core influences on child psychoanalysis (Peters 1985; Grosskurth 1986). A more recent review (Donaldson 1996) has concluded that Anna Freud focused on theory and the strength of the ego, following in her father's footsteps, whereas Klein's observations challenged the traditional psychoanalytic account, resulting thereby in the development of object-relations theory. It is of note, however, that both Anna Freud and Melanie Klein were lay psychoanalysts, the former being a qualified school teacher who derived her initial guidance from a retired teacher and lecturer in

child education in Vienna, Hermine Hug-Hellmuth. In fact, Hug-Hellmuth was murdered in 1924, at the age of 53, by her 18-year-old nephew, apparently a young man brought up on liberal and psychoanalytic principles by his mother and aunt. This inauspicious start reflected a number of difficulties in the early history of child psychoanalysis, necessitating, for example, Ernest Jones' removing to Toronto from the UK, and other accusations of abuse (Kern 1973) directed by children at male analysts in particular. The influence of Maria Montessori, for example, in her popular work *The Montessori Method* (1919), derived from a popular series of lecture tours. She emphasized the importance of children freely choosing their own activities merely guided by teachers or parents.

Anna Freud's early work propagated the view that it was possible to carry out a proper Freudian psychoanalysis even on difficult patients such as children. The difficulties included minimum insight, a maximum of resistance and no possible transference apart from through the parents. She combined therapeutic and educational approaches, using drawing, knitting and play, and felt that a special theory was not needed. Her later *The Ego and the Mechanisms of Defence* (1936) extended her views into the adult world.

By contrast, Melanie Klein, whose first analysis was carried out on her own sons, tended to be aggressive in symbolically interpreting every act and suggested that it was possible to analyse children at a much younger age. Moving to the UK in 1926, and treating among her first patients Ernest Jones' children, her first written piece was *The family novel in status nascendi* (see Donaldson 1996). More detailed discussions of her technique occurred in her 1932 book, including over 570 sessions on one 6-year-old child with a compulsive neurosis. The first overt clash arose in 1927 when the proceedings of a symposium on child analysis were published in the *International Journal of Psychoanalysis* (editor Ernest Jones). This was, in fact, a response to Anna Freud's criticism of Klein's technique published in a monograph entitled 'Introduction to the technique of child analysis' (see Donaldson 1996), and in September 1927 Sigmund Freud wrote to Ernest Jones accusing him of organizing a 'regular campaign' against his daughter. The technical difficulties in this debate are not relevant to a broad survey but are central to understanding the differing strands of child psychotherapeutic practice. The modern use of studying children's play, drawings and non-verbal expressions, for example in paediatric assessments of possible sexual abuse, have developed a considerable sophistication. Klein felt that all children should be psychoanalysed as a prophylactic measure, whereas Anna Freud felt that all school teachers should be psychoanalytically trained to deal with young pupils within the educational system. The most important effect, the development of Bowlby's investigations into the effects of maternal deprivation, initially on behalf of the World Health Organization (Bowlby 1951), has been the central influence in the day-to-day routine of the modern child guidance unit.

The practical outcome of these issues can be seen in a contribution by Winnicott (1964) on the training for child psychiatry.

Winnicott felt that 'the basis of much of the work of the child psychiatrist is the psycho-therapeutic interview with the child', while acknowledging that the child psychiatrist is also engaged in working with the parents, and work that is 'essentially practical' in that 'in respect of each case we meet a challenge'. However, Winnicott felt that 'paediatrics has failed as a parental figure for child psychiatry, and so has psychiatry', and thus he insisted on autonomy for the child psychiatric profession. He felt that the only solution was for 'child psychiatry to become a thing in its own right and to devise its own training' as, in his view, 'the really necessary preparation for child psychiatry is in the psychoanalytic training'. Apart from the emotional development of children, he considered that 'the interferences with maturational processes that come from the environment and from conflict within the child' were the essence of the problem, and in that sense child psychiatry was akin to paediatrics (Phillips 1988).

Conclusions

To Leo Kanner, the twentieth century was 'the century of the child', and the richness of both 'vitalist' and 'mechanist' research into the normal and disordered child may represent one facet of this understanding. Whether or not the range of insights (e.g. Kahr 1991) and treatment approaches has served to improve the quality of childhood, in itself a much more prolonged process in the twentieth century, remains a moot point. The development of child psychiatry as a speciality at first concentrating on the mentally retarded, then moving into areas of education and delinquency, incorporating sociological and psychological disciplines, and growing into the widespread child guidance clinic established throughout much of the world after the Second World War, was a paradigm of the increasing acceptance of psychiatry as part of the history of ideas. Paradoxically, the work in the USA—Eric Erikson, Margaret Mahler, Moritz Tramer, Beata Rank and Rene Spitz, among many others—reflected a strongly psychotherapeutic tradition, yet medication and the use of inpatient care, especially for adolescents, have been prominent in treatment. The more clinical, epidemiological and neuropsychological approach of the English school (as represented at the Maudsley Hospital) generated more practical insights, yet a less medicalized therapeutics.

For example, the celebrated study of the children of the Isle of Wight (Rutter *et al.* 1970) provided the reassuring news that most adolescents actually like their parents. The importance of the family, the effects of parental mental illness on children, the influence of subtle learning or emotional difficulties (e.g. ADHD, dyspraxia, dyslexia) on subsequent 'difficult' or antisocial behaviour, and the establishment of robust treatment approaches can all be seen as advances. As Wardle (1991a) has pointed out, 'Studies of social and family factors underlying childhood disorder have helped clinicians to build more accurate models of the interaction of causes, enabling them to focus on attainable therapeutic aims and to look for positive and protective factors to work with in the child's environment and family.' The same author lamented the unfortunate role of fashion in

terms of the public's view of child psychiatric services. From autism in the 1950s and 1960s, to anorexia and hyperactivity in the 1970s, and sexual or even satanic abuse in the 1990s, the speciality has been peculiarly prone to political, media and populist interference (e.g. Wolff 1989). The establishment of a robust classification (Rutter *et al.* 1975) brought some order to an often obscure descriptive system but future developments must take a grasp of the strange eventful history that has already preceded them.

If, as Bowlby has emphasized, 'the proper care of children deprived of a normal home' (whatever 'normal' may mean) remains of the essence, perhaps the iconic heart of twentieth century child psychiatry lies in the experience of the child in wartime. Whether it be Anna Freud's monthly reports of children's reactions to sleeping in underground stations, and bombings, etc., or Wicks' (1988) memories of children in his collection of personal records entitled *No Time to Wave Goodbye*, the simple requests of the children cannot be ignored. Their song from Lionel Bart's musical 'Blitz' echoes the metaphor of their journey.

'We're going to the country, we're going to see the cows,
We are going to have a real good time, in a country house,
It's called evacuation
They take you to the station,
They put you on a train,
Let's hope it doesn't rain,
We are going to the country.'

Clinical Syndromes

Syndromes of Hyperactivity and Attention Deficit

Russell Schachar and Rosemary Tannock

Introduction

Restlessness, inattention and impulsiveness are common behavioural problems during the preschool- and school-age years. Adolescents and adults also exhibit these traits but usually to a lesser extent. In the extreme, these characteristics are impairing to the affected individuals and disturbing to those around them. Consequently, they are thought to be symptoms of a mental disorder. Persons affected by this disorder in childhood are at risk for learning, conduct and social problems, and are more likely to develop serious impairment in adolescence and adulthood. As a result, this disorder places substantial demands on the health care, educational and legal resources of the community and is of considerable importance from a public health perspective.

The purpose of this chapter is to review the current understanding of the aetiology, nosology and treatment of this disorder. We begin by describing the clinical features and by tracing the evolution of our understanding of the syndrome.

As a result of enduring controversy about nosology, we adopt the convention suggested by Taylor (1998) of using the term 'hyperactivity' to refer to the cardinal symptoms (overactivity, inattention, impulsiveness) that define the syndrome and of using specific diagnostic terms, such as hyperkinetic disorder (HD) or attention deficit hyperactivity disorder (ADHD) when addressing a particular diagnostic entity and set of criteria. We will use the acronym AD-HKD when referring to characteristics that are shared by ADHD and HD. In referring to the syndrome as 'hyperactivity' we do not intend to convey the impression that gross motor activity is either the defining symptom of the disorder or its essential deficit. In fact, motor activity is only one of the important manifestations of the disorder and may not be as important as others such as inattention and cognitive deficit. Hyperactivity is used in a purely descriptive manner as a proxy for all the other labels that have been used. A wide range of terms have been used to describe this syndrome and each has taken on a specific meaning. Any choice of label such as ADHD or HD would convey the impression that the chapter pertains to children defined by one set of diagnostic criteria only.

Even though clinicians, scientists and authors find 'ADHD' or 'hyperactive children' a convenient shorthand, diagnoses actually describe disorders not individuals. People change as do labels. In this chapter, all references to hyperactive individuals should be understood as statements about disorders not people.

Clinical features

The cardinal features of children with AD-HKD are excessive motor activity, inattention and impulsiveness. Compared with their peers, these children are restless, fidgety and boisterous when required to be still and quiet. This is true both in structured situations, such as the classroom, and in unstructured situations, such as the playground. They have difficulty attending to instructions in academic and social situations. They tend to look away when spoken to, require frequent repetition of directions or appear unable to comprehend the nuances of an instruction. At school, their work is characterized by careless errors, poor organization and forgetfulness. They lose things such as books, notes and assignments that are crucial to school work but they also lose possessions that are of obvious personal value. They are typically the last to start a designated activity (often because they cannot find the necessary materials, forget to gather them together or have been daydreaming) and last to finish (because of staring off into space, failing to concentrate and being distracted). They shout out their replies, interrupt others and are reckless and accident-prone. On the other hand, they may not speak when they are supposed to (Zentall 1988). They seem to have trouble interrupting their course of action, and appear unable to adjust an incorrect or maladaptive response. They make careless errors in their school work and in other activities.

The characteristics of AD-HKD are variable both within and among individual children. It is rare to find a person who exhibits every characteristic of hyperactivity to a comparable extent. Some children are particularly restless and impulsive but are quite attentive (Goldstein 1987). Others are primarily inattentive and relatively inactive or even hypoactive (McGee *et al.* 1992). The behaviour of hyperactive children is context-dependent; a child may be highly distractible and inattentive in the classroom setting but restless and impulsive around the home. Moreover, the extent of behavioural excess varies with the demands of the situation. A child who is markedly symptomatic at school may be described as quite average in behaviour by their parents, or a child who is highly distractible while performing a structured task in the classroom may be described as perfectly average when playing a computer game, interacting with peers or while engaged in an unstructured activity. Parents frequently comment that it is the marked variability day-to-day, hour-by-hour and minute-by-minute that is the most salient feature of these children.

The manifestations of this syndrome change with development. In preschool-age children, overactivity is most obvious and possibly most impairing. Inattention becomes more salient once a child confronts the demands of the classroom. As children reach adolescence and adulthood, the motor overactivity seems to diminish and inattention and impulsiveness become most impairing and are particularly noticeable in social situations.

Some authorities point to the variability described above and question the objectivity of the symptoms of hyperactivity and therefore the validity of the syndrome. To others, this variability is not surprising given the complexity of human behaviour and psychopathology. Ample research demonstrates that hyperactivity is more than the subjective impression of adults. There is sufficient convergence between ratings of hyperactive, inattentive and impulsive symptoms and direct measures of the same behaviours to support the validity of the core symptoms of the syndrome (see Sandberg *et al.* 1996 for review). For example, when observed in a playroom, hyperactive children are more often off-task and persist less on a particular activity than their non-hyperactive peers (Milich & Fitzgerald 1985). Hyperactive children are demonstrably more active throughout the day (Porrino *et al.* 1983) and are less attentive in a range of laboratory situations (Sergeant 2000). However, the extent to which agreement between subjective ratings of hyperactive symptoms and objective measures of the same behaviours is only modest suggests that we do not fully understand the exact nature of these behaviours, the role of context or the factors that influence observer judgement (Sandberg *et al.* 1996).

There are many reasons for these modest levels of agreement among informants.

1 Informants may not share a common definition of each behaviour. An observer might consider failure to persist in a task to be evidence of defiance, lack of interest, low motivation, boredom or learning disability rather than inattention.

2 Children's behaviour is a function of the demands of the setting. Parents may have fewer opportunities than teachers to observe their child in situations that demand attention. Inattention might be particularly impairing in school and therefore salient to a teacher's judgement of psychopathology, whereas restlessness might be more conspicuous at home (Hewitt *et al.* 1997). By contrast, parents and teachers are more likely to agree about which children are impaired than they are to agree about the presence of particular symptoms (Mota & Schachar 2000).

3 The informant's mental state or cultural expectations may influence perceptions of child behaviour (Boyle & Pickles 1997). Age-appropriate levels of activity may seem more aversive for a depressed socially isolated mother, for those with high expectations for academic attainment or for a teacher of a class that does not include other children with special needs.

4 Cultures may differ in their sensitivity to hyperactive behaviours. Leung *et al.* (1996) reported that parents in Hong Kong rated their children as highly hyperactive even though objective measures did not distinguish them. Informants seem to have difficulty discriminating among various dimensions of distur-

bance. This inability to discriminate among behaviours may result in a halo effect whereby the presence of defiance and disobedience is taken as evidence of hyperactivity (Schachar *et al.* 1986; Abikoff *et al.* 1991).

5 Parents have a tendency to exaggerate the differences among their children when making behavioural judgements (Eaves *et al.* 1997).

It is also true that many of these features describe all children to some extent at some times, such as when a child is tired or unwell. However, in hyperactive children, these behaviours are more frequent, severe and persistent and interfere with a child's peer and parental relationships, impede their academic performance and undermine their psychological well-being. The problem is how much of which behaviours in what settings assessed in what way by whom is sufficient to constitute a discrete disorder. We return to this issue in the discussion of nomenclature and assessment.

Associated impairment

Children with AD-HKD experience serious social, academic and psychological impairment at every stage of development. They are rejected by peers and adults and are treated in a controlling and negative fashion by them (Barkley *et al.* 1985; Hinshaw & James 1991). Their parents experience considerable stress and feelings of incompetence. Child management problems can increase social isolation and marital discord. Hyperactivity in a child may even be a risk factor for parental alcohol consumption (Pelham *et al.* 1998). The economic burden of having a hyperactive child is considerable but currently unspecified. Children with AD-HKD are more likely than their unaffected peers to live in families that are disrupted by poverty, characterized by marital discord and parental psychopathology and to have siblings who are at risk for the development of psychopathology (Faraone *et al.* 1996a; Hechtman 1996; Woodward *et al.* 1998).

Compared with their normally developing peers, children with AD-HKD get lower marks, fail more grades at school, and are more likely to have a diagnosis of a learning disability (Weiss & Hechtman 1993; Zentall *et al.* 1994; Mannuzza *et al.* 1998). Failure at school results in demoralization, low self-esteem, peer rejection and feelings of anxiety and depression. In turn, these responses result in premature school drop-out, increased exposure to delinquent peer groups and consequent risk of delinquency and substance abuse.

Hyperactive adolescents and adults show many of the same features as their younger counterparts, although earlier overt restlessness may be replaced by a sense of inner restlessness. Affected adolescents are more likely to drop out of school with lower marks and to have lower paid and lower status occupations than their non-hyperactive peers and siblings. Their self-esteem may suffer, although sometimes one observes what appears to be a defensively inflated sense of self-esteem (Slomkowski *et al.* 1995). Poor driving habits, accidental injuries or death are more common among hyperactive individ-

uals as are suicide attempts and substance abuse disorder (Barkley *et al.* 1996; Nada-Raja *et al.* 1997). Hyperactive adults are more likely than others to have a discordant marriage and to have hyperactive children (Weiss & Hechtman 1993; Biederman *et al.* 1995).

Comorbidity

Many children with ADH-HKD meet the criteria for another psychiatric disorder—a phenomenon known as comorbidity (see Taylor & Rutter, Chapter 1). Estimates of comorbidity depend on the criteria used to define hyperactivity, the criteria used to define the comorbid disorder and the sample under study. In general, oppositional/defiant disorder is observed in 35–50% of cases, conduct disorder in 25%, depressive disorder in 15% and anxiety disorder in 25% (Jensen *et al.* 1997; Kuhne *et al.* 1997). In fact, over 50% of children with AD-HKD meet criteria for two comorbid conditions (Szatmari *et al.* 1989a). Learning disability occurs in 15–40% of children, particularly among those with inattentive symptoms, and language impairment in about 15–75% of children (Cohen *et al.* 2000; Tannock 2000).

Several factors may contribute to the rate high rate of comorbidity but none accounts for it completely (Caron & Rutter 1991).

- 1 The rate of comorbidity is affected by referral bias (individuals with more than one disorder get preferentially referred for services), overlapping diagnostic criteria (e.g. inattention counts as a symptom of AD-HKD and of depression), or the inability of informants and clinicians to draw precise distinctions among disorders (e.g. an aggressive child may appear restless).
- 2 AD-HKD may increase the risk of a second disorder. For example, school failure associated with hyperactivity may result in gravitation toward delinquent peer groups or in demoralization that develops into depression.
- 3 AD-HKD and a comorbid disorder, such as reading disability, may occur together because they are alternate manifestations of a shared underlying cause.
- 4 AD-HKD in the presence of a comorbid disorder may be a distinct condition.
- 5 The comorbid condition could represent a phenocopy of one of the ‘pure’ disorders (e.g. conduct disorder children are restless, impulsive, etc. but their AD-HKD symptoms do not carry the same implications as does AD-HKD in the absence of conduct disorder (Schachar & Tannock 1995).

There are several ways to test the validity of these competing hypotheses. One way is to compare AD-HKD with and without the comorbid disorder with individuals affected only by the pure comorbid disorder on a range of important correlates such as impairment, aetiological indicator, associated pathology, natural history and the like. Secondly, one can treat each of the two conditions and examine the impact on the other. Thirdly, one can use family genetic strategies to determine the risk in family members of each of the separate disorders.

Although these strategies have been applied widely, none of the common comorbidities has as yet been fully explained. For

example, AD-HKD with comorbid conduct disorder differs from ‘pure’ AD-HKD on a wide range of cognitive, prognostic and family measures suggesting that it may be a distinct entity (MacDonald & Achenbach 1996; Jensen *et al.* 1997; Faraone *et al.* 1998a). Conversely, the hybrid hypothesis for AD-HKD and conduct disorder gains support from the considerable clinical and neuropsychological research showing that the comorbid group shares the characteristics of both AD-HKD and conduct disorder (Szatmari *et al.* 1989b); from twin studies that point to a shared genetic risk for conduct disorder and AD-HKD (Silberg *et al.* 1996; Faraone *et al.* 1997a); and from studies that show improvement in symptoms of conduct disorder following the reduction in hyperactivity that occurs with methylphenidate (Klein *et al.* 1997).

Similarly, there is evidence for each of the mechanisms of comorbidity acting in comorbid AD-HKD and reading disability. Neuropsychological and family history studies demonstrate that AD-HKD and reading disability are distinct conditions with separate correlates and causes, but that they frequently co-occur as a true hybrid (Douglas & Benezra 1990; Faraone *et al.* 1993; Shaywitz *et al.* 1995). Twin studies indicate that AD-HKD and reading disability have shared genetic influences suggesting that they may be heterogeneous manifestations of a single genetic diathesis (Gillis *et al.* 1992; Stevenson *et al.* 1993). Others argue that the combined condition may be a phenocopy of AD-HKD and that comorbid AD-HKD and reading disorder is a variant of reading disorder not AD-HKD (Pennington *et al.* 1993).

In summary, existing research does not clarify which mechanism is responsible for comorbidity of AD-HKD with other conditions. It is possible that each of the mechanisms for comorbidity described above accounts for some of these comorbid cases.

Development of the concept

Excessively hyperactive, inattentive and impulsive children have been described in the medical literature since the late-nineteenth century (for reviews see Schachar 1986; Sandberg & Barton 1996). In fact, early descriptions and aetiological theories of hyperactivity were, in many ways, strikingly similar to current descriptions of the syndrome (Still 1902; Tredgold 1908). The syndrome was characterized by morbid inability to sustain attention, a lack of will or self-control (insufficiency of inhibitory volition), restlessness and impulsiveness (exaggeration of excitability) together with soft neurological signs such as clumsiness and minor congenital anomalies or stigmata (Tredgold 1908). Befitting prevailing Darwinist and evolutionary views of society and psychopathology, these early concepts focused on a lack of sustained ‘will’ as the cardinal manifestation of the disorder and labelled the disorder a syndrome of ‘moral dyscontrol’. The prevailing notions of ‘will’ and ‘morality’ were rather like theories of executive control and self-regulation that play such an important part in current neuropsychological theories of AD-HKD.

Will, morality, sustained effort and the like were held to be the

highest and latest achievements of evolution and were localized in the most recently evolved parts of the brain (Tredgold 1908). As a result, these processes were especially vulnerable to loss as a result of relatively minor pre- or postnatal brain injury, infection, malnutrition or exposure to toxins, especially in individuals with a hereditary predisposition. Moral dyscontrol was not thought to be a result of adverse social circumstances that were common at the time but rather was thought to be a biological affliction. This perspective reflected the prevailing philosophical and sociological inclination of the late-nineteenth century that attributed extremes of behaviour, as well as poverty and its correlates (e.g. medical illness, alcoholism and immorality), to physiological rather than to psychological or social causes (Tredgold 1908). Defined in this way, moral dyscontrol provided a neurobiological formulation for many of the childhood problems of the times.

In many respects, essential theories of AD-HKD changed little over the decades. However, with detailed study of the behaviour of hyperactive children and accumulating knowledge of brain function during the century, concepts of the fundamental behavioural and neuropathological deficit of AD-HKD changed dramatically. By the middle of the nineteenth century, the manifestations and impairment associated with AD-HKD were attributed to restlessness arising from abnormal arousal mechanisms in the reticular activating system. More recently, the fundamental deficit in AD-HKD was believed to be deficient sustained attention (Douglas 1972, 1988), a central impairment in self-regulation, and impairments in executive processes (Barkley 1998). Current theory favours the fundamental role of deficient inhibition—the future-orientated, delaying mechanism involved in the timing, initiation and interruption of action and of neuropathology in the frontal and related regions of the brain (Barkley *et al.* 1992a). Competing models have also been proposed, which attribute poor performance in ADHD to the impact of state moderators (e.g. arousal, activation, effort, motivation), or to differential sensitivity to reward, rather than to fundamental cognitive deficits (Laufer *et al.* 1957; Chess 1960; Wender 1971; Glow & Glow 1979; Haenlein & Caul 1987).

Evolution in nomenclature

Many different diagnostic terms have been used to label the hyperactive child over the years. When the syndrome first appeared in the modern North American diagnostic classifications of mental disorders, *Diagnostic and Statistical Manual of the American Psychiatric Association*, it was known as hyperkinetic reaction of childhood (DSM-II; American Psychiatric Association 1968). This term stressed overactivity as the cardinal feature of the syndrome rather than notions of minimal brain damage or dysfunction that had been current until that time (Clements 1966). The name of the disorder was changed to attention deficit disorder (ADD) in 1980 (DSM-III; American Psychiatric Association 1980) to reflect the opinion emerging, particularly in North America, that inattention and impulsive-

ness rather than motor overactivity *per se* was the cardinal behavioural manifestation of the disorder and possibly the central deficit (Douglas 1972).

DSM-IV (American Psychiatric Association 1994) differs from DSM-III-R (American Psychiatric Association 1987) and DSM-III in that it separates inattention criteria from those of hyperactivity and impulsiveness but does not distinguish the later two aspects of the syndrome. The shifts in diagnostic criteria complicate research efforts because it is not possible to extrapolate from studies using earlier criteria to those based on DSM-IV criteria.

Over the last half century, diagnostic traditions of North America and Europe diverged. In Europe, two parallel notions of hyperactivity evolved. The average hyperactive child was thought to have a behaviour disorder arising from the effects of social or familial adversity. These children were typically diagnosed with conduct or behaviour disorder rather than hyperactivity. The few children with severe persistent and pervasive symptoms and with documented neuropathology, such as a history of head injury or seizure disorder (Ounsted 1955; Bax & McKeith 1963), were diagnosed with hyperkinetic disorder (International Classification of Diseases, ICD; World Health Organization 1978).

Current approaches to categorization

The most recent editions of the DSM and ICD classifications reflect an effort to bring the definitions of ADHD and HD closer together. DSM-IV and ICD-10 (World Health Organization 1994) have adopted almost identical criteria for the identification of inattentive, hyperactive and impulsive symptoms. However, significant differences between the European and North American approaches are still evident in their diagnostic algorithms (the number of criteria in each domain required for a diagnosis), the role of inattention, the definition of pervasiveness and the handling of comorbidity.

According to DSM-IV, the diagnosis of ADHD requires the presence of six inattentive or six hyperactive-impulsive symptoms, or both. Three different subtypes of ADHD are therefore permitted:

- 1 predominantly inattentive—the presence of six or more symptoms of disordered attention and fewer than six symptoms of hyperactivity-impulsivity;
- 2 predominantly hyperactive-impulsive—the presence of six or more symptoms of hyperactivity-impulsivity and fewer than six symptoms of inattention; and
- 3 combined—the presence of six or more inattentive and six or more hyperactive-impulsive symptoms.

To establish a diagnosis of HD based on ICD-10, at least six inattentive, three hyperactive, and one impulsive symptom must be present. The diagnosis cannot be made in the absence of each type of symptom so no symptomatic subtypes are permitted. The relative weight given to inattention in ICD criteria is ironic given the name but accurately reflects current emphasis on inattention as the cardinal and most impairing symptom.

ICD-10 is also more demanding about cross-situational pervasiveness, requiring that all necessary criteria be present, both at home and at school (or other situations such as in the clinic). DSM-IV is more lenient: it demands that criteria be met in at least one situation and that impairment arising from ADHD symptoms be present in another. The definition of impairment, the number of symptoms that must be present or the severity of the symptoms in this second situation are not stipulated. Nevertheless, DSM-IV is an advance over DSM-III-R, which instructed clinicians to give priority to the judgement of teachers over that of parents.

Perhaps the most salient difference between the DSM-IV and ICD-10 classifications is the approach to the diagnosis when more than one disorder coexists with AD-HKD. DSM-IV recognizes all diagnoses that are present, except for schizophrenia, autism and pervasive developmental disorder. In contrast, ICD-10, in general, discourages multiple diagnoses. In the presence of internalizing disorders, such as anxiety or mood disorders, ICD-10 does not recommend the HD diagnosis. The only exception occurs when both HD and conduct disorder coexist. ICD-10 labels this combination hyperkinetic conduct disorder. This new subcategory is intended to deal with the tendency of clinicians in Europe to prefer the diagnosis of conduct disorder to HD when both disorders are evident (Prendergast *et al.* 1988).

Considerable evidence supports the validity of both ADHD and HD. Children with ADHD diagnosed according to DSM criteria or HD diagnosed according to ICD can be distinguished reliably from children with other disorders, such as conduct disorder, and differ in important ways from normally developing children on a wide range of laboratory measures of attention, social interaction and outcome (Barkley 1995). For example, conduct disorder is associated with hostile attributional bias, greater exposure to psychosocial adversity and higher prevalence of delinquency in adolescence. By contrast, ADHD and HD are associated with cognitive deficit of various kinds (Schachar 1991; Tannock 1998a) and with later antisocial behaviour above and beyond the risk associated with early conduct disorder (Taylor *et al.* 1996).

There have been few direct comparisons of non-overlapping groups of ADHD and HD children (Tripp & Luk 1997). Based on available evidence, ADHD that is not severe enough to fulfil criteria for HD is common in the general population. In many cases, these children are not particularly impaired (Taylor *et al.* 1991). Nevertheless, ADHD of this degree of severity may identify a group of children at high risk for the development of disturbance. HD (as defined by ICD-10) constitutes the most severe 20% of those with ADHD (as defined by DSM-IV) as judged by an increased rate of important clinical correlates, such as neurodevelopmental delay, risk of comorbidity, psychosocial impairment, poor academic and cognitive function and comorbid psychopathology. HD may also be more responsive to methylphenidate (Taylor *et al.* 1987, 1991).

Northern European clinicians continue to stress the centrality of delay in motor development to the diagnosis (Bax & McKeith 1963; Kalverboer 1975; Nichols & Chen 1981). Accordingly,

disorder of attention, motor control and perception (DAMP) came to refer to the coincidence of these deficits (Gillberg & Gillberg 1988, 1989). DAMP overlaps with but is not coincident with ADHD or HD. Approximately half of children with ADHD meet criteria for DAMP (Landgren *et al.* 1996). DAMP plus ADHD delineates a subset of children with more marked classroom dysfunction and poorer academic test scores than either ADHD or DAMP alone. By contrast, the majority of those with HD meet criteria for DAMP (Taylor *et al.* 1991). The validity of the concept of DAMP has been questioned because the association of neurodevelopmental abnormality and hyperactivity does not appear to be specific to hyperactivity nor is there a uniform behaviour consequence of brain injury (Rutter 1982; Rutter *et al.* 1983; Shaffer *et al.* 1985; Rydelius 2000).

Subtypes

Various subtypes of AD-HKD have been distinguished, based on phenomenology, pervasiveness of symptoms and patterns of comorbidity. Subgrouping based on the children's response to treatment is less well established, but is suggested by the existence of differences between children who do and do not respond favourably to methylphenidate (Buitelaar *et al.* 1995; Taylor *et al.* 1987). Subgroups based on the presence or absence of genetic risk factors involved in the dopaminergic and noradrenergic systems remains speculative (Swanson *et al.* 2000).

DSM-IV makes a distinction between hyperactive-impulsive, inattentive and combined hyperactive-impulsive and inattentive subtypes, although the true significance of this distinction is unknown. The inattentive and combined subtypes are about equally prevalent among school-age children and are more common than the hyperactive-impulsive subtype (Morgan *et al.* 1996; Faraone *et al.* 1998b). The hyperactive-impulsive subtype is more common in very young children but decreases in prevalence with age. Many children with the hyperactive-impulsive subtype have combined subtype on follow-up (Cantwell & Baker 1988), suggesting that subtypes may represent developmental stages rather than distinct entities.

Hyperactive and impulsive behaviour tends to be predictive of delinquent and aggressive behaviour (Taylor *et al.* 1996; Eiraldi *et al.* 1997; Babinski *et al.* 1999). Inattentive behaviour predicts lower IQ, more abnormalities in cognition and delayed language development. Inattentive children are also less impulsive, aggressive, distractible and socially disinhibited (Lahey & Carlson 1991; Cantwell & Baker 1992; McBurnett *et al.* 1999; Warner-Rogers *et al.* 2000). Taylor *et al.* (1991) found that the majority of attention deficits associated with the inattentive subtype (DSM-III ADD without hyperactivity) were artefacts of lower IQ: differences in attention between ADD and normal children disappeared once IQ was controlled.

Quantitative and categorical approaches to diagnosis

Arguments about the relative validity of criteria for ADHD, HD

and DAMP are all conducted from a categorical perspective on diagnosis. This approach assumes that individuals who meet specific criteria and those who do not differ in kind rather than in degree. There is another broad perspective on classification of AD-HKD: the dimensional approach. According to this approach, the constituent behaviours of AD-HKD vary widely in the general population and so individuals are more or less affected and impaired (Fergusson *et al.* 1991; Meehl 1995). Accordingly, AD-HKD is best viewed as the extreme of some continuously distributed but unobservable or latent trait, rather than as a discrete entity: affected persons are quantitatively but not qualitatively distinct from unaffected persons. Which approach is correct is not easily resolved. It is likely that certain aspects of the syndrome are captured best by the categorical approach, while others are better characterized by the dimensional, or quantitative, perspective.

The quantitative approach is supported by the observation that no bimodal distribution of scores is observed in behavioural data and that there does not seem to be an obvious discontinuity between a group of individuals with high hyperactivity and a group with low hyperactivity. A bimodal distribution, if present, would indicate that there is both temperamental variation and the presence of a discrete 'hyperactive' group (Meehl 1995). In addition, one typically observes a continuous and generally linear dose-response function relating symptom severity and outcome risk (substance abuse behaviour, juvenile offending, heritability and school drop-out at age 16; Fergusson & Horwood 1995; Levy *et al.* 1997). Dimensionally scored variables are often better predictors of outcome than are measures based on a diagnostic classification (extreme scores; Fergusson & Horwood 1995).

Course and prognosis

Hyperactive preschool-age children are referred for clinical assessment. However, most individuals are referred after they start school. In most but not all cases, the history reveals AD-HKD symptoms from an early age.

Originally, AD-HKD was thought to be a transient phenomenon because of the tendency for symptoms, especially restlessness, to diminish as children reached adolescence. Inattention and impulsiveness are more persistent manifestations (Hart *et al.* 1995). It is now clear that the disorder persists into adolescence in half or more of affected persons, and into adulthood in half or more of adolescent cases (Klein & Mannuzza 1991; Weiss & Hechtman 1993; Mannuzza *et al.* 1998).

Compared with their non-AD-HKD peers, previously affected persons are at approximately five times greater risk for substance abuse (tobacco, alcohol, illicit drugs), antisocial behaviour (aggression, trouble with the law, admission to juvenile facilities), and other psychiatric disorders, such as depression and anxiety (Levin & Kleber 1995; McArdle *et al.* 1997). Academic and educational problems persist into adolescence; by the time they are adults, hyperactive children have completed

significantly less schooling and hold lower status jobs than their non-hyperactive peers (Fergusson *et al.* 1997; Mannuzza *et al.* 1997). Even those who no longer meet the criteria for AD-HKD in adolescence are at increased risk for substance abuse and antisocial disorders, suggesting the persistence of some residual or latent deficit (Mannuzza *et al.* 1993).

Poor outcome in adolescence and young adulthood is more likely when the affected child experiences stressful life circumstances, such as those that are commonly associated with poverty, overcrowding, negative expressed emotion in the parent-child relationship, and parental psychopathology (Barkley *et al.* 1990a; Farrington *et al.* 1990; Fischer *et al.* 1993; Taylor *et al.* 1996). Prognosis is also worse when the AD-HKD symptoms are severe, and predominantly hyperactive-impulsive in nature and when the child exhibits early conduct, language or learning disorder (Moffitt 1990; Lynskey & Fergusson 1995; Babinski *et al.* 1999; Merrell & Tymms 2001). Nevertheless, the poor outcome of children with AD-HKD is not simply a function of these early associated impairments; AD-HKD increases the risk of a poor outcome, even when due allowance is made for the associated risk factors (Babinski *et al.* 1999; Farrington *et al.* 1990; Taylor *et al.* 1996).

Epidemiology

The prevalence of AD-HKD depends, to a great extent, on the diagnostic measures used (e.g. questionnaires or interviews), diagnostic criteria (ICD-10, DSM-IV), sampling method, number of informants used (parents only, teachers only or both), handling of comorbidity (exclusion of cases with comorbid diagnosis), age of population, country, and the nature of the population studied (e.g. inner city or rural; Boyle *et al.* 1996). Screening with behavioural questionnaires identifies 10–20% of the population as affected (Wolraich *et al.* 1998). Studies that use definitions based on DSM, requiring some degree of pervasiveness and impairment and include comorbid cases, report prevalence rates in the 5–10% range (Offord *et al.* 1987; Fergusson *et al.* 1993; Newman *et al.* 1996). When the more stringent ICD-based criteria are used and the diagnosis is restricted to the presence of the full syndrome without comorbid conditions, 1–2% prevalence rates are found (for review see Danckaerts & Taylor 1995; Swanson *et al.* 1998a). The prevalence of combined ADHD and DAMP is about 6% (Kadesjo & Gillberg 1998). In clinical samples, fewer than half of children meeting criteria for ADHD also meet criteria for HD (Tripp *et al.* 1999).

Prevalence of the diagnosis of AD-HKD varies by culture although there is little difference among cultures in rates of hyperactive behaviour as assessed by questionnaire rating (Leung *et al.* 1996). The diagnosis of AD-HKD is only recently becoming more common in Mediterranean countries.

The ratio of males: females with the diagnosis in community samples is approximately 3:1 (Szatmari *et al.* 1989c). The prevalence of AD-HKD is highest among school-aged boys and lower among adolescents. In contrast, its prevalence among

females is lower, but is more stable across ages. AD-HKD is more common in urban than rural communities (Szatmari *et al.* 1989c).

There has been a lot of speculation about the apparent increase in prevalence of the disorder over the last half century. The rapid increase in prevalence of the diagnosis was largely a North American phenomenon (Danckaerts & Taylor 1995). One reason for increased prevalence lies with the broadening of diagnostic criteria resulting from changes in DSM. However, rates may be increasing in Europe of late as clinicians shift from emphasizing only the social and psychological factors in hyperactivity to appreciating the role of neurobiological influences. Some have emphasized the potential impact that the marked changes in the *pace* or *speed* of everyday life could have on neural development. Others attribute the increasing use of the diagnosis to the discovery by Charles Bradley (1937) that dexamphetamine was a safe and effective treatment. Changes in educational practice, societal expectations and allocation of health care resources have also played a part.

Aetiology

AD-HKD is an aetiologically heterogeneous disorder that can be caused by a range of biological, psychological and social conditions that act individually or together to increase the risk of AD-HKD. Although we now know a good deal about the individual genetic, neurochemical, neuropathological and cognitive mechanisms involved in AD-HKD, we do not understand fully how these influences interact to cause AD-HKD, what part is played by environmental factors or whether there are distinct subgroups caused by particular factors or combinations of factors.

Much of the available evidence points to the importance of abnormal higher order cognitive functions caused by dysfunction in catecholamine metabolism and neurotransmission in the prefrontal cortex and associated subcortical structures. Primate lesion studies as well as human imaging, electrophysiological and neuropathological studies (Pardo *et al.* 1990; Corbetta *et al.* 1993; Posner & Raichle 1998) indicate that executive functions, self-regulation, arousal and motivation involve a distributed neural system that includes the orbital prefrontal, anterior cingulate cortex and related subcortical structures (basal ganglia) (Goldman-Rakic 1996, 1987; Posner *et al.* 1997). These higher order functions are the delaying, future-orientated and intentional control processes of the cognitive system that guide action and behaviour (Denckla 1996). They have a role in maintenance of alertness, sustaining of attention and effort, inhibition of inappropriate actions, and adjustment of response strategies when errors are made or circumstances change. Deficits in these processes are common among children with AD-HKD and are thought to be the proximal cause of their poorly regulated everyday behaviour and impaired performance on laboratory tasks (Pennington & Ozonoff 1996; Barkley 1997).

The neurones in the regions of the brain implicated in executive control are particularly rich in catecholamines (dopamine, adrenaline and noradrenaline), as well as other neurotransmitters. These neurotransmitters have multiple functions and vary in their distribution but are involved in motivation, action and attention. Other neurotransmitters, such as serotonin, may have a role in modulating dopamine transmission and in the expression of AD-HKD (Swanson *et al.* 1998b; Zametkin & Liotta 1998; Gainetdinov *et al.* 1999; Quist *et al.* 2000).

At low doses, stimulants reduce locomotion in both humans and animals. These drugs raise the resting extracellular levels of dopamine primarily by blocking the dopamine transporter that is involved in re-uptake of dopamine at presynaptic neurones thereby preventing re-entry of dopamine into the neurone. Dexamphetamine also directly releases dopamine from presynaptic neurones. The result is a resting increase in the availability of dopamine at the synaptic cleft and at dopamine receptor sites. During a normal nerve impulse, there is a transient rise in extracellular dopamine. The net effect of the rise in resting dopamine level with low-dose drug treatment is a reduction in the relative rise in dopamine that is triggered by an impulse (Seeman & Madras 1998).

Neuroimaging studies confirm structural and functional abnormalities in those regions of the brain that are implicated in executive function (for a review see Casey *et al.* 1997; Tannock 1998b). These studies report significantly smaller less symmetrical prefrontal and basal ganglia structures, particularly on the right side, in children with AD-HKD than in matched controls (Giedd *et al.* 1996; Casey *et al.* 1997; Filipek *et al.* 1997).

Family, twin, adoption and molecular studies offer strong evidence of genetic susceptibility to AD-HKD. Relatives of individuals with AD-HKD have an increased risk for AD-HKD (Schachar & Wachsmuth 1990; Szatmari *et al.* 1993; Faraone *et al.* 1996b). For example, siblings of children with AD-HKD have a 2–3 times greater risk of AD-HKD than siblings of normal controls (Faraone & Biederman 1994). Twin studies find a markedly higher concordance of AD-HKD for monozygotic (79%) than dizygotic (32%) twins that is consistent with high heritability of AD-HKD. Heritability estimates range from 0.7 to 0.9 (Goodman & Stevenson 1989; Gilger *et al.* 1992; Edelbrock *et al.* 1995; Eaves *et al.* 1997; Levy *et al.* 1997). Adoption studies (van den Oord *et al.* 1994) provide further evidence of a genetic component to AD-HKD; biological parents of AD-HKD individuals are more likely to exhibit AD-HKD or related disorders than are adoptive parents.

The strong evidence of genetic effects, the effect of stimulant medication on children with AD-HKD, and the concentration of neurones rich in dopamine and norepinephrine in the neural areas involved in executive function led to investigation of the role of candidate genes involved in the noradrenergic and dopaminergic systems (McCracken 1991; Castellanos 1997). To date, AD-HKD has been associated with the dopamine transporter gene (*DAT1*) (Cook *et al.* 1995; Gill *et al.* 1997; Barr *et al.*

2000) and the dopamine D4 receptor gene (LaHoste *et al.* 1996; Smalley *et al.* 1998).

Presumably, these polymorphisms or mutations in the respective genes may give rise to the AD-HKD phenotype by altering the function of the proteins involved in the transcription of the various receptors in these pathways. For example, signal transmission is blunted when dopamine binds to the 7-repeat allele receptor compared to the 2- or 4-repeat alleles. The association between specific alleles and AD-HKD could be caused by a direct pathophysiological effect or the observed polymorphism could be a marker for a nearby DNA site that influences risk for AD-HKD.

Although the evidence for a genetic mechanism involving the neurochemical and structural substrate of executive control is strongly supported by these lines of research, there is ample evidence that other mechanisms also have an important role. For example, twin studies show a small but important shared and non-shared environmental effect for AD-HKD (Eaves *et al.* 1997). Gene–environment interactions may be more important than currently believed and may be inflating estimates of the genetic component of AD-HKD in twin studies. Moreover, the magnitude of genetic influence in AD-HKD may be inflated in family, adoption and twin studies by methodological eventualities, such as parental rater bias, contributing to sibling contrast effects (Simonoff *et al.* 1998) and bias in selection of adoptive parents.

A range of psychosocial factors are associated with AD-HKD, including maternal stress during pregnancy and poor quality or disrupted early caregiving as may be seen in children in institutions or foster care (Jacobvitz & Sroufe 1987; Roy *et al.* 2000). Neurobiological risk factors, especially those acting during the period of rapid brain growth during fetal development and early life, could have a direct adverse impact on cognitive development or an indirect effect through increasing risk for neurobiological hazards. These factors include fetal exposure resulting from the mother's use of alcohol, drugs or cigarettes, and the adverse effects of perinatal obstetrical complications or prematurity (Streissguth *et al.* 1994; Breslau *et al.* 1996; Milberger *et al.* 1998). AD-HKD occurs after traumatic brain injury in 25% of cases (Max *et al.* 1997; Gerring *et al.* 1998) or after exposure to environmental toxins such as zinc or lead (Toren *et al.* 1996). The brain region involved in executive control may be particularly sensitive to perinatal hypoxia or toxins because of the terminal nature of the arterial supply to the anterior forebrain. These environmental risks probably interact among themselves and with genetic risks, making the specific role of any single factor difficult to assess accurately.

Treatment

Currently, the accepted approach to treatment involves long-term multimodal intervention in which various pharmacological and psychological treatments and combinations of treatment are used together with a supportive management

strategy. Family, school and other agencies have a major role in intervention. The mainstay of treatment is stimulant medication (Miller 1999). Psychological therapy involving family, group or behaviour therapy or those involving special education are thought to be effective but have received relatively less empirical support. Special diets, dietary supplements, megavitamins, antionion-sickness medication, and electroencephalographic biofeedback are also used but are not proven therapies (Goldstein & Ingersoll 1992; Richters *et al.* 1995; Jadad *et al.* 1998).

Current estimates place the number of US children receiving special education provisions for AD-HKD at 1 million although they are typically labelled as learning disabled, emotionally disordered or as having 'other health impairments'. The costs associated with these provisions are estimated to be in the order of 3 billion dollars annually above what is typically spent on children with a learning disability. Yet, two-thirds of children with AD-HKD receive no services: females, members of minority groups, the poor, those living in rural areas and those in health maintenance organizations are less likely to be served. AD-HKD is associated with a high family burden arising from the cost of psychological testing, tutoring, medication and other out-of-pocket expenses.

Methylphenidate (Ritalin) and, to a much lesser extent, dexamphetamine are the most frequently prescribed treatments for AD-HKD in North America (Rappley *et al.* 1995; Safer *et al.* 1996). Tricyclic antidepressants and α_2 -noradrenergic agonists, such as clonidine and guanfacine, are second-line drug treatments for children who have an inadequate response to stimulants (Greenhill *et al.* 1996; Cantwell 1998).

The number of prescriptions of medication for children with AD-HKD has more than doubled over the last two decades to 5 million in the USA: about 3% of persons aged 5–18 years (1.5 million children) are taking medication for AD-HKD (Safer *et al.* 1996). The prevalence of the use of medication is lower in Canada, Europe and Australasia (about 1%) than in the USA, but is beginning to rise (Miller 1999). Community physicians rely heavily on medication for the treatment of AD-HKD: as many as 88% of diagnosed children receive drug treatment at some point in time (Wolraich & Baumgaertel 1997).

The steady growth in the use of medication is driven by the more frequent identification of affected persons, in particular, those with inattention only; the growth in rate of identification and treatment of girls, preschool-age children, adolescents and adults; and the increased length of the treatment for each individual. The rising prevalence of the use of medication may also be linked to a lack of affordable and feasible non-drug treatment; greater familiarity with and acceptance of medication; and an absence of convincing evidence that non-pharmacological interventions are as effective as those involving medication.

Therapeutic effects of stimulants

Heyman & Santosh (Chapter 59) deal with the main efficacy

and pharmacokinetic issues for these medications. Numerous placebo-controlled randomized control trials (for meta-analyses see Jadad *et al.* 1998; Miller 1999) confirm the substantial short-term benefits of stimulants. Stimulants markedly and rapidly reduce the overt clinical manifestations of AD-HKD, such as restlessness, inattentiveness and impulsiveness, improve the quality of social interactions, decrease aggression and increase compliance (Cunningham *et al.* 1991; Hinshaw & James 1991; Whalen & Henker 1991). By comparison, the effect on laboratory measures of attention is evident but less robust. Stimulants increase accuracy, facilitate error detection, improve the ability to focus on the most relevant aspects of a stimulus array and decrease impulsive responses without causing undue narrowing of attention or rigidity of thought in most cases (Douglas *et al.* 1995; Tannock *et al.* 1995; Brumaghim & Klorman 1998). Moreover, stimulants increase persistence, effort and frustration tolerance (Milich *et al.* 1991). Improvement is evident on a range of demanding divergent thinking tasks, not just on boring, simple or repetitive tasks (Nigg *et al.* 1997) and stimulants also improve academic productivity (Tannock *et al.* 1989; Rapport *et al.* 1994). However, stimulants have far less of a beneficial effect on school work. There is no evidence that the information learned while a child is receiving medication is recalled less easily later when the child is not medicated (this is known as state-dependent learning; Becker-Mattes *et al.* 1985).

In a substantial proportion of children mood, self-esteem and anxiety improve (Buhmester *et al.* 1992; Ahmann *et al.* 1993; Pelham *et al.* 1997) although in some there is a decrease in social interaction (Whalen *et al.* 1989). Medication does not seem to engender attribution of success to external factors rather than to personal effort (Pelham *et al.* 1997). Even prolonged treatment with stimulants does not appear to increase the risk of drug use or abuse and may even prevent them (Hechtman & Weiss 1986; Biederman *et al.* 1999). No adverse events or reduction in height or weight have been demonstrated over long periods of treatment (Schertz *et al.* 1996; Spencer *et al.* 1998).

Preschool-age children and those with low intelligence respond favourably to stimulants (Firestone *et al.* 1998) but are somewhat less responsive to stimulants than are school-aged children of average intelligence and somewhat more prone to develop side-effects (Pisterman *et al.* 1989; Handen *et al.* 1991; Mayes *et al.* 1994). Stimulants are effective among adolescents (Klorman *et al.* 1990), adults (Spencer *et al.* 1996) and children with neurodevelopmental delay (Handen *et al.* 1991), aggression (Klorman *et al.* 1994; Klein *et al.* 1997) or comorbid tics (Gadow *et al.* 1995). A greater severity of AD-HKD symptoms, younger age and, possibly, absence of symptoms of anxiety predict a better clinical response to stimulants (Taylor *et al.* 1987; DuPaul *et al.* 1994; Pliszka *et al.* 1994; Buitelaar 1995; Diamond *et al.* 1999). Tolerance to methylphenidate can develop in some children over months or years of continuous therapy (Sleator *et al.* 1974; Kupietz *et al.* 1988; Swanson *et al.* 1999). About one-third of these children may require increased dosage (Safer & Allen 1989).

Limitations of stimulant medication

Although stimulants have proved effective, they have their limitations. They are thought by many to be prescribed too frequently and inappropriately and to be a public health risk in their own right because of their potential for undetected long-term adverse events, for abuse and for the way that they can distract from 'genuine' treatments.

Medication is not an acceptable treatment option for many children and families. Many families believe that their child's problems reside in the context of key relationships or in the child's school. Others are more concerned about comorbid learning, behaviour or emotional disorders and less interested in treatment of hyperactivity *per se*. Other families are concerned about the biological or ethical implications of treating young children with drugs or about the potential for unknown long-term risks of treatment.

Lack of adherence limits the effectiveness of medication, as it does with all medical treatments. Adherence is lower among adolescents because of their increased autonomy, their determination to make important decisions for themselves and their dislike of being 'different' from their friends. A substantial number of individuals are able to manage quite well after discontinuing medication but many choose to restart medication following a medication-free period because of deteriorating behaviour or school performance.

Typically, children take immediate-release stimulant medication twice daily or a sustained-release preparation once daily. Medication has a limited duration of action and difficulties may arise during medication-free periods (Schachar *et al.* 1997). Administration of medication three times daily can have advantages when tolerated but can be associated with an increase in side-effects in some children (Kent *et al.* 1995; Greenhill *et al.* 1996; Corkum *et al.* 1998).

Even though a beneficial impact of behaviour, as rated by their teachers, may occur in about 70% of treated children (Spencer *et al.* 1996), treatment normalizes the behaviour of only about half of children (Rapport *et al.* 1994) and many disabilities remain. Stimulants have only a limited impact on school grades (Rapport *et al.* 1994). One-quarter of children with AD-HKD who are aggressive before treatment show no increase in prosocial behaviour or improvement in processing of social information (Hinshaw *et al.* 1989). Stimulant medication may increase socially inhibited behaviour, social withdrawal and dysphoria. Consequently, the child may be perceived as socially unresponsive, with the result the child may be less liked by peers or adults (Buhmester *et al.* 1992; Granger *et al.* 1993a,b).

Children with AD-HKD and comorbid anxiety may have a somewhat less robust behavioural response to stimulants and possibly a greater incidence of side-effects than children with AD-HKD without comorbid anxiety (DuPaul *et al.* 1994). However, a differential treatment response has not been detected with long-term treatment (Diamond *et al.* 1999) and many children with AD-HKD and comorbid anxiety may show a reduction in anxiety as their hyperactivity abates.

Although generally safe, stimulant medication does have side-effects in a significant proportion of recipients that, in some cases, result in the termination of treatment. Loss of appetite, weight loss, insomnia, headaches and stomach aches are the most frequent side-effects although many children with AD-HKD have these complaints before starting treatment (Barkley *et al.* 1990b; Ahmann *et al.* 1993). Stimulant-related disruption of sleep is not uncommon (e.g. delayed sleep onset; Corkum *et al.* 1998; Tirosh *et al.* 1993; Kent *et al.* 1995). Initial physiological side-effects tend to persist, whereas other side-effects, such as irritability and moodiness, tend to have delayed onset (Schachar *et al.* 1997).

One of the most significant limitations of stimulant medication is the lack of evidence of its efficacy over prolonged periods of treatment. Available evidence indicates that extended treatment with stimulants improves core behavioural symptoms for as long as it is taken, although few subjects become indistinguishable from their normal peers (Conrad *et al.* 1971; Abikoff & Gittelman 1985). On cessation of the medication, benefits dissipate rapidly (Brown *et al.* 1986; Gillberg *et al.* 1997). Even with prolonged administration, stimulants may not reliably improve academic attainment, reduce the risk of developing antisocial behaviour, facilitate peer relationships or enhance self-esteem (Barkley *et al.* 1990a; Fischer *et al.* 1993).

Health care costs are an important measure of effectiveness. However, no evidence is available about how well stimulant medication reduces the overall health care costs associated with AD-HKD.

Psychological treatments

Various psychological therapies have been used for AD-HKD, either as an alternative to medication or as a method of augmenting the effects of medication. Behaviour parent training is the most commonly prescribed psychological intervention for AD-HKD. Parent training is predicated on the observation that parents of children with AD-HKD use overly controlling and inefficient parenting strategies (Mash & Johnston 1990) and that adversity in the parent-child relationship is predictive of poor outcome (Taylor *et al.* 1996). Parent-training programmes are based on social learning theory. They use direct instruction, modelling and role-playing to teach parents to reinforce positive behaviour, decrease the use of punitive strategies, and manage defiant, stubborn and inappropriate behaviour effectively (Cunningham *et al.* 1993).

Parent-training programmes improve the parents' child-management skills, enhance their self-confidence, reduce family stress and mitigate oppositional behaviour (Barkley *et al.* 1992b; Pisterman *et al.* 1992; Anastopoulos *et al.* 1993; Webster-Stratton & Hammond 1997). The important advantages of parent training are its relatively low cost, its ability to be delivered in the community rather than in clinics, thereby reducing barriers to participation, and its ability to be adapted to the needs of specific ethnic or cultural groups (Cunningham *et al.* 1995). However, parent training does not reduce the core symp-

oms of AD-HKD as effectively as does stimulant medication, nor does it appear to enhance the effectiveness of stimulants (Firestone *et al.* 1986; Horn *et al.* 1991; Jadad *et al.* 1998). Benefits tend not to persist beyond the period of treatment.

Behavioural therapy involves trained therapists, parents or teachers who reinforce positive behaviour and academic accomplishment, and who use response-cost procedures (withholding rewards when inappropriate behaviour occurs) to reduce disruptive behaviour (Abramowitz *et al.* 1992). Cognitive-behaviour therapy attempts to enhance self-control by teaching children self-instructional strategies. Social skills training targets the child's problems with peers and adults, typically in a group setting. These therapies may yield short-term improvement when administered on their own (Abikoff 1991; Carlson *et al.* 1992; Frankel *et al.* 1997; Pfiffner & McBurnett 1997), but there is little evidence that they are as potent as medication or routinely add to the effects of medication (MTA Cooperative Group 1999a,b).

Multimodal treatment

Families most frequently choose combined treatments, although the additional benefits accruing from treatment combinations are unclear (Jadad *et al.* 1998, 1999). A large multisite study in the USA recently tested the relative effectiveness of various treatment strategies delivered individually and in combination in 576 school-aged children with AD-HKD (MTA Cooperative Group 1999a,b). Four treatment strategies were compared:

- 1 drug treatment (mostly methylphenidate);
- 2 drug treatment combined with an intensive psychosocial intervention strategy (family therapy, social skills training, an intensive summer camp programme and classroom management);
- 3 psychosocial intervention alone; and
- 4 a typical community-based intervention.

All subjects received the same assessment, but those in the community-based intervention were referred to facilities in the community and their family physicians for treatment. The other treatments were administered by research personnel.

The implications of this study are currently being debated. Psychosocial treatment, when administered without medication, was generally equivalent to that of community-based treatment even though community treatment involved medication in two-thirds of cases. Combined intervention was minimally superior to medication administered alone across the entire group of participants. The additional benefit was most evident among the small subgroup of children who had more emotional symptoms and poorer home life. Combined treatment achieved equivalent improvement to medication alone but with lower doses of medication. Many children in the community-based intervention received medication, but they did not seem to progress as well as those who received medication from study physicians. This was particularly true for children with AD-HKD who also had prominent anxiety symptoms. This finding suggests that medication management that is intensive and

coupled with supportive counselling and that is responsive to the presence of anxiety may be superior to the medication treatment most children receive in the community.

In summary, psychological interventions are an important treatment option, particularly for families who do not wish to use medication. On their own, they are less effective than well-delivered medication but as effective as medication administered in the community. The primary benefit of combined parent training and medication may be reduction of secondary impairments, such as the conflict between parents and children in subgroups of AD-HKD cases with emotional symptoms or poor parent-child relationships (MTA Cooperative Group 1999a,b). However, both the medication management protocol and the intensive psychosocial interventions used in this study are not typically available in the community. There are many unanswered questions about timing, intensity, duration, availability and cost of psychological interventions (Boyle & Pickles 1997; Cunningham 1999; Pelham 1999).

Management

Diagnosis and assessment

The preceding description of the range of AD-HKD manifestations, situational variability, comorbidity and associated impairment points to the complexity of the assessment and treatment of the disorder (Dulcan & Benson 1997; Goldman *et al.* 1998). Reports of hyperactive behaviour are quite subjective and there is considerable variability across settings. Consequently, the diagnostician would be wise to employ converging measures of behaviour derived from more than a single informant. Typically, the assessor will obtain information from the child's parents, the child and the child's classroom teacher. The diagnostician should elicit descriptions of child behaviour because global impressions of AD-HKD symptoms can be very misleading and subject to bias or halo effect arising from the informant's mental state or beliefs about the nature of AD-HKD. Behaviour rating scales provide a valuable, simple and inexpensive means to collect descriptions of child behaviour from various informants but they are subject to the same bias and error as other measures.

During the assessment, the physician must investigate the presence of a concurrent disorder and the relationship of the symptoms of a comorbid disorder and AD-HKD. For example, are the restlessness and inattention of a child limited to a period of anxiety or depression? Are the AD-HKD symptoms part of a conduct disorder, substance abuse disorder, or Tourette syndrome?

Children with AD-HKD are able to suppress their inattention, restlessness and impulsiveness to a great extent in novel and highly structured situations, such as those afforded by the typical visit to the physician's office. Direct examination of the younger child may be limited by the child's apparent lack of insight into his or her behaviour or an inability to communicate

as a result of learning or language impairment. Nevertheless, the interview with the child may be useful for identifying comorbid disorders, assessing the relationship of symptoms to anxiety or academic demands, monitoring treatment, and establishing the rapport that is required to sustain a prolonged intervention.

Because many children meet AD-HKD criteria almost exclusively on the basis of behavioural difficulties within the school context, it is essential to assess the presence of learning difficulties, the nature of the educational experience and the quality of the child's relationships with peers and teachers. Consultation from an educational psychologist and speech pathologist is very important in assessing the nature of the academic difficulties and the potential contribution of speech and language delay to deviant child behaviour.

Assessment of adolescents and adults

The diagnostic process in adolescents and adults is complicated in several ways. The manifestations of the disorder change with age. Gross motor activity decreases and an inner sense of restlessness, fidgeting and inattention emerges as the primary expression of disorder. It becomes more difficult to obtain an accurate description of the adolescent's behaviour, especially in the school and work settings, because of the absence of a consistent informant. These considerations place increased importance on the interview of the adolescent concerning their own social, scholastic and behavioural problems.

It is generally accepted that an adult diagnosis of AD-HKD requires a childhood history of AD-HKD (Shaffer & Greenhill 1979). In many cases, there is no informant who knew the person as a child and there may be no possibility of obtaining reliable school records. Despite these obvious difficulties, the diagnosis of AD-HKD in adults based on self-report seems to be reliable (Spencer *et al.* 1994; Faraone *et al.* 1997b).

The diagnostic process among adolescents and adults is also complicated by high rates of anxiety, mood disorder, personality disorder and substance abuse, for which they may have received extensive treatment. AD-HKD uncomplicated by comorbid psychopathology is rare in this age group, in part because of the consequences of lifetime AD-HKD. Distinguishing 'primary' hyperactivity that has led to secondary psychopathology from hyperactivity that arises as a secondary manifestation of another disorder can be challenging.

Differential diagnosis

There are several conditions that can mimic AD-HKD but which require very different treatment. These conditions include the effects of prescription medication (phenobarbital, antihistamines, theophylline, sympathomimetics or steroids), substance abuse, metabolic disorders (hyperthyroidism), toxic conditions (lead poisoning), anxiety and mood disorder. In its early stages, Tourette syndrome may be evident in symptoms of hyperactivity. Despite robust evidence for cognitive, neuropsychological, neurophysiological and biochemical deficits in children

with AD-HKD, there are no known laboratory tests that have sufficient diagnostic sensitivity and specificity to distinguish children with AD-HKD from unaffected children or from those with other disorders. Specific laboratory tests may be necessary to exclude suspected problems, such as poor hearing or vision, metabolic disease, drug abuse or exposure to toxins. Although there is an increased prevalence of AD-HKD among persons with a generalized resistance to the thyroid hormone, thyroid abnormalities are rare among individuals with AD-HKD and routine screening for thyroid abnormality is not indicated (Hauser *et al.* 1997; Woodward *et al.* 1989).

Not infrequently, children with AD-HKD also present with severe emotional and behavioural dysregulation, high irritability, extremely low frustration tolerance and episodes of aggression. Although these individuals show subtle rather than clear evidence of mania, euphoria or grandiosity, some believe that a diagnosis of bipolar disorder is warranted and a trial of mood-stabilizing medication appropriate. This subgroup of AD-HKD individuals is more likely than others to have a family member affected by bipolar disorder (Wozniak *et al.* 1995a,b). It is not yet clear whether the disturbance of these individuals is best understood as a variant of mood disorder or as a particularly extreme form of AD-HKD.

Other conditions may be identified at the time of assessment, such as fetal alcohol syndrome or the consequences of traumatic brain injury. For the most part, hyperactivity associated with these disorders leads to the same treatment as for primary AD-HKD although the evidence to support this practice is largely lacking.

Management strategies

AD-HKD is a chronic condition that affects many aspects of a child's life over a prolonged period of time. Consequently, it requires a comprehensive management strategy that targets all facets of the disorder. The persistent nature of the disorder dictates the need for consistent long-term case management. Treatment must be flexible, both in kind and in intensity, to reflect the social, physiological and cognitive developments and variations in the life of each child and his or her family. Medication is unlikely to be the only course of action. Drug and psychological interventions need to be layered according to the needs of the child and family. There are families who are not ready for or capable of undertaking treatments other than those involving medication. For many of these families, a period of symptomatic improvement resulting from successful drug therapy may provide the impetus for entry into other essential non-pharmacological components of therapy. Some families may not consider non-pharmacological interventions until they observe that an immediate increase in academic productivity does not necessarily translate into better grades at the end of the year and that teachers' report of improved behaviour at school does not ensure improved family and peer relationships. Other families may be too chaotic to use medications appropriately and may first need to try psychological interventions under close supervision. Some

components of behavioural intervention, such as time out or punishment tactics, can be used in a punitive manner and are not necessarily more benign than medication. Some families are more content with the decision to use medication if it follows a period of counselling or behavioural intervention (Slimmer & Brown 1985).

It is often recommended that pharmacological treatment commence with a systematic double-blind trial of immediate-release methylphenidate or dexamphetamine. Many parents are reassured by the rigor of a systematic trial (Johnston & Fine 1993). Systematic trials are not particularly complicated and can be organized in typical clinical practice. On the other hand, systematic trials seem to have little advantage over open trials. There is little evidence of a sustained placebo effect, and doses determined by a systematic trial tend to be similar to those determined by open titration. Consequently, the extra cost of a double-blind trial may not be justified (Pliszka *et al.* 2000).

Education is an important part of treatment because it helps parents and the affected child to develop an understanding of the nature of the disorder. Moreover, increased knowledge may result in more realistic expectations of and better adherence to treatment. Regular contact with the child's teacher is useful to monitor behavioural improvement and side-effects in the school setting. Behavioural response and side-effects must be monitored regularly (MTA Cooperative Group 1999a,b).

Comparison of physicians' actual clinical practice with the results of recommendations of authorities for the medical management of AD-HKD show that management may be suboptimal in about one-third of cases (Miller 1999). Diagnosis often fails to include consideration of behaviour in multiple settings, presence of comorbid psychopathology, and associated impairments. Medication may not be monitored closely enough and non-pharmacological components of care are not implemented. Although stimulant medication may be relatively easy to prescribe because of its favourable effects and low risk of adverse effects, there is ample evidence that the quality of medical management has an impact on treatment outcome (MTA Cooperative Group 1999a,b).

Prevention

Primary prevention of AD-HKD, like that of other mental illnesses, requires intervention to alter identified population health risks. Apparently, hyperactivity has a multifactorial aetiology and each factor accounts for only a small portion of the variance in the incidence of the disorder or outcome. Unless we can identify subgroups in which specific causes have a large impact, it will be very difficult to effect a public health intervention.

The validity of HD, the most narrowly defined syndrome, is most easily supported by current research. Consequently, this may be the optimal subgroup for research purposes. However, the most narrowly defined syndrome might not be optimal from a public health perspective because it may be more effective to

reduce the overall burden of suffering in the population by diminishing impairment across the severity spectrum.

Several groups of hyperactive children seem to be at particularly great risk and targeted intervention seems appropriate for these groups. For example, preschool-age children with the triad of AD-HKD, aggression and impairment of language and learning are at particularly high risk for persistent AD-HKD and for significant impairment in later life (Moffitt 1990). Children at any age who have marked learning problems, pervasive hyperactivity and conduct disturbance are also at high risk. Early detection and intervention for targeted groups of children with AD-HKD may reduce impairment for the affected child and the burden of suffering for the families and communities. Given the high prevalence of AD-HKD, it is not reasonable to assume that traditional clinic-based services will be able to meet this considerable mental health need. Nevertheless, there is a clear need for a multidimensional, multidisciplinary and comprehensive clinical assessment to establish the initial diagnosis, plan treatment and support the long-term management of affected persons.

Conclusions

AD-HKD is likely to remain a controversial disorder among professionals and lay individuals. This is not surprising given questions about the measurement of individual symptoms and differences in diagnostic practice among professionals. Moreover, the widespread use of stimulant medication will rightly remain a contentious social and scientific issue. The same social factors that aided the development in the nineteenth century of the concept of hyperactivity as a medical condition may be operating today. A clearer understanding of these social factors can benefit our understanding of this entity, enhance our ability to prevent disorder and assist affected individuals.

We have learned much about the biological, psychological and social causes of this particular constellation of behaviours. There is little doubt that hereditary and acquired biological factors have a role in the genesis of hyperactivity, although no single genetic or biological risk factor seems adequate to account for AD-HKD in most cases. Psychosocial factors also increase the risk of hyperactivity. There is clear evidence that cognitive factors are involved in AD-HKD and may serve to span the gap between brain and behaviour. Despite frequent changes in nosology, hyperactivity has aided communication among professionals, facilitated our understanding of the relationship between brain and behaviour and stimulated the development of intervention programmes and research.

Much remains to be learned about the effective management of hyperactivity. Despite our growing understanding of the role of the cognitive, genetic and neuropathological substrate of AD-HKD, our clinical and therapeutic concepts of the disorder remain primarily at a descriptive level, emphasizing and treating the observable behavioural deficits and associated impairments rather than the fundamental abnormality of the disorder. Med-

ication is effective for many children and can provide respite from the symptoms of AD-HKD during which time other essential aspects of therapy can be implemented. Nevertheless, several of the worst outcomes of AD-HKD are seen in adolescence and adulthood. The risk for these adverse outcomes must be reduced. To date, no intervention in childhood is demonstrably effective for this purpose. The development of acceptable, cost-effective and widely available non-pharmacological therapies for AD-HKD remains a priority for the field, as is the development of further pharmacological options for those children who do not benefit from stimulants or other currently available medications. In the short term, there is much to be done to improve the quality of care provided to affected children and their families even given our current limited understanding of the disorder and its treatment.

Introduction

Conduct disorder constitutes a constellation of antisocial and aggressive behaviours that may become prominent in early childhood and persist through adolescence, even into adulthood. Sufficient understanding of the risk factors and early presentation of this disorder holds the promise of not only reducing the prevalence of a common childhood dysfunction, but also preventing much negligent, abusive and criminal behaviour. Oppositional disorder shares the negative and conflictual attributes of conduct disorder, but presents in a more limited fashion.

In this chapter these two disorders are examined from historical and theoretical perspectives prior to reviewing knowledge about their prevalence, course, causes, treatment and prevention. Two principal concepts are emphasized throughout. First, conduct disorder frequently develops in social and family contexts that are marked by conflict and adversity. This finding raises the question of the extent to which the specific symptoms of the disorder represent deviations from normal behaviour and emotions that are precipitated and sustained by pathogenic situations and relationships. The primacy given the social setting and interpersonal relationships does not mean that individual differences are unimportant. Even when children are exposed to high-risk conditions, many do not develop the disorder. Secondly, the dysfunctional nature of conduct and oppositional disorders can be conceptualized either in terms of a categorical diagnostic category or as a dimension of behaviour that everyone shows to a greater or lesser degree. A categorical approach is necessary for clinical decision-making but a dimensional one may better reflect the quantitative way that many causal processes, involving risk and protective factors, operate. In practice, both orientations can operate simultaneously in a complementary fashion.

Historical background

A historical excursion into efforts to understand and treat conduct disorder is warranted because it marks one of the earliest organized activities that defined the discipline of child psychiatry. With the establishment of clinics attached to juvenile courts and the ascendancy of the mental hygiene movement, a systematic and therapeutic approach to delinquent and antisocial youths began (Levy 1952). William Healy, an obstetrician and founder of the first juvenile court clinics in Chicago and Boston,

interpreted the presence of both physical and mental defects in patients as supporting hereditary origins of delinquent behaviour. Cyril Burt (1925), the English psychologist, also recognized this combination of factors, but stopped short of placing primary emphasis on either hereditary or social factors.

As psychoanalytic ideas gained prominence, the concept of a poorly developed superego became a popular approach that attracted a great deal of speculation and some interesting therapeutic approaches (Aichorn 1935; Johnson & Szurek 1952). Because these approaches were seldom systematically evaluated, there is little evidence to support their success in the literature.

Cleckley's monograph, *The Mask of Sanity* (1941), provided an influential summary of clinical experience with adults over the first half of the twentieth century. His detailed case descriptions were based on an assessment of prevailing constitutional and psychodynamic theories of psychopathy. The review of his own patients, many of whom were outwardly successful in their occupations, led him to devise an inventory of cardinal features that still remains useful:

- 1 an absent sense of responsibility;
- 2 refusal to accept blame for wrongdoing;
- 3 an absent sense of shame, humiliation, regret;
- 4 lying and cheating;
- 5 a failure to learn from experience;
- 6 a marked self-centredness that interferes with the capacity to love;
- 7 poverty of affect;
- 8 a lack of insight;
- 9 alcoholic indulgences;
- 10 sexual peculiarities; and
- 11 lack of goal directedness, resulting in a chaotic life style.

Cleckley was careful to claim that not all cases exhibited these behaviours at young ages and that some psychopaths came from undeniably 'good stock.' He did, however, postulate that the basic defect was a deep-seated one, justifying use of the term 'emotional dementia' to describe the apparent absence of personal insight and responsibility in the lives of the patients he treated.

While this work in adults was becoming influential, clinicians working with children were endeavouring to understand the origins of behavioural syndromes that were conceivably linked to adult psychopathy. John Bowlby carried out some of the most influential work in this vein. In his early studies, the developmental histories of delinquent boys were systematically recon-

structed (Bowlby 1944). In acknowledging the need to classify these cases as a first step towards studying their origins, Bowlby devised a system consisting of six types, the most common of which were the affectionless character, the hyperthymic character and the depressive character. As will be seen in a later section of this chapter, this subtyping is similar to the major classes of conduct disorder currently adopted in the International Classification of Diseases (ICD-10; World Health Organization 1987). Bowlby was particularly drawn to the affectionless character as the prototype of the psychopath:

'It is my hope that the Affectionless Characters will be studied in great detail in the future, for I believe that they form the real hard core of the problem of recidivism. There can be no doubt that they are essentially delinquent characters, which is not true of the other characters discussed in this paper. The Depressed, Circular, Hyperthymic and Schizoid all had counterparts among the controls. We can get a Depressive who does not steal as well as one who does; we can find a law-abiding Hyperthymic as well as his antisocial brother. I am doubtful, however, whether the law-abiding Affectionless Character exists.' (Bowlby 1944, p. 39)

Making this diagnostic distinction led him to characterize the early histories of such children as marked by 'prolonged separations from their mothers and foster-mothers'. His intense interest in the early development of this subgroup became the inspiration for his subsequent work on attachment and has had a major influence on the field of developmental psychology (Bowlby 1969; Ainsworth *et al.* 1978; see also O'Connor, Chapter 46).

Although the multiple determinants of delinquency and psychopathy have not led to the isolation of specific causal factors, the work of Robins (1966) provided a grasp of its natural history. This work ranks as one of the most important empirical studies in psychiatry of its era. By tracing the adult outcomes of children who were initially seen in a St. Louis child guidance clinic, a convincing link was established between childhood conduct problems and adult psychopathology. The most common outcome was antisocial personality disorder, a constellation of problems that was similar to the descriptions provided by Cleckley. This important study has been replicated in several different samples and the findings remain some of the most secure in modern psychiatry (Robins 1978). Recognition of this fact has been of enormous value in underscoring both the seriousness and chronicity of antisocial disorders (Loeber & LeBlanc 1990).

Classification

The effort to classify conduct and oppositional disorders has been informed by both theory and empirical research. The work of Hewitt & Jenkins (1946) was of fundamental importance in demonstrating that there were two distinct organizing features of conduct disorder: a socialization dimension and an aggressive behaviour dimension. Building on this work, the

major contemporary classification systems used in psychiatry, the Diagnostic and Statistical Manual (DSM) of the American Psychiatric Association (APA) (1994) and the International Classification of Diseases (ICD) of the World Health Organization (WHO) (1992), capture these two cardinal features, but in somewhat different ways.

Compared to previous renditions of this system (DSM-II and DSM-III), the criteria in the current edition of DSM (DSM-IV) for making the diagnosis of conduct disorder have been made more stringent, with greater emphasis placed on objectively defined behavioural symptoms rather than on the moral or socialization elements of this disorder. The diagnosis is subclassified according to age of onset, broadly reflecting Moffitt's (1993b) distinction between 'adolescence-limited' and 'life-course-persistent' antisocial behaviour, the latter typically being first manifest in early childhood. Although important questions remain on these categories there is now a substantial body of empirical evidence supporting the validity of the distinction (Rutter *et al.* 1998).

ICD-10 includes socialized and unsocialized types of conduct disorder. In this system the concept of 'socialized' has been widened to include those who are integrated into either deviant or non-deviant peer networks. Both classification systems have specified symptom thresholds and duration criteria. Similar to the changes brought about in the revisions of DSM, the revisions of ICD have raised the threshold of clinical severity by including more seriously harmful and negligent behaviours to the list of possible symptoms.

However, important distinctions between these two systems remain. In contrast to DSM, which appears to have diminished the centrality of the quality of the child's social relations as a diagnostic feature, ICD places a higher priority on the quality of socialization than on the 'severity of the offence'. It has been pointed out that the latter feature may be most important in determining the prognosis of the disorder, especially as it is in keeping with the personality characteristics that are of fundamental importance to the definition of the adult syndrome (Rutter 1989; Christian *et al.* 1997).

The relationship between oppositional and conduct disorders is also handled somewhat differently in the two systems. In DSM the rules specify that oppositional disorder is to be excluded if conduct disorder is present. This reflects the inclination to view oppositional disorder as a milder form of conduct disorder, one that may represent a developmental precursor of conduct disorder (Schachar & Wachsmuth 1990; Frick *et al.* 1991a; Loeber *et al.* 1991a). ICD views the symptoms of oppositional/defiant disorder as a subcategory of conduct disorder, a position that is consistent with the classic work of Levy (1952) who described persistent patterns of resistant and negativistic behaviour as follows:

'Negativism has been contrasted with aggression and referred to as a more primitive and also safer expression of antagonism. In the form of open defiance it is difficult and probably unnecessary to differentiate it from aggression. As in the case of aggression, numerous modifications of the

extreme act are seen . . . The mixtures or patterns of both forms of behaviour depend on the situation and on the available aggression in the personality.' (Levy 1952, p. 225)

The distinction between normative and deviant forms of negativism is especially important in pointing how a feature of one's temperament may be shaped into a maladaptive syndrome (Lahey *et al.* 1999). In a study that independently examined symptoms of children with oppositional and conduct disorders, it was found that fighting and lying were present in both groups (Loeber *et al.* 1991a). The suggestion was made that these two symptoms could effectively be eliminated from the definition of conduct disorder and placed on an expanded list of symptoms associated with oppositional disorder. The effect of such a change would be to make oppositional disorder a more serious problem, thereby enhancing the rationale to consider it a psychiatric disorder. Consistent with this proposal is some evidence that oppositional disorder in young children is more likely to predict mood disorders than conduct disorder on follow-up to middle childhood (Speltz *et al.* 1999). Whichever choice represents the more valid case, the separation of the two disorders splits the more interpersonal symptoms of oppositionality from the violations of social norms that characterize the prevailing definition of conduct disorder.

Another difference between the two systems is reflected in the distinction between 'splitters and lumpers'. The DSM system has a penchant for subdividing diagnostic groups into smaller categories, as illustrated by its separation of oppositional and conduct disorder. An important consequence of this convention is to encourage the tendency to diagnose multiple disorders in the same child. On the other hand, a preference is shown for maintaining larger domains of symptoms in ICD. For example, the broad category 'mixed disorder of conduct and emotions' includes three subtypes:

- 1 depressive conduct disorder;
- 2 other mixed disorders of conduct and emotions (implying anxiety symptoms); and
- 3 unspecified mixed disorders of conduct and emotions.

Another example of this type of convergent definition is the ICD-10 category of hyperactive conduct disorder.

The observation that antisocial behaviour can exist transiently or in relative isolation from other conduct problems is reflected in the categories, Adjustment Disorder with Disturbance of Conduct and Adjustment Disorder with Disturbance of Conduct and Emotion. In this instance, symptoms are observed to be triggered by acute stressful events, such as birth of a sibling, death of a relative or exposure to a catastrophic event. DSM makes it explicit that these symptoms should not last for more than 3 months. DSM-III-R also includes a V code diagnosis, Childhood or Adolescent Antisocial Behaviour. This is to be used in cases of an isolated behaviour which is not associated with a recognizable stressful event.

Another approach to definition and classification in child psychiatry has been to assume that these disorders represent statistical departures from normal behaviour. If the categorical approach is fuelled by assumptions about the nature of a disorder,

the statistical or dimensional approach rests on a tradition that avoids such assumptions. Many instruments have been devised for this purpose over the years (see Verhulst & Van der Ende, Chapter 5). Two of the most widely used in current research are the Child Behaviour Checklist (CBCL) (Achenbach *et al.* 1989) and the Revised Behaviour Problem Checklist (RBPC) (Quay & Peterson 1987). The two methods include nearly the same number of conduct disorder related items (38 and 39), but the CBCL makes none of the distinctions (socialized, unsocialized, oppositional) discussed so far in its single factor termed 'aggressive'. The RBPC, on the other hand, lists two separate factors: conduct disorder and socialized aggression.

The statistical approach is based on empirically derived behavioural items that can be shown to distinguish clinically referred from non-referred children, while the categorical approach relies on inductive process derived from consensual observations and clinical experience. Despite their conceptual differences, considerable overlap exists between these two approaches in practice (Edelbrock & Costello 1988; Jensen *et al.* 1996). In relation to conduct disorder, the issue concerns the nature of the disorder. Is it more like a deviation from normal, or a category with boundaries that separate it from normal behaviour as well as other types of disorders (Hill & Maughan 2001)? It is important to note that scale scores that include aggressive behaviour frequently capture other types of behaviour, while by concentrating on boundaries between disorders, the categorical approach excludes this possibility (Jensen *et al.* 1993).

Prevalence

Epidemiological studies over a 20-year period provide a developmental profile on the prevalence of conduct and oppositional disorders and specific antisocial behaviours (Costello 1989). From the preschool period to middle childhood there is an overall decrease in the frequency of temper tantrums, management problems, bullying and destructiveness, behaviours relating more to oppositional disorder than conduct disorder (Olweus 1979). Nevertheless, about half of those found to display early aggressive behaviour as preschool-age children develop persistent problems (Richman *et al.* 1982; Fischer *et al.* 1984). Any trend towards reduction of aggression in the first decade of life would appear to be offset by the increase in more serious antisocial behaviour during early to middle adolescence. In late adolescence the reduction in antisocial behaviour appears nearly as marked as the increase did in early adolescence. However, this picture is the sum of several cross-sectional and short-term longitudinal studies (Earls 1989). What is less clear is how often the same individuals might receive the diagnosis of conduct disorder at different points in time.

One of the first investigations to estimate the prevalence of conduct disorder in the general population was the Isle of Wight study (Rutter *et al.* 1970). Given an overall rate of 4.2% among 10–11-year-olds, the rate in boys was four times higher than the

rate in girls: 6.2% compared to 1.6%. Conduct disorder was found to be by far the most common disorder in males, accounting for about three-quarters of all disorders in this group. When similar methods were used in a relatively poor area of London, the rate of conduct disorder doubled (Rutter *et al.* 1975).

The Ontario Child Health Survey provides a comprehensive picture of conduct disorder in the general population (Offord *et al.* 1987, 1991). In this study of children ranging in age from 4 to 16 and sampled throughout the province of Ontario, a diagnostic method was produced that conformed to criteria established in DSM-III. For younger children (4–11 years), scales were used to rate both parent- and teacher-reported symptoms, while for adolescents (12–16 years) parent and self-report data were collected (teacher data were found not to be reliable). Care was taken to measure the accuracy of the scales prior to launching the project.

The overall rate of conduct disorder, 5.5%, is similar to the rate reported 25 years earlier in the Isle of Wight study. The male:female ratio was also similar, 8.2% for males and 2.8% for females. However, geographical area differences were not found, the urban rate being just slightly higher than the rural rate: 5.6% compared to 5.2%. There was an unexpected reversal in relationship of area differences to age. For both sexes younger children in urban areas had a higher rate, but rural adolescents had higher rates than urban adolescents. The investigators interpret these findings as showing the importance of socioeconomic factors. The effect of geographical area was diminished when the degree of poverty in the different contexts was taken into account.

The prevalence of individual symptoms varied in a number of ways. As expected, the frequency of symptoms of lesser seriousness declined with age while those of a more serious nature increased with age. Predictably, males exceeded females in prevalence for most symptoms. For all 15 symptoms surveyed, adolescents reported more symptoms than did their parents. This was especially true for the more serious symptoms, such as vandalism, threats to hurt someone and cruelty to animals. For younger children, parents and teachers varied considerably in their reporting patterns.

The amount of agreement between any pair of informants was so slight as not to exceed that expected by chance alone. Thus, less than 10% of males had a pervasively defined disorder and not a single case of pervasive conduct disorder was found in young females. The proportion of cases defined by both parents and adolescents increased slightly at the older age level, but it still left over 80% of males and 90% of females with a disorder defined by only one informant. An interesting and perhaps unanticipated result was the large number of cases of conduct disorder found among the younger children, which were defined only by teachers (80%). Offord *et al.* (1991) suggest that this finding reflects the fact that conduct disorder is highly conditioned by school settings. This reasoning, however, may not extend to the findings with the older group, because self-reported symptoms cannot be regarded as suggesting situation specificity.

Further confirmation that the prevalence rate for conduct

disorder is in the range of 3–5% is reported in a study of a predominantly rural population of children between the ages of 9 and 13 in the state of North Carolina in the USA (Costello *et al.* 1996). The overall rate of conduct disorder was 3.3%, males experiencing a fourfold higher rate than females (5.4% compared to 1.3%). The prevalence of oppositional disorder was 2.7% with a lower sex ratio still favouring males (3.2% compared to 2.3%). As in the Ontario study, but not in keeping with the London study of several decades ago, these results show that exposure to urban life does not increase the rate of conduct disorder appreciably. Family income, on the other hand, is strongly and inversely correlated with prevalence of conduct disorder. This picture of the prevalence and demographic correlates of conduct disorder is nearly paralleled by findings of antisocial personality in adults (Kessler *et al.* 1994).

In contrast to the consistent replications of estimates of the prevalence and correlates of conduct disorder in developed countries, much less information exists from studies in developing countries. There is reason to believe that conduct disorder may vary as a function of cultural differences in the strength of family preservation and child-rearing methods (Weisz *et al.* 1988). A relatively low prevalence of conduct disorder was reported by Bird *et al.* (1988) in Puerto Rico, suggesting that local cultural factors were at play. Bird (1996) discussed some of the challenges surrounding cross-cultural and cross-national research in child psychiatric epidemiology.

Risk factors and correlates

Many characteristics of children and their environments have been studied in relation to conduct disorders of childhood and adolescence. However, few have been examined in such a way as to establish causal relationships to conduct disorders. Understanding temporal relationships is critical to the process of identifying causal relationships between any set of relevant indices (Kraemer *et al.* 1997). Causal risk factors precede the onset of the disorder and to the extent that they can be manipulated, such factors should then alter its course.

Identification of risk factors is an important step in eventually identifying the causal mechanisms of morbidity. For example, child abuse is an identified causal risk factor for conduct disorder. Child abuse, in turn, has been associated with concurrent alterations in a variety of cognitive, emotional, neurohumoral and neuroendocrinological regulatory processes. Variations in each of these dimensions have also been associated with conduct disorder, and may contribute directly or indirectly to its symptoms and course. More detailed investigation of temporal–developmental relations between child abuse and these underlying regulatory processes is likely to lead to a better understanding of the pathogenesis of behavioural disturbances resulting from child abuse.

Some causal risk factors are important throughout the course of development, and merely change form according to the developmental level of the child (e.g. caregiver involvement and dis-

ciplinary practices). Other factors appear to be more crucial during particular developmental stages (e.g. peer influences during pre-adolescence and the acceptance/rejection of a child into deviant or adaptive social groups, and the biases present in social information processing that influence how an individual responds in ambiguous social situations).

Environmental causal risk factors loom large in the onset and evolution of conduct disorder. These factors begin in the intrauterine environment. Maternal smoking has been one of the more extensively studied prenatal risk factors for later psychopathology in children, adolescents and adults. Maternal smoking during pregnancy has been associated in a number of prospective longitudinal studies with an increased risk of conduct disorder in children and adolescents, and antisocial personality disorder in adults (Wakschlag *et al.* 1997; Fergusson *et al.* 1998; Brennan *et al.* 1999; Rasanen *et al.* 1999; Weissman *et al.* 1999). The preponderance of these studies examined only males. Where gender effects were studied, maternal smoking was markedly stronger for males than for females. In most of these studies, the effect of maternal smoking during pregnancy was either specific to, or more strongly predictive of violent criminality, than non-violent criminality. It also seems that maternal smoking predisposes to more persistent forms of conduct disorder, rather than transient forms. In all instances, the effects of maternal smoking were noted above and beyond those effects caused by a host of other postnatal environmental factors.

To date, the most compelling evidence for causal elements in the onset and course of conduct disorder is the familial aggregation of disturbances of conduct and antisocial behaviour in those children identified with early onset aggressive conduct disorder. Such familial aggregation of disturbances of conduct and antisocial behaviours reflects multiple interacting genetic and environmental determinants. The factors repeatedly identified in this body of literature include parental psychopathology, particularly antisocial behaviour, and parent child-rearing practices. The latter cover a range of behaviours from supervision, attentiveness–responsiveness, validation, and conflict resolution and disciplinary tactics.

The genetic component(s) of such familial aggregation of conduct and antisocial disorders have been difficult to study and quantify for a variety of reasons, even in the case of carefully conducted twin studies. Foremost among these is the dependence of the statistical estimates of genetic and environmental contributions to conduct disorder on the methods used to ascertain conduct disorder, and on the informant providing the data upon which the ascertainment of conduct disorder is based. Estimates vary depending on whether children or adults provide relevant information, and on whether questionnaires or structured interviews are used to ascertain conduct disorder. Secondly, it is not clear if inherited aspects apply broadly to all or many forms and symptoms of conduct disorders, or if inheritance patterns are more specific to certain symptoms or types of conduct disorder, such as the overt or covert subtypes of conduct disorder.

Reliable estimation of the shared and unique environments of children is critical to obtaining valid estimates of the genetic contributions to conduct disorders. Such reliable estimation of environmental contributions is often difficult to obtain. In the Virginia Twin Study of Adolescent Behavioural Development (Eaves *et al.* 1997; Simonoff *et al.* 1998), child ratings of twin differences in conduct disorder suggested stronger unique environmental influences, and a genetic contribution that was common to both aggression and property violations, as well as overt destructive forms of conduct disorder behaviours. Maternal ratings, on the other hand, not surprisingly suggested the importance of the shared environment as well, when compared with child ratings of differences between twins in conduct disorder outcomes. Mothers' ratings gave some, but less importance to unique environmental factors, and little or no support to a common genetic factor, but some support for specific genetic factors contributing to aggression, to property violations and to oppositional behaviours.

Finally, despite all indications that a genetic component is present, what is very unclear in the case of conduct disorders is exactly what is inherited. The syndrome of conduct disorder itself, with all its attendant complex behavioural patterns, is unlikely to be inherited *in toto*. In this regard, some of the correlates of conduct disorder identified below, such as autonomic underarousal, insensitivity to punishment, deficiencies in neurohumoral regulation and deficits of executive controls, have been put forth in a speculative fashion by various investigators as those heritable traits that may predispose an individual singly or in concert to develop conduct disorder. These trait predispositions would presumably lead to conduct disorder when the environment also presents with factors that act to increase risk for conduct disorder by modelling the sorts of complex social behaviours that are characteristic of the syndrome, and through the absence of other behaviours considered essential to healthy and adaptive development.

The risk factors for conduct disorder reported in the Ontario Child Health Survey (Offord *et al.* 1987) are similar to those noted in many other studies. The three most significant risk factors exerting independent effects on conduct disorder were:

- 1 family dysfunction (relative odds 3.1);
- 2 parental mental illness (relative odds 2.2); and
- 3 low income. Low income had its effect on children aged 4–11 (relative odds 3.7), but not on adolescents.

These factors resemble the six described by Rutter (1978) as general indicators of psychosocial adversity: low socioeconomic status; criminality of the father; overcrowding; maternal neurosis; chronic marital discord; and institutional care.

Throughout the age range covered, those children with conduct disorder were more likely to have impairments as reflected in school underachievement and interpersonal problems. At the younger age level, 62% were thought to be in need of intervention compared to 8% without conduct disorder; in adolescence 74% of those with conduct disorder were in need of treatment compared to 44% of those without this disorder. These findings

provide a source of external validity for the method of selecting children with conduct disorder.

In terms of peers and social relations outside the home, causal risk has been identified for peer rejection/acceptance, and for the part played by social information processing biases. Aggressive individuals often exhibit biases in interpreting the intent of others, whereby hostile attributions are more likely to be generated over more benign interpretations of the ambiguous social-interpersonal behaviours of others (Dodge *et al.* 1995).

Risk factors that may be causal factors

In studies comparing children with conduct disturbances to those with emotional disturbances and those without disturbances, those with conduct disorder have consistently shown lower levels of electrodermal activity (EDA), lower mean resting heart rate (HR), lower heart rate reactivity (HRR), and lower heart rate variability (HRV). These characteristics are most marked in individuals whose behavioural disturbances and impairments are earlier in onset, and involve predatory aggression and poor socialization. This has led to theories suggesting that autonomic underarousal is a fundamental characteristic of individuals manifesting such forms of conduct disorder. Many of these findings are closely linked conceptually and physiologically to sympathetic modulation, which in turn is known to be associated with anxiety and arousal mechanisms subserving the inhibition of behaviours associated with negative consequences.

Of all the physiological indices examined in relation to conduct disorder, HR is by far the most extensively studied. Taking the body of literature on HR indices together, the fact that similar relationships between HR regulatory indices and behaviour have been reported in samples of different ages, from infancy and preschool through adolescence and adulthood, suggests several things.

1 HR indices are, at the very least, important time-varying correlates of behaviour throughout the life span, from infancy to adolescence and beyond. Individual differences in HR regulation appear to be present from very early on in life, in both genders (Raine *et al.* 1990, 1995, 1997; Porges *et al.* 1996; Mezzacappa *et al.* 1997; Pine *et al.* 1998).

2 The direction of reported effects appears to be consistent across studies, and over the life span. Where difficult, disruptive, aggressive or antisocial behaviours are concerned, it is lower HR or lower HR variability that are consistently associated with these behavioural patterns (Raine *et al.* 1990, 1995, 1997; Mezzacappa *et al.* 1997; Pine *et al.* 1998).

3 The status of a risk factor for onset or for persistence of conduct disorder has been established for HR and HRV. HR indices have been noted to predict later onset of aggression in childhood (lower HR; lower vagal tone) (Porges *et al.* 1996; Raine *et al.* 1997), and the desistence of antisocial behaviour in young adulthood (higher HR) (Raine *et al.* 1995).

Correlates and concomitants of conduct disorder

These indices have been found to co-occur in time with manifestations of conduct disorder. In many instances, temporal relations have simply not been studied (correlates). Therefore some of these may very well turn out to be risk or causal risk factors, or they may simply be concomitants of conduct disorder.

Associations of conduct disturbances with alterations in the regulation of neuroendocrinological and neurohumoral indices—such as plasma or salivary cortisol and testosterone levels; activity of platelet monoamine oxidase (MAO); and plasma, cerebrospinal fluid or urinary levels of the monoamines dopamine, norepinephrine, serotonin and their respective metabolites—have been less consistent than those found with the autonomic indices (McBurnett *et al.* 1991; Rogness *et al.* 1992; Scerbo & Kolko 1994; Coccaro & Kavoussi 1996; Schaal *et al.* 1996; Stoff & Vitello 1996; Pine *et al.* 1997). None the less, when individuals with disturbances of conduct are subcategorized, and those with earlier onset, persistent aggression are identified, then findings of diminished levels of salivary cortisol and elevated levels of salivary testosterone have been replicated in some studies.

Another finding that has been replicated in both animal and human studies, including those involving children and adolescents, has been the deficiency of serotonergic (5-hydroxytryptamine; 5-HT) activity in subjects displaying patterns of aggressive behaviour (Coccaro & Kavoussi 1996; Stoff & Vitello 1996; Pine *et al.* 1997). Individuals with histories of earlier onset and persistently high levels of impulsive aggressive behaviours were those whose serotonergic activity was found to be the most deficient.

Three principal neuropsychological deficits have been reported in relation to conduct disorder (Moffitt 1993a): differences in IQ, language deficits and impaired executive control functions (ECF). The presence of conduct disorder has been associated with lower IQ scores, even after controlling for socioeconomic and demographic factors. On specific tests of language function, conduct disorder is associated with deficits even when IQ and demographic variables are controlled. Performance IQ (PIQ)–verbal IQ (VIQ) differences, where PIQ is noticeably higher than VIQ, are among these findings.

Executive control functions (e.g. planning or delay of actions, anticipation of outcome, inhibiting or changing responses, maintaining purposeful effort and self-monitoring of behaviour) have been noted to be impaired in children and adolescents affected with conduct disorder. These deficits, when present, can add characteristics to the conduct disturbances such as impulsivity, and may also influence the course of disorder through factors such as academic underachievement.

Recent studies (Seguin *et al.* 1995, 1999; Toupin *et al.* 2000) of both population-based and clinical samples, using well-specified models and methods for assessing ECF, improved classification of subjects, and inclusion of relevant confounds such as IQ and socioeconomic status, indicate that ECF and disturbances of conduct are related, even in the absence of attention

deficit hyperactivity disorder (ADHD). Children with more persistent pervasive conduct disorder with aggression seem more likely to demonstrate such ECF deficits. The relationship of ECF indices to behavioural problems also appears to be relatively independent of IQ and non-executive cognitive functions such as memory (Seguin *et al.* 1995, 1999; Oosterlaan & Sergeant 1996; Oosterlaan *et al.* 1998).

A study of adults by Raine *et al.* (2000) lends further support to the notion that ECF may be important to the understanding of conduct disorder and its course. Using magnetic resonance imaging and autonomic indices, these investigators studied adult males with antisocial personality, and compared them to matched controls with other psychiatric disorders and no disorder. They found volumetric reductions in prefrontal cortical regions in the antisocial group only, which are believed to subserve ECF.

Challenges to ECF with strong motivational influences have been utilized to identify individuals with difficulties in the monitoring and modification of behaviour resulting from a lack of concern over the consequences of behaviour. Tasks of passive avoidance learning, which require withholding responses to avoid negative consequences, have been used to demonstrate deficits in this capacity in children with undersocialized aggressive forms of conduct disorder (UACD). In the opinion of some investigators, it is the children with UACD who are at greatest risk for persistent disorder and adult antisocial personality disorder (ASP) (Daugherty & Quay 1991; Quay 1993). These authors ascribe the course and persistence of disorder to this lack of concern for the consequences and outcomes of behaviour.

Course and persistence

In the classic study by Robins (1966), 45% of those with conduct disorders went on to develop ASP, highlighting the potential lifelong course of these disturbances. The progression of conduct disorders through childhood and adolescence and into adulthood has since received considerable attention, and a number of conceptually useful, overlapping pathway models have emerged.

Some models focus on the timing of onset, and the accrual and persistence of disturbances of conduct over time (Farrington 1995). Here primary distinctions have been made between earlier and later onset disturbances, and the timing of desistence of disturbances. In an effort to integrate knowledge in the existing empirical literature, Moffitt (1993b) proposed that multiple pathways could lead to the same constellation of antisocial behaviours. She outlined in some detail two developmental trajectories: one termed 'early onset, life-course-persistent', and the other termed 'adolescent limited'. The early onset variety was postulated to include children with neuropsychological and temperamental profiles that represented enduring traits placing them at high and continuing risk for antisocial behaviour. The adolescent onset type includes persons who are particularly susceptible to the influence of deviant peers.

The type and severity of the symptomatology, and the progression to include more symptom types over time, is also a useful manner of conceptualizing the course of disturbances in conduct (Loeber *et al.* 1993). Here distinctions are made between prevalence of symptoms related to conflicts with authority (e.g. truancy and disobeying curfew), symptoms related to covert delinquent behaviours (e.g. theft, deceit and destruction of property) and symptoms related to overt disturbances of conduct (e.g. cruelty and predatory aggression towards persons or animals).

Applying and integrating these two approaches to the course of conduct disorder, early onset disturbances of conduct are more frequently persistent and more often associated with symptoms involving conflictual, covert and overt delinquent behaviours. Individuals whose course begins with conflictual behaviours later in the course of development rather than earlier, are much less likely to progress on to covert and overt delinquent acts, or to have persistent disorder into adulthood (Loeber *et al.* 1993; Moffitt 1993b). Those individuals who manifest disturbances of conduct earlier in life, not only tend to display more symptoms of greater severity, they commit more severe criminal offences, and account for a disproportionately large number of the total offences in their respective age groups. In some reports, the most problematic 10% of individuals account for more than half the criminal offences committed (Farrington 1995).

An important qualifier in the matter of life-course symptoms and patterns of comorbidity of conduct disorder is the influence of gender (Cohen *et al.* 1993; Zahn-Waxler 1993; Zoccolillo 1993; Loeber & Keenan 1994). While reports of the overall prevalence of conduct disorder tend to highlight the male preponderance for this syndrome, sex-related differences in prevalence vary with age, being least in mid-adolescence (Moffitt *et al.*, 2001). The sex difference is most marked with respect to life-course-persistent antisocial behaviour, which is decidedly uncommon in females. This means that both early onset conduct problems (often accompanied by hyperactivity) and crime in adult life are much more frequent in males.

Despite the strong relationships repeatedly identified between early onset, aggressive variants of conduct disorder, and persistent problems throughout childhood and adolescence often leading to adult antisocial behaviours, not all children displaying this more severe form of conduct disorder become antisocial adults. The work of Magnusson & Bergman (1988) is especially instructive in this regard, highlighting the complex multifactorial relationships involved with the features and course of conduct disorders. Taking a developmental, person-orientated approach to the study of aggressive conduct disorder, these investigators noted that highly aggressive children who were impaired in other ways, including poor peer relations, low school motivation and academic underachievement, frequently progressed on to adult antisocial behaviour. Children with comparable levels of aggression without such impairments did not persist and progress on to adult antisocial behaviours nearly as often.

An additional distinction useful in understanding the course of conduct disorders is whether or not deviant behaviours occur in the company of a peer group (Reiss & Farrington 1991). It appears that the majority of delinquent offences committed by adolescents occur in the company of small groups of two or more persons, highlighting the impact of social networks on behaviour in this age category (Cairns *et al.* 1988). It also seems that those children and adolescents whose symptoms of conduct disorder involve aggression, and who carry out their deviant behaviours in isolation of others, sometimes referred to as UACD (Quay 1993), are at increased risk for more persistent and impairing disorder.

Perhaps the most useful way of conceptualizing the evolution of disturbances of conduct is to apply a developmental model to the transactional processes occurring between the characteristics of the individual, and the multiple levels of environment (home, school, neighbourhood, and the larger community and culture) to which he or she is continuously exposed. In such transactional models one may construct a number of plausible pathways leading to serious and persistent disturbances of conduct, and serious impairment in the life of the child (Nagin & Tremblay 1999).

Central to reconstructing the evolution of the symptomatology of conduct disorders is the matter of time-variance. Rarely do all the manifestations and complications of these disorders present simultaneously, nor do they manifest at maximum levels of severity at all times. Risk factors for conduct disorder are generally also time-varying in nature. The time-variance of symptoms and the relations of symptomatic behaviours to time-varying risk factors within the child and in the environment are an extremely important perspective for understanding the developmental psychopathology of conduct disorders. Three examples are considered here.

1 Children of difficult temperament raised by caregivers who themselves have difficulty with impulse control, may become involved in transactions around behavioural control and coercion that involve increasingly severe forms of discipline aimed at controlling problematic behaviour. The 'slippery slope' to child maltreatment is not difficult to imagine in such instances, and may be more likely to occur during times when caregivers themselves are under greater stress from extraneous factors. Child maltreatment is known to be a particularly virulent risk factor for subsequent persistent conduct disorders.

2 Children with language deficits, or problems with executive control, such that the requirements of planning and maintenance of effortful work will often find them at odds with the demands of the classroom. This process culminates in both disciplinary problems and academic underachievement. The consequences of this may fuel frustration, loss of self-esteem and a gravitation towards increasingly disruptive behaviours, disenchantment with school, and gravitation towards more deviant peers.

3 Children whose frustration tolerance is lower, and whose responses to frustration tend to be more aggressive or disruptive in nature, often find themselves excluded from peer groups and

later in the course of development find social affiliations only with more deviant individuals in their peer cohort. The nature in which individuals are accepted or rejected by networks of peers operates as an important conduit into either socially conforming or deviant behaviour (Cairns *et al.* 1988). For example, a child who behaves aggressively in elementary school in response to exposure to domestic violence, may by virtue of these experiences have acquired a bias in social information processing whereby he or she is inclined to attribute hostile intentions to others in ambiguous situations, and to reactively behave in an aggressive fashion towards them (Dodge *et al.* 1995). This may lead to increasing alienation, anger and more maladaptive behaviours on the part of the isolated individual, and eventually to association with other (deviant) peers. This group of deviant peers may enhance the repertoire of maladaptive behaviours of the individual, often at the expense of the acquisition of age-appropriate adaptive social skills. The increasingly maladaptive behaviours and relative lack of age appropriate skills then reinforce the cycle of rejection by more functional peers, and the more stable socialization of the individual into a deviant peer group, thereby contributing to the evolution of conduct disorder into a more intractable variant.

Diagnostic assessment

The point was raised previously that changes in the number and type of symptoms, thresholds and boundaries between closely related disorders have changed frequently over the past few decades. Cognisant of these distinctions, the process of making a diagnosis represents a means of putting a classification system to work. However, it is important to realize that the diagnosis should be viewed as only one component of an overall process of assessment.

The reliability and validity of diagnostic groupings are important metrics used to establish the utility of classification systems. A number of considerations are involved in these determinations, including identifying the informant (parent, teacher, child), determining the situation or setting in which the symptoms are manifest (home, school), estimating the degree of impairment associated with the symptom load, and selecting an instrument to conduct the assessment. In general, the results of studies using highly structured interviews indicate that conduct disorder is among the most reliable and valid disorders in children (Jensen *et al.* 1995; Schwab-Stone *et al.* 1996). Despite this, there remain sufficient levels of inconsistency between parent, teacher and child reports to leave open the question of situational specificity in the expression of symptoms in a majority of cases. Unlike the assessment of attentional and oppositional disorders, child reports are at least as reliable and valid as are parent reports (Jensen *et al.* 1995).

Because the nature of conduct disturbances is such that they are more likely to be of concern to others than to the patient, such children are prone to view themselves as victims of adult authority. Indeed, the clinic contact may all too readily be per-

ceived as punishment for the conflict generated at home or school. To counteract this tendency, it is wise to establish direct contact with the child.

Evaluation of a child's personality and peer relations is of great importance in terms of understanding the nature of the child's disturbance. Research has shown peer unpopularity to be an unstable feature among aggressive children (Cairns & Cairns 1991), thus personality traits weigh in heavily along with peer acceptance and the number of friends. The types of activities engaged in with peers and their apparent behavioural norms is important because these factors may represent important indicators of the potential for escalation (Elliot *et al.* 1985).

Keeping in mind the issues of different classification systems as discussed in an earlier section, the pattern of symptoms becomes especially significant when evaluating the presence of problems that fall outside the realm of narrowly defined conduct disturbance. As demonstrated in several studies, children with symptoms of ADHD and conduct disorder are at greater risk for poor outcomes than children with ADHD or conduct disorder alone (Stewart *et al.* 1981; McGee *et al.* 1984; Gittelman *et al.* 1985; Moffitt 1990; Mannuzza *et al.* 1991). Moreover, the combination of cognitive impairment and antisocial behaviour may act synergistically (Loeber *et al.* 1990a; Frick *et al.* 1991a). Children with conduct and anxiety symptoms, on the other hand, are less likely to have police contacts or to be perceived by their peers as bullies than conduct disordered children without anxiety symptoms (Walker *et al.* 1991). The assumption is that the presence of anxiety acts as a 'braking system' on the seriousness of antisocial behaviour.

Conduct disorder appears to be more closely related to substance abuse than to other psychiatric disorders. The association covers alcohol and several types of drugs, including stimulants, depressants, inhalants, opiates and cocaine (Kandel *et al.* 1978; Elliot *et al.* 1989; Greenbaum *et al.* 1991; Milin *et al.* 1991). In a large group of seriously delinquent youths, Weisz *et al.* (1991) found that substance abuse predicted the escalation of violent behaviour.

The assorted nature of antisocial symptoms makes it essential to obtain the reports of teachers as well as parents. While children and parents agree to a fair extent on symptoms of conduct disorder, greater degrees of disagreement are found when inquiring about attentional, impulse control and oppositional symptoms. On analysing these patterns of agreement and disagreement, Loeber *et al.* (1990b, 1991b) found that parents and teachers report more symptoms of ADHD and oppositional behaviour than did children. Information from parents was found to be more useful in predicting police contacts than the two other sources. Both parents and teachers predicted placement in special classes better than children. However, the three informants were about equally good in predicting school suspensions.

Because the pattern of symptoms in conduct disorder follows a developmental trend to become more heterogeneous over time, it is essential to establish a history of antisocial behaviour at the time the clinical assessment is made. A number of studies

have shown that symptoms may become prominent in the preschool period, creating a noticeable pressure on parental authority and control (Campbell & Ewing 1990; White *et al.* 1990; Tremblay *et al.* 1991). Early onset may be an indicator of persistence simply because it reflects a degree of skill and control acquired by the child in adapting to his or her environment. As Patterson *et al.* (1989) adroitly stated, '... the child can become both victim and architect of a maladaptive lifestyle in which investment in aggressive behaviour is paramount'.

The evaluation should include a search for diagnosable and possibly treatable diseases of the central nervous system. In addition to a neurological examination, the history should include a detailed review of head injuries, especially those associated with a loss of consciousness, infectious diseases involving the brain, and seizures. It is essential to inquire specifically about exposure to sources of lead contamination. Often young children will have had lead levels determined in the past and, if so, a record of the actual level should be ascertained. The neuropsychiatric status of a child may be particularly important in the case of more severe offences. A study of adolescent youths incarcerated for homicide revealed a disproportionately high incidence of head injuries and other insults to the central nervous system in the medical histories of the inmates (Lewis 1990; Lewis *et al.* 1988). The authors speculated that compromise to cognitive functions and impulse control as a direct result of the central nervous system insult may have been a contributing factor to the commission of such serious crimes.

A psychological assessment is a critically important component to the overall evaluation. Measures of intellectual capacity, language development, reading and arithmetic skills should be included to evaluate school performance and intelligence and the extent to which one predicts the other. It is worth emphasizing that careful attention to performance in these areas is important at all ages, including adolescence. The presence of above average intellectual functioning and achievement should be considered as a good prognostic sign (White *et al.* 1989). Under circumstances where detailed psychometric assessment is impractical or not obtainable, a careful review of academic performance from school records may be substituted and still be very helpful for identifying areas of weakness or underachievement. Addressing these areas will not only improve competence and self-esteem, but will also likely improve long-term prognosis where conduct disorder is concerned.

School records are a valuable source of information beyond their contribution to the evaluation of academic performance. Information on behaviour problems, absenteeism, truancy, reasons for parent conferences and extracurricular activities may all be helpful in completing a comprehensive picture of the child's functioning. Review of such records prior to contacting the school may also assist in preparing for an efficient use of time with school personnel.

Once these multiple sources of information are at hand, a differential diagnosis can be entertained. Other disorders may be of primary or secondary importance relative to symptoms of oppositional and conduct disorders. Among the diagnoses to con-

sider are psychoses, seizure disorders, mental retardation, specific developmental disorders, attention deficit disorders, substance abuse, post-traumatic stress disorder as well as other anxiety disorders and major depressive disorder.

Conduct disorder is routinely associated with impairments in the areas of family and peer relations, and school and job performance. These should be carefully assessed because they may have implications for the types of treatment recommended. In judging the seriousness of behavioural disturbance, attention must also be given to patterns of risk-taking. Frequency of fighting and the types of injuries sustained in such conflicts, the possession and use of weapons, patterns of offending and co-offending, gang membership, use of drugs, and the use of coercion in sexual encounters are the areas of inquiry that will help determine severity.

As a final step in determining prognosis, two other considerations should be added to knowledge about the severity of the symptom pattern. These are the degree to which the individual manifests a restricted range of reasoning about interpersonal relationships and conflict negotiation, and the degree of support provided by immediate family members. The inability to view social encounters as events that require thinking about the feelings and rights of others and the consequences of one's actions in these regards, may well represent the most profound problem associated with conduct disorder (Joffe *et al.* 1990). The child's lack of sensitivity to other family members may make parents feel futile in knowing how to help the child. This, in turn, may serve to justify their withdrawal of support and care. Of course, these problems exist in a nexus, which is usually impossible to disentangle during a clinical evaluation. More important than understanding the dynamics of such predicaments, is the need to acknowledge their presence as a complicating factor towards recovery.

Another way to evaluate the family in this regard is in relation to the resources available to them that might be mobilized to support the well-being or rehabilitation of an antisocial child. Much has been made of the role of family conflict and harsh rearing conditions as risk factors in the development of conduct disorder. If these conditions are present, the treatment plan must undoubtedly address efforts to reduce the level of disharmony in the home or the child's exposure to it but, at the same time, the presence of a caring adult within the family or in the community should not be missed (Jenkins & Smith 1990).

Treatment

General considerations

Given the multiplicity of factors identified as risk, causal or perpetuating forces in the onset and evolution of conduct disorder, it is fundamentally inconceivable to envision interventions for this condition that do not comprehensively address all these facets. In assessing conduct disorder, it is essential to obtain information from multiple informants who know the child

in a variety of contexts. This is important in order to place disturbances of conduct in a perspective that allows one to address not only individual symptoms, but possible risk and causal factors as well, in a fashion that is developmentally appropriate. Self-reports of behaviour are essential to uncovering covert behaviours that have been successfully kept from the awareness of adults.

A comprehensive diagnostic assessment and history-gathering from multiple informants will have helped to identify the presence of conduct disorder and any coexisting conditions and problem areas that must be addressed in order for the healthy development of adaptive functioning to be restored over time. The most common coexisting clinical conditions found with conduct disorder are ADHD, mood and anxiety disorders, and substance use disorders. Furthermore, it is common to encounter academic underachievement and outright school failure, even in the absence of any learning disorders. Social isolation and arrest of development of age-appropriate social skills often result.

Once a child or adolescent has been identified as exhibiting conduct disorder, the clinician must be thinking along multiple, intersecting dimensions as he or she plans the approaches to the treatment of the patient. These dimensions include the developmental level and gender of the child, the presence of any coexisting problems and conditions, the planning and provision of interventions that will be carried out by the clinician in the clinical setting itself, the planning and co-ordination of interventions that will evolve outside the clinical setting, the involvement of caregivers and educators, and the possible recruitment of other agencies and providers, particularly those representing community resources, including the courts and juvenile justice system. For the extremely resistant child or adolescent, it may be necessary to involve the juvenile court to implement and supervise assessments and treatments.

Many of the interventions that evolve outside the clinical setting are similar both in principle and implementation to those interventions designed to prevent the onset of conduct disorder discussed elsewhere in this chapter. The clinician is unlikely to be a direct agent of change in these types of interventions. However, it is important for the clinician to be aware of the existing community resources, such as after-school programmes, and to recommend and assist if necessary the enrolment of the patient in such programmes. This may be especially indicated in situations where adult-supervised activities are deemed appropriate to either prevent association with deviant peers, or to enhance the acquisition of adaptive social skills. Advocating that the child receive supplementary academic services when indicated, is another crucial role of the child clinician, and will serve to enhance developmental competence in academic skills.

The literature concerning the clinical treatment of conduct disorders acknowledges the multifactorial causality of this group of disturbances, and their chronicity. Hence, once conduct disorder has been identified, it is not surprising that multimodal approaches, and extended time periods for the treatments are recommended and carried out. These multi-

modal approaches address not only the symptomatology of the conduct problems, but the fact that many children so affected require remediation in the areas of academic and social skills. Few studies have examined the long-term outcomes of programmes providing such complex interventions. The work of Grizenko *et al.* (1993; Grizenko 1997), suggests that such multimodal treatment approaches can lead to sustained benefits long after termination of the interventions, particularly when there is good parental participation during the intervention.

Specific psychosocial interventions

To a large extent, interventions that have been shown to be effective in randomized clinical trials follow closely from those factors that have been clearly identified as causal risk factors or risk factors of conduct disorder. In the case of conduct disorder, the most compelling evidence has been accrued around the causal role of caregiver practices. As a result, interventions targeted at this level are essential and most likely to lead to positive behavioural change, particularly when combined with strategies supporting the role of parents in the community and school. Some of the intervention strategies to address parenting behaviours may serve both as therapeutic and as preventive efforts.

Interventions will follow according to the developmental level of the child. For preschool- and elementary school-aged children, interventions will focus heavily on the training of primary caregivers and educators. The training will involve how these adults should alter and structure the environment of the child, how to prevent maladaptive behaviours, how to respond to the child when such behaviours do occur, how to teach the child to assume responsibility and control for his or her own behaviours, and how to impart adaptive skills and behaviours to the child. These techniques all draw heavily from operant-behavioural and cognitive-behavioural approaches to behavioural change (see Herbert, Chapter 53).

For adolescents, considerations involving the training of adults remain valid. Here, however, the need to provide interventions that impact the socialization process is critical. It is not that younger children would not benefit from socially based interventions, but adolescents are considerably more mobile than younger children, and can access peer groups far beyond those of their homes, immediate neighbourhoods, and their schools. Therefore it is important to devise interventions that can instill the inherent desire to associate with more functional peers, and the skills to engage successfully in such peer interactions.

For the interventions that are provided in the clinical setting itself by clinicians, those involving parent management training (PMT) have been the most successful and promising for altering the course of conduct disorder (Offord & Bennett 1994; Kazdin 1997; Brestan & Eyberg 1998). A number of studies involving randomized assignment to treatment or control conditions have been conducted, attesting to the efficacy of this general approach. Among the most widely studied of these approaches is the method developed by Patterson & Guillon (1968). This

method stresses an operant-behavioural approach to behaviour management. This involves parental monitoring, ignoring or punishing deviant behaviours, and rewarding appropriate and incompatible (with problems) behaviours.

Various methods of imparting PMT are employed. For example, Webster-Stratton (1994; Webster-Stratton & Hammond 1997) have successfully conducted PMT with groups of parents using video tapes and group leaders, to model effective parenting behaviours. This modality of treatment delivery renders a technique of known efficacy and even more cost-effective intervention. These same investigators have also highlighted the importance of identifying and addressing how parents resolve marital conflicts, as a means of reducing behavioural problems in children (Webster-Stratton 1994; Webster-Stratton & Hammond 1999).

Home-based family therapy, such as the Family Project Approach (Verwaaijen *et al.* 1993a,b; Van Acker & de Kemp 1997), provides a means of working intensively with severely disturbed children and adolescents. By providing in-home training and support to primary caregivers in their parenting roles, such interventions may avert the need for institutional care of symptomatic children and adolescents. Furthermore, in vulnerable families, such interventions may reduce the risk of escalation of conflicts to the point where caregivers become overwhelmed and child maltreatment results.

Other therapeutic techniques aimed at individuals, that have shown clear promise in treating conduct disorders but are lacking in the type of evidence accrued for the various forms of PMT, include anger management and assertiveness training techniques, problem-solving skills training, and interventions designed to address biases in social cognition and information processing (Offord & Bennett 1994; Kazdin 1997; Brestan & Eyberg 1998). Each of these approaches is targeted to a specific factor thought to have a potential role in the onset or the evolution of conduct disorder. Symptomatic children may receive interventions to improve anger and aggression management, to learn appropriate means of asserting themselves in non-aggressive ways, to recognize and address biases in social cognition, and to improve problem-solving skills, so that during conflicts more adaptive solutions may be generated that can avoid outcomes such as aggressive confrontations.

A conceptual-empirical approach that is gaining increasing attention for the understanding and treatment of conduct disorders is attachment theory. Interventions for conduct disorder based on attachment theory begin with the premise that the children who display persistent disturbances of conduct are first and foremost 'disconnected' from the individuals and the norms of the society within which they live. Therefore, it is insufficient to focus on the identification and management of maladaptive behaviours. First, a meaningful connection must be established with the child, and with key individuals in the child's life (Moretti *et al.* 1994; Moore *et al.* 1998). Interventions informed by this theory have been extended to caregiving adults too. Studies indicate that mothers of children with conduct disorders report histories of problematic attachment to caregivers in their

own childhood (Routh *et al.* 1995). Reparations in adult attachment behaviours towards their children is seen as central to influencing both child attachment behaviours and the symptoms of conduct disorder.

Psychopharmacological interventions

The psychopharmacological management of symptoms of conduct disorder *per se* has been a relatively neglected area of child psychiatric treatment. In fact, the longstanding clinical wisdom has been such that coexisting conditions, such as ADHD and mood disorders, are routinely treated medically. However, there has been widespread belief that symptoms specific to conduct disorder are not responsive to medications. This belief has been understandably sustained by the clear salience of environmental contributions to the causation of conduct disorder. However, this stance has recently been placed in question by the growing evidence of biological correlates of conduct disorder (Rogeness *et al.* 1992; Coccaro & Kavoussi 1996; Stoff & Vitiello 1996) and by a few well-designed and conducted medication trials involving randomized double-blind conditions, with assessment of change in some of the defining features of conduct disorder.

Once again, one would not consider medications in the absence of other interventions, nor would one expect that the complexity of a syndrome such as conduct disorder would respond *in toto* to medications. However, judicious targeting of certain conduct disorder-specific symptoms may be indicated where there is considerable severity and impairment resulting from such symptoms. Among the symptoms most commonly targeted with medical interventions are those involving the overt behaviours of explosive temper, interpersonal aggression and destruction of property. In two randomized double-blind placebo-controlled trials involving psychiatric inpatients, Campbell *et al.* (1995) and Malone *et al.* (2000) found that lithium carbonate reduced target symptoms of aggression and temper outbursts significantly more than placebo, independent of other mood effects of lithium. In an open-label study Kafantaris *et al.* (1992) found carbamazepine to be useful in reducing aggressive and explosive behaviours in hospitalized children diagnosed with conduct disorder. A follow-up study of inpatients by these investigators using double-blind placebo-controlled conditions and randomized assignment (Cueva *et al.* 1996), however, did not find carbamazepine to be superior to placebo in reducing these same target symptoms. It is important to recognize in the case of these studies, that inpatients were targeted for medication intervention. These results may not apply equally to outpatients, who might presumably display less severe forms of the same symptoms.

The use of psychostimulants has generally been reserved for the management of symptoms of ADHD. Klein *et al.* (1997) recently explored the efficacy of methylphenidate in reducing conduct disorder-specific symptoms in a randomized double-blind placebo-controlled trial of outpatients. They found that independent of pretreatment levels of comorbid symptoms of

ADHD, methylphenidate significantly reduced levels of some conduct disorder-specific symptomatology, including verbal and physical aggression, stealing and cruelty.

There have been a number of other open-label studies involving the use of a variety of psychotropic medications to treat conduct disorder, including stimulants, beta-blockers, alpha-2 adrenergic agonists, antidepressants, mood stabilizers and neuroleptics (Lavin & Rifkin 1993). These studies suffer not only from the limitations inherent in the open-label design—including the lack of blinding of patients and raters, and the absence of randomized assignment to treatment conditions—but they often also suffer from the absence of a differentiated focus on symptoms of conduct disorder and on other comorbid conditions. Therefore it is difficult to ascertain in many of these trials if improvement was a direct result of treatment effects on conduct disorder-specific symptoms, or an indirect effect on behaviour caused by improvement in comorbid symptoms such as mood or hyperactivity.

Given the rapidly expanding field of paediatric psychopharmacology, and the increasing pressures and indications for biological therapies in multimodal approaches to conduct disorders, it will be necessary for more well-conducted clinical trials to be carried out involving blinded conditions and randomized assignment of patients, together with the use of well-validated assessment tools, to evaluate the efficacy of the wide range of medications that could plausibly be utilized to ameliorate specific target symptoms of conduct disorder.

Prevention

The high prevalence and chronicity of conduct disorder, combined with its refractoriness to treatment and high costs to society, make it a prime candidate for primary prevention (see Offord & Bennett, Chapter 52). It is far from obvious, however, what to emphasize in a programme of prevention, because the risk factors represent such a complex configuration of environmental and personal factors (Price *et al.* 1989; Walter *et al.* 1991).

Public health approaches to prevention generally work in one of two ways: either the environment harbouring the risk conditions is improved; or the personal resources and competence of children to deal with such conditions are strengthened. Offord (1987, 1989) has supplied a balanced account of prevention efforts in this area, and provided a rationale for the design of experiments based on the analysis of risk factors from the Ontario Child Health Study (Boyle & Offord 1989). While considerable effort has been directed towards community- and school-based efforts to reduce prevalence, it is important to contrast these with those that target high-risk groups of families or children. The decision to design programmes that can be universally applied, in contrast to interventions that target high-risk groups, is a major source of uncertainty in the prevention of conduct disorder.

An informative community-based experiment conducted in a

public housing area in Canada reported limited but important results (Offord & Jones 1983; Jones & Offord 1989). A comprehensive programme of non-academic skill development was established in one of two comparable areas for boys between 5 and 15 years. In the area receiving the intervention, the number of police and fire calls was reduced, as was the frequency of vandalism over a 3-year period. At the same time evidence was amassed to show that the children actually achieved new levels of athletic and physical skills. A cost analysis demonstrated that the money saved by government agencies far exceeded the programme's expenditures. These results are in keeping with the findings of studies that have examined the contribution of lack of adult supervision to and monitoring to disruptive behaviour in adolescents (Pettit *et al.* 1999). A caveat of this experiment is that the benefits were limited to non-academic areas. There was little evidence that the results generalized to areas of school performance or social skills.

School-based interventions have been popular for a number of years but have produced varying degrees of success in prevention (Gottfredson 1987). Recently, Hawkins *et al.* (1991) combined parent and teacher training programmes to promote social skill development in children aged 6 to 8 years old. The intervention, carried out over the first 2 years of primary school, significantly reduced the level of aggressive behaviour for white students, but did not have a significant impact on African-American children. While the possibility of biased teacher ratings cannot be discounted, it is conceivable that the level of risk in African-American children was beyond the level reachable by this experiment. These results are broadly similar to the Newcastle experiment in which group therapy and behaviour modification produced improvements in behavioural outcomes in children in primary school (Kolvin *et al.* 1981).

As the execution of well-designed school level intervention experiments have improved, the problems that complicate programme effectiveness have been better documented. Two examples will suffice. The Tri-Ministry study in Canada compared academic and social skills components separately and in combination, and followed children over a sufficiently long interval to document both transient and more lasting benefits (Hundert *et al.* 1999). The findings were sporadic and inconsistent in showing the expected increases in prosocial and decreases in antisocial behaviour. Among the several limitations discussed by the authors of this report, a particularly sobering one concerns the heavy reliance placed on outside experts in the design of the intervention. They suggest that a more collaborative approach from the beginning of conceptualizing such a programme may be fundamental to maximizing programme effectiveness. A similar prevention trial designed for children in the elementary school years and conducted in a US public school system demonstrated the formidable problems of random classroom and teacher allocation. The system's bias to cluster aggressive children in the same classroom worked to undermine interventions to reduce aggressive behaviour (Kellam *et al.* 1998).

The nationwide effort to reduce the level of interpersonal vio-

lence among school children in Norway is unique in its scope (Olweus 1991). The intervention was initiated by the Ministry of Education in the wake of an outbreak of suicides among boys who had apparently been victimized by peers. The endeavour involved mobilizing all the resources of the school system to educate teachers, administrators, parents and students in understanding the nature and seriousness of the aggressor-victim relationship. The programme was designed as a quasi-experiment in which results were assessed in a time-lagged fashion, permitting an estimate to be made about the size of the intervention effect in the absence of a control group. Judged by this standard, the effort was not only remarkably successful in reducing the level of violence, but also in diminishing antisocial behaviour in the school environment.

Prevention experiments that target preschool-aged children should conceivably have a more powerful impact than those that start later (McGuire & Earls 1991). Some evidence that this approach might work to reduce the prevalence of conduct disorder was provided by the Perry preschool intervention. Although this effort was designed as an educational enrichment programme for poor children, one follow-up study indicated that reduction in officially recorded delinquency was achieved in the experimental group (Schweinhart & Weikart 1997). To date, preschool experiments explicitly designed to reduce the rate of conduct problems have not been conducted, but the evidence derived from studies such as these must be regarded as promising.

Experiments designed to judge the long-term benefits of home-based parent training interventions beginning in the prenatal period and extending through the first few years of post-natal life have been closely watched. Although many of the same problems confronting school-based experiments have strained these types of efforts, the results represent a somewhat more optimistic picture. The work of Olds *et al.* (1998) is noteworthy in showing a long-term reduction of antisocial behaviour through adolescence. The positive effects of this intervention were restricted to the children at the highest risk in the sample. Such results argue for targeting resources to selective subgroups in contrast to interventions designed for universal application (Earls 1998).

The Montreal Prevention Experiment is a prime example of a high-risk design (Tremblay *et al.* 1992). In this study of kindergarten boys, all from low-income families, positive screening for oppositional and aggressive behaviour was performed prior to randomly assigning the subjects to one of three groups: experimental, control and placebo (these subjects were observed frequently but did not receive an intervention). The 2-year programme of intervention included PMT, social skill development for children, and a television viewing training curriculum for both parents and children. Follow-up at 3 years post-intervention demonstrated higher levels of grade retention, less fighting and delinquent behaviour in the experimental group. The study is now tracking subjects into their adolescent years to observe if these promising results endure (Vitaro *et al.* 1999).

Conclusions

As this chapter reveals, a considerable body of knowledge and experience exist about conduct problems, yet it would be an overstatement to say that this understanding is any where near being sufficient to address the disruptive and potentially dangerous consequences that are associated with this disorder. The control of this problem remains a challenge for child psychiatry and its associated disciplines and services. A necessity for meeting this challenge requires professionals to be closely attuned to the ways in which modern societies are changing in responding to the unvarying needs for nurture and guidance that all children require.

This is far from a straightforward task. Efforts to isolate the causes of conduct disorder have been complicated by a variety of contributing factors. The heterogeneity of factors exist at different levels of organization rendering a reductionistic approach inadvisable (see [HTTP://phdcn.harvard.edu](http://phdcn.harvard.edu) for description of a research programme that is designed to capture such multiple levels of influence in a single design). Yet, treatment plans and prevention efforts must have a target. Maintaining a balance between a comprehensive approach towards assessment and a focused intervention is one of the most demanding aspects of caring for children with this disorder.

Substance Use and Abuse: Epidemiology, Pharmacological Considerations, Identification and Suggestions Towards Management

Warren A. Weinberg, Caryn R. Harper and Roger A. Brumback

Introduction

One of the major problems confronting society at the beginning of the twenty-first century is the increasing substance use and abuse by young people. Despite many studies of this problem, there is still little understanding of the causes, appropriate treatment and, most importantly, successful approaches to prevention. Farrell & Taylor (1994) and Bukstein & Tarter (1998) reviewed much of the relevant literature. An excellent review of adolescent substance abuse and dual disorders was published in 1996 in *Child and Adolescent Psychiatric Clinics of North America* with S.L. Jaffe as guest editor. Rather than duplicating those efforts, this chapter highlights important older studies, introduces some newer information, and then emphasizes an approach to identifying and studying those underlying conditions that may predispose children and adolescents to substance use and abuse.

Definitions

One of the stumbling blocks to understanding substance use and abuse has been the confusion over terminology and definitions. People query whether nicotine and alcohol are 'drugs', whether the abuse of medically prescribed drugs (e.g. benzodiazepines) is comparable with the abuse of illicit drugs (e.g. heroin), whether drug use is synonymous with abuse, and whether abuse and dependence are different. There has also been a reluctance to label young people as having substance abuse problems because of the wide-spread pejorative lay usage of terms such as 'junkie' or 'addict' to describe adults with these problems.

There are many prescribed and illegal substances that can be used recreationally and which can result in abuse (see Table 27.1). They share the quality of having mental effects that are considered desirable, and most can give rise to some form of intoxication, but they vary in the extent to which there is pharmacological dependence, and some do not result in withdrawal symptoms. There are also performance-enhancing illicit drugs that involve substantial health risks but they are not considered here, other than in terms of a note on pharmacology, because the problems with which they are associated are rather different.

For medical purposes, substance use, abuse, misuse, dependence and withdrawal must all be differentiated (Farrell & Taylor 1994). The problem drug-taker may be defined as: 'Any person who experiences social, psychological, physical or legal problems related to intoxication and/or regular excessive consumption and/or dependence as a consequence of his own use of drugs or other chemical substances' (Advisory Council on the Misuse of Drugs 1982). The World Health Organization (1992, 1996) in their ICD-10 defined *acute intoxication* as psychoactive substance use resulting in disturbed 'level of conscience, cognition, perception, affect or behaviour, or other psychophysiological functions and responses . . . directly related to the acute pharmacological effects of the substance and resolve with time, with complete recovery, except where tissue damage or other complications have arisen'. *Harmful use* was defined as 'a pattern of psychoactive substance use that is causing damage to health . . . physical . . . or mental.' *Dependence* was defined as 'a cluster of behavioural, cognitive, and physiological phenomena that develop after repeated substance use and that typically include a strong desire to take the drugs, difficulties in controlling its use, persisting in its use despite harmful consequences, a higher priority given to drug use than to other activities and obligations, increased tolerance, and sometimes a physical withdrawal state . . . chronic alcoholism . . . drug addiction'. *Withdrawal state* was defined as 'a group of symptoms of variable clustering and severity occurring on absolute or relative withdrawal of a substance after persistent use of that substance.'

The Diagnostic and Statistical Manual of Mental Disorders, fourth edition (DSM-IV; American Psychiatric Association 1994) distinguishes between *substance use disorders* (substance dependence and substance abuse) and the *substance-induced disorders* (e.g. intoxication, withdrawal or delirium). *Tolerance* is the 'need for greatly increased amounts of the substance to achieve intoxication (or the desired effect) or a markedly diminished effect with continued use of the same amount of the substance.' *Withdrawal* is defined as 'a maladaptive behavioural change, with physiological and cognitive concomitants, that occurs when blood or tissue concentrations of substance decline in an individual who had maintained prolonged heavy use of the substance. After developing unpleasant withdrawal symptoms the person is likely to take the substance to relieve or to avoid

Table 27.1 Substances of abuse. After Halikas (1990).

Alcohol

- Ingested through drinking.
- Manifestation of intoxication—slurred speech; staggering gait; slowed reflexes; and personality change, including argumentativeness, belligerence, melancholia, irritability, euphoria, social disinhibition, and a variety of other significant personality changes. Memory blackouts, related to the rapidity of the rise in blood alcohol level, which in turn is related to the rapidity of ingestion coupled with the lack of other food contents in the stomach, are the most common medical consequence. Overdose, especially in this non-tolerant population, can result in death.
- Treatment—a youngster who is non-arousable and believed to have ingested significant quantities of alcohol (or any other drug) should be considered a medical emergency and hospitalized for close management. There, appropriate intervention including support, gastric lavage and dialysis, if necessary, can be instituted.

Amphetamines (stimulants)

- Generally taken orally, although occasionally injectable amphetamine preparations are still used.
- Manifestation of intoxication—acute effects are generally those of stimulation, with increased energy, euphoria, grandiosity, increased irritability, increased physical activity and decreased sleep. Acute toxicity generally includes paranoid symptoms and panic and can easily include spontaneous violence. Hypertension leading to cerebral haemorrhage and cardiac failure, hyperthermia and seizures may occur.
- Treatment—caution should be exercised in dealing with adolescents intoxicated with amphetamines. Any rapid movement or any movement in the direction of the patient may be misinterpreted as an aggressive act, and the patient may become violent. Use of injections may be seen as particularly threatening. Intervention must include a great deal of supportive talk and calming agents such as benzodiazepines. Chronic amphetamine use generally requires hospitalization for withdrawal because of the withdrawal depression that occurs uniformly.

Cannabis (marijuana, hashish)

- Generally smoked but occasionally ingested.
- Manifestation of intoxication—generally sedating with a euphoriant quality. It has a relatively rapid onset of action by inhalation and the intoxication lasts 15–30 min unless renewed. Time is slowed down, the senses seem heightened, the person is happy, and everyone is ‘mellow’. The most consistent physiological concomitant is hunger, and snacking is common. Occasionally, novice users develop symptoms of a panic anxiety attack because of tachycardia or sensory effects. Sensory effects that are generally perceived as pleasurable, but can be seen as frightening, include visual distortion with trails or streaks of light following movement of objects (e.g. shimmering of walls or waving of light or air). These misperceptions can become frightening and reach the proportion of hallucinations in the panicked user. A marijuana toxic delirium exists but is rarely seen.
- Treatment—in the face of a marijuana-induced panic attack, benzodiazepine might be used to provide some sedation. In the face of a toxic delirious state, brief hospitalization and supportive care would be appropriate, because the active constituents of marijuana, the cannabinoids, are fat soluble and can have impact over several days.

Cocaine

- Generally snorted or smoked, although injectable forms are also occasionally used.
- Manifestation of intoxication—similar to the amphetamines but subtler and more reinforcing. Apparently there are fewer adverse acute effects. This drug has a rapid onset of action by the routes used. Cardiac failure and seizures can be lethal.
- Treatment—this is probably the hardest single drug in which to achieve abstinence and stable remission. The relapse rate is almost universal. Withdrawal cannot hope to be achieved on an outpatient basis. Inpatient withdrawal could include therapy with amantadine and desipramine. There is some recent interest in carbamazepine as an adjunct to control cravings. Many drugs are being tried in the management of this resistant addiction. The acute intoxication requires hospitalization and appropriate treatment of the medical symptoms.

Hallucinogens (phencyclidine [PCP], LSD, mescaline, and ‘designer drugs’)

- Ingested orally.
- Manifestation of intoxication—will vary from mild stimulation, euphoria, sensory enhancement and increased energy to delirious states with hallucinations, fluctuating sensorium and disorientation.
- Treatment—acute intoxication with hallucinogens that result in a ‘bad trip’ can be managed generally with verbal supportive care and the use of calming agents such as the benzodiazepines. However, PCP is an extremely troublesome drug. Toxic psychotic states associated with its use seem to occur among chronic users, while the acute delirious toxic state occurs among more irregular or novice users. This chronic toxic state requires long-term inpatient management and has been known to last several months: it clears very slowly. Hallucinations and delusions, confusion and bewilderment, and an overall decrease in mental functioning are hallmarks of this chronic state. It is often misdiagnosed as a schizophrenic condition when seen in adolescents. Treatment of the acute intoxication includes acidification of the urine with ammonium chloride in an effort to accelerate the excretion of the substance from the body. Management of the long-term condition generally includes major neuroleptics, which unfortunately are not very useful but are commonly used for behaviour control.

Opiates including heroin (narcotics)

- Oral narcotics are occasionally used with regularity and are frequently at least tried among multiple-drug users in this group. Intravenous use is also prominent.
- Manifestation of intoxication—the opiate overdose is often acute and life-threatening with the patient found in semicomatose condition with evidence of a recent intravenous injection. Physical signs will often show decreased respirations, cyanosis, pinpoint pupils and, if life-threatening, evidence of pulmonary oedema, cardiac dysrhythmias and/or convulsions progressing to cerebral oedema (Schuckit 1979).

Table 27.1 *continued*

- Treatment—narcotic overdose is a medical emergency requiring aggressive management. Any adolescent brought to an emergency department in a comatose state should receive an intravenous narcotic antagonist, naloxone hydrochloride, because of the possibility of a narcotic overdose. Should the patient be roused by this medication, it would indicate that at least one of the drugs that this person has overdosed with was a narcotic. Multiple drugs are generally involved so that the management is not just for narcotics. Also, illegal availability of the long-acting narcotic methadone in large cities means that some youngsters will overdose with that substance. While they will be aroused by naloxone, left to themselves they will soon become unconscious again. They should therefore be watched closely for at least 24 h. Cardiac dysrhythmias and pulmonary oedema, if present, will require appropriate medical management.

Inhalants (hydrocarbons, glue-sniffing, toluene-sniffing)

- The sniffing of any of the volatile hydrocarbons, whether directly from cans of gasoline, from glue, or from other substances placed into plastic bags, is a habit or behaviour that is likely to occur at ages 10–14 years. It is the most common type of adolescent drug abuse, after alcohol, in developing countries. In recent years, for example, the sniffing of typewriter-correcting chemicals became popular among 10–12 year-old children.
- Manifestation of intoxication—these young people are only brought to the attention of the medical community in an acute state when toxic and delirious. At that time they have all of the usual signs and symptoms of an acute delirium.
- Treatment—hospitalization is usually required. Supportive care, close observation and close protection are necessary. Aggressive treatment for the long-term problem is crucial. It would appear that the volatile hydrocarbons have the worst long-term impact on the user. A chronic organic state can result that will include decreased cognitive functions, hallucinations, irritability and aggressiveness, and a persistent drive for an altered euphoric mental state. Because of their youth, this drive and their aggressiveness, these patients often require chronic hospitalization and generally are mislabelled as ‘young chronic schizophrenics’.

Nicotine

- Inhaled or ‘chewed’ as in snuff and chewing tobacco.
- Manifestation of intoxication—similar to stimulants, including improved alertness, memory and decreased appetite.
- Treatment—transdermal patch (slowly tapering the dose) with adjunctive psychological support.

Sedative and tranquilizers (barbiturates, methaqualone, sleeping pills, benzodiazepines)

- Ingested orally in pill or capsule form.
- Manifestation of intoxication—includes sedation, somnolence or sleep. The state sought and achieved, while awake, is that of ‘mellow’ oblivious neutrality. These drugs are sometimes used in conjunction with one of the stimulants to counteract agitation or other adverse psychological effects.
- Treatment—overdose with these drugs is a medical emergency. The barbiturates and barbiturate-like compounds can cause severe respiratory depression. The benzodiazepines, when combined with alcohol, can be especially lethal from respiratory depression. Unresponsive patients should be hospitalized and medically treated. Withdrawal from the benzodiazepines can last up to 2 weeks because of their fat solubility. Therefore, it is not surprising that patients addicted to these substances become irritable and paranoid and demand discharge at day 10–14 of hospitalization. Withdrawal from these drugs should proceed at about a 10% reduction per day after changing the patient to a second or diazepam withdrawal schedule.

those symptoms.’ *Compulsive substance use* refers to taking a substance in larger amounts or over a longer period than was originally intended, often accompanied by a persistent desire to cut down or discontinue usage. Typically, the individual spends a great deal of time obtaining the substance, using it or recovering from its effects. Despite recognizing the contributing role of the substance to a psychological or physical problem, the person continues to use the substance.

The American Academy of Pediatrics (1996) used broadly similar definitions. *Substance intoxication* was applied to the ‘development of a reversible substance-specific syndrome due to recent ingestion of (or exposure to) a substance resulting in clinically significant maladaptive behavioural and psychological changes’.

Substance use starts with the experimental initiation of occasional drug-taking, progresses to regular usage to achieve the pleasurable effects, the development of tolerance and increasing ‘dosage’ to obtain the same effects, the development of associated psychosocial impairment or other harmful consequences,

and finally dependence or compulsive usage (Chaltos 1996; see Fig. 27.1). The risk factors that have been identified are many and various (American Academy of Pediatrics Committee on Substance Abuse 1998; Bukstein & Tarter 1998; Reinherz *et al.* 2000; Table 27.2).

Epidemiology

Over the last 20 years, there have been several large-scale epidemiological studies of drug use and abuse in young people, in both North America and Europe (Silbereisen *et al.* 1995; Kandel & Davies 1996; McKeganey *et al.* 1996; Miller & Plant 1996; Reid 1996; American Academy of Pediatrics Committee on Substance Abuse 1998, 1999; Bukstein & Tarter 1998; Maxwell & Liu 1999; Silberg *et al.*, unpublished data; Weinberg N.Z. *et al.* 1998). The precise rates vary somewhat across investigations, according to methods of assessment, definition and population studied. However, there is broad agreement on most key findings.

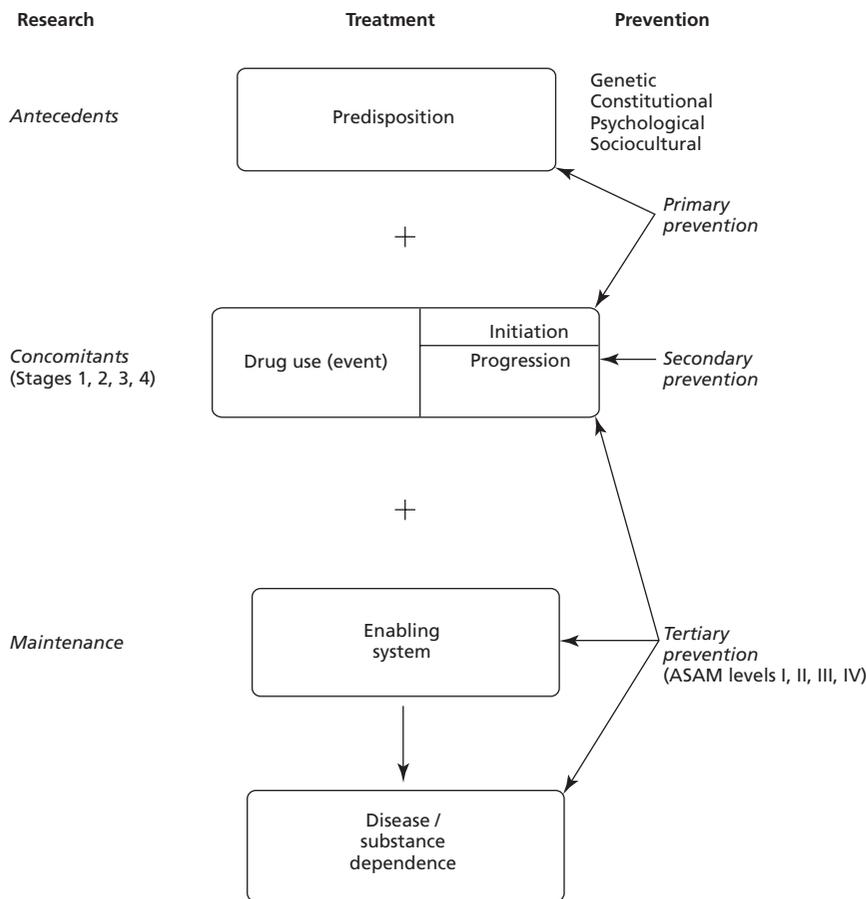

Fig. 27.1 Developmental biopsychosocial disease model. With permission from Chatlos, J.C. (1996).

- Alcohol and nicotine are the most frequently used substances, followed closely by marijuana, with inhalants (e.g. glue-sniffing), ‘uppers’ (e.g. stimulants such as amphetamines), ‘downers’ (e.g. sleeping pills) and hallucinogens next in frequency, and cocaine or opiates somewhat less frequent.
- About one-half to three-quarters of older adolescents have taken an illicit drug at some time.
- A substantial minority (20–40%) of those who have used drugs have tried multiple drugs.
- Only about 1 in 12 who have taken drugs are heavy users.
- Drug use is uncommon in children under the age of 12 years but becomes much more frequent during the teenage years, with the exception of inhalants which are more used by younger age groups.
- Drug use, overall, is about as common in girls as boys but there are marked gender differences in types of drug used, with alcohol abuse much more common in males.
- Although secular trends vary according to type of drug, overall drug usage in young people tended to increase during the 1990s.
- Associations with social background vary considerably, according to type of drug.
- Drug use is more frequent among young people with poor scholastic achievement.

Longitudinal course

General population studies have been consistent in showing that the younger people are when they first use drugs, the more likely they are to progress from experimental usage to dependence or abuse (Robins & McEvoy 1990; Tubman *et al.* 1990; Anthony & Petronis 1995; Fergusson & Horwood 1997; Maxwell & Liu 1999). This finding has been used to argue for the value of prevention programmes to delay drug use, on the grounds that this should reduce major drug problems (Robins & McEvoy 1990). However, although that might be so, it seems equally likely that the late onset is itself a reflection of a lower liability (in which case, any success in delaying first drug usage might have little or no effect).

Longitudinal studies of drug abusers have all shown the very considerable psychopathological and physical risks, especially with respect to suicide and accidental deaths, delinquency, depression and psychosocial malfunction (Crumley 1990; Deykin & Buka 1994; Kandel & Davies 1996; Kandel *et al.* 1997; Brook *et al.* 1998; Borowsky *et al.* 1999). Oyefeso *et al.* (1999) found a teenage-specific mortality excess of 11 times the general population rate in males, and 21 times in females. Conversely, studies of suicide have shown the high frequency with which it was preceded by substance abuse (Fowler *et al.* 1986). There is also a

substantially increased risk of HIV and of hepatitis C among drug users who inject, because of transmission of infection by contaminated needles (Gilvarry 2000; see also Havens *et al.*, Chapter 49).

Neuropharmacology of substances

The substances used can be grouped according to chemical or pharmacological similarities. We highlight the major points adapted from the following exhaustive reviews: Schuckit (1979), Cooper *et al.* (1991, 1996), Karch (1996), Stahl (1996), Carvey (1998) and Siegel *et al.* (1999). Sites and pharmacological actions of common drugs of abuse are shown in Table 27.3. All these substances produce dysemotionality symptomatic of depression, mania, or a rapid cycling between these affective states. Affective symptoms can be acutely induced and chronically promoted by the continued substance use. Sedation, lethargy and the impairment in diligence and volition are also common, both in acute and chronic substance use.

Alcohol (Carvey 1998)

One of the most ubiquitous substances used and abused is 'alcohol' (ethyl alcohol), which is a product of the fermentation of a variety of sugars. It is consumed orally ('drinking'). It is rapidly and almost completely absorbed from the gastrointestinal tract (primarily the duodenum) and is quickly distributed throughout the body. Because of its partial lipid solubility, alcohol easily penetrates tissues but is preferentially distributed in the brain, which has a particularly high lipid content. Alcohol is metabolized primarily through the alcohol dehydrogenase system in the liver where it is converted to acetaldehyde and then acetate. It interacts with membranes, reducing function of embedded proteins (e.g. interfering with the sodium-potassium adenosine triphosphatase pump in the cell membrane and interfering with the electron transport chain in the mitochondrial membrane). Alcohol has numerous and variable effects on neuronal function, including:

- potentiating the gamma-aminobutyric acid (GABA) (A) receptor (inhibitory ligand-gated chloride channel);
- decreasing excitability of the N-methyl-D-aspartate (NMDA) glutamate receptor (excitatory ligand-gated calcium channel);
- facilitating the release of dopamine, norepinephrine, serotonin and endogenous opioids;
- inhibiting the release of acetylcholine;
- binding to the delta opioid receptors; and
- reacting (as acetaldehyde) with catecholamines (dopamine and norepinephrine) to form tetrahydroisoquinolines and sal-solinol (which possess opiate-like properties).

The interaction with GABA (A) receptors explains the additive and perhaps synergistic effects that occur when ethanol and benzodiazepines are used together (Carvey 1998). The

Table 27.2 Risk factors for adolescent substance use disorders. Adapted from American Academy of Pediatrics Committee on Substance Abuse (1998) and Bukstein & Tarter (1998).

Individual risk factors

Early childhood characteristics

Early conduct problems, aggression

Poor academic performance/school failure

Early onset of substance use

Adolescent's attitudes and beliefs about substance use

Risk-taking behaviours or antisocial behaviours

Rebelliousness and alienation

Low self-esteem

Psychopathology, particularly affective disorders (depression, bipolar disorders) and conduct disorders

Negative character traits (e.g. lying, lack of empathy)

Previous dependence on substances (tobacco, alcohol, drugs)

Early sexual activity

Peer-related risk factors

Peer substance use

Peer attitudes about substance use

Greater orientation (attachment) to peers

Perception(s) of peer substance use/attitudes

Disorganization in the community

Parent/family risk factors

Parent, sibling or other family member with history of substance use

Parental beliefs/attitudes about substance use

Parental tolerance of substance use/deviant behaviour

Lack of closeness/attachment with parents

Lack of parental involvement in youth's life

Lack of appropriate supervision/discipline

Family history of antisocial behaviour

Child abuse and neglect

acute opiate-like actions contribute to analgesic, euphorogenic and sedative-hypnotic properties of alcohol (Carvey 1998). Effects on peripheral and central biogenic amines are competitive on cardiovascular function but eventually produce an overall depressant effect on cardiac output. The inhibition of acetylcholine release in the brainstem reticular formation probably contributes to the acute sedating properties of alcohol. Effects on the hypothalamus include an alteration in temperature homeostasis (usually resulting in a reduction in body temperature) and an inhibition of the antidiuretic hormone release (resulting in increased urine production).

Considerable interest relates to the proposed teratogenic effects of alcohol on the developing fetus in women who abuse alcohol during pregnancy. It is not clear whether the reported alterations in body development and facial features and changes in head size and brain function are actually an effect of alcohol or the result of other genetic and environmental factors that may have predisposed the mother to alcohol abuse as well as nutritional factors during the pregnancy.

Alcohol is not only a sedative, but also induces dysphoric states of agitation, anxiety and depression. Symptomatic of in-

Table 27.3 Sites and pharmacological actions of common drugs of abuse. Used with permission from Bukstein & Tarter (1998).

Substance	Proposed action	Brain site
Alcohol	Facilitation Inhibition	GABA receptors NMDA (glutamate receptors)
Cannabis/marijuana	Agonist	Cannabinoid receptors
Hallucinogens (e.g. LSD)	Partial agonist	5-HT ₂ receptors
Opiates	Agonist	Opioid receptors
Cocaine	Inhibition	Monoamine reuptake systems (dopamine, norepinephrine, serotonin)
Nicotine	Agonist	Nicotinic acetylcholine receptors

GABA, gamma-aminobutyric acid; 5-HT₂, 5-hydroxytryptamine (serotonin); LSD, lysergic acid diethylamide; NMDA, N-methyl-D-aspartate.

toxication is impaired alertness, decreased cognitive functioning and motor impairment (including ataxia) that may progress to coma and even death.

Nicotine (Stahl 1996; Carvey 1998; Siegel 1999)

Nicotine is the major psychoactive substance in tobacco. It can be released by burning tobacco leaves (cigarettes) and then inhaled in the cigarette smoke, or it can be released by saliva digestion of tobacco leaves (snuff and chewing tobacco). It is a tertiary amine that readily crosses membranes of the lungs and mouth to enter the bloodstream, where it can be quickly metabolized to cotinine; it is also rapidly distributed in the brain (Carvey 1998). Nicotine is a direct-acting nicotinic cholinergic receptor agonist (Carvey 1998; Siegel *et al.* 1999). It acts on the autonomic nervous system ganglia to increase both sympathetic and parasympathetic activity, and it stimulates the nicotinic acetylcholine receptors at the neuromuscular junction (Carvey 1998; Siegel *et al.* 1999). In the central nervous system it stimulates nicotinic cholinergic receptors (Siegel *et al.* 1999). Its action on the brainstem reticular activating system probably has some relationship to its alerting effects, and its action on emotion and memory areas of the temporal lobe limbic system structures has some relationship to the behavioural patterning associated with individual use of the substance. Its enhancement of release of biogenic amines (e.g. dopamine and norepinephrine) probably contributes to its euphorogenic properties. Overall, the effects of nicotine and its metabolites are similar to those of stimulants, including improved alertness and memory and decreased appetite (Carvey 1998).

Marijuana (Carvey 1998)

Marijuana is the dried female flower of the *Cannabis sativa* plant of the hemp family. The major psychoactive chemicals in marijuana are a class of substances called cannabinoids of which delta-9 tetrahydrocannabinol (THC) is the chemical thought to

be most responsible for the mental effects, but other cannabinoids, such as delta-8-tetrahydrocannabinol, cannabidiol and cannabivone, have not been systematically evaluated (Carvey 1998). Burning marijuana releases about 20% of the cannabinoids in the smoke which when inhaled allows the lipid-soluble cannabinoids to rapidly pass into the bloodstream. In contrast, only about 6% of cannabinoids are released by oral ingestion of marijuana (Carvey 1998). Soaking the flower buds of the *Cannabis sativa* plant in resin concentrates the cannabinoids in a material called hashish.

Cannabinoids are metabolized almost exclusively in the liver and excreted in the bile but do not induce the P-450 system. THC is an exceptionally lipophilic substance that quickly distributes throughout the body but it is only slowly cleared and remains detectable for months. THC readily dissolves in membranes, disrupting functioning in a manner similar to alcohol. THC enters membranes of specific receptors that are widely distributed in the brain with highest density in the basal ganglia, cerebellum, hippocampus, and layers I and VI of the cerebral cortex (Carvey 1998). These THC binding sites interact with G-proteins and other secondary messenger systems serving as neuromodulators effecting the action of various neurotransmitters (except THC receptor sites seem to have little effect on dopaminergic systems). One effect is to inhibit the voltage regulated N-channel for calcium that regulates neurotransmitter release (Carvey 1998).

In various situations THC can have effects ranging from stimulant/euphoric, to depressive/sedative, to marked anxiety and panic/toxic delirium (Carvey 1998). Acute effects include: euphoria, relaxation and disinhibition; impaired problem-solving skills and difficulty organizing thoughts and conversing; and significantly lowered cognitive function (such as reaction time). Chronic use in adolescents and young adults is associated with decreased diligence and volition—the ‘amotivational syndrome’ (Musty & Kaback 1995; Carvey 1998). However, this may not be the direct result of the marijuana use, but rather the result of genetic and environmental factors that produce

such behaviour and also predispose the individual to chronic marijuana abuse. Depression can be induced or promoted by the ongoing use of marijuana; marijuana appears to be a 'gateway' illicit drug towards the use of other drugs (American Academy of Pediatrics Committee on Substance Abuse 1999). It is our experience that acute marijuana use induces depression in genetically susceptible adolescents, and chronic use of marijuana promotes deepening depression and the maladaptation associated with a chronically depressed state (Musty & Kaback 1995).

Inhalants (Schuckit 1979; Karch 1996; Carvey 1998)

Inhalants are a diverse set of volatile organic compounds found in aerosols, glues, cleaning fluids, marking pens, lighter fluid, fingernail polish, typewriter correction fluid, paint and paint removers, room deodorizers, engine fuels and gasoline, and gaseous anaesthetic agents. These agents are inhaled by 'sniffing' through the nose or 'huffing' through the mouth either directly from the container or from bags into which the substance has been placed (Carvey 1998). The effects of the inhalants generally last approximately 30 min or less but can be sustained by repeated usage (Carvey 1998). Because the inhalants are strongly lipophilic chemicals, they readily pass through mucous membranes of the upper respiratory tract and lungs to enter the bloodstream (Karch 1996). They are also rapidly distributed throughout the body and easily pass into the brain (Karch 1996). Despite their structural diversity, the major effect is to dissolve in membrane lipids and disrupt membrane function in a manner similar to alcohol (Carvey 1998). Depending upon the compound, metabolism varies from excretion unchanged through the lungs, catabolism through the liver P-450 system with excretion in the bile, or excretion in the urine. The act of inhaling the vapours in a closed environment can result in hypoxaemia with consequent central nervous system neuronal injury. Disruption of mitochondrial membranes in cells of both the central and peripheral nervous systems can also produce cell injury or cell death. Damage to organ systems, other than the brain, such as the kidneys, liver or bone marrow, which occurs with use of benzene or halogenated hydrocarbons, can produce metabolic derangements that secondarily disrupt brain functioning (Carvey 1998). Contaminants, such as lead in gasoline, can also damage the nervous system. Death is rare but can occur from cardiac dysrhythmias with the halogenated hydrocarbons (Carvey 1998). Inhalants are used as illicit drugs by younger age groups (children and adolescents). Chronic inhalant users have been found to have a high rate of depression (Zur & Yule 1990).

Cocaine (Karch 1996; Carvey 1998)

Cocaine is derived from the leaf of the coca plant. In powder form it can be inhaled and after dissolving in mucous membranes it is rapidly transported into the blood. 'Crack' cocaine is

a more powerful concentrated form of cocaine produced by extracting the free base into an organic solvent, such as ether, and smoking it (Carvey 1998). Crack smokers have blood levels twice as high as those who snort cocaine. It is quickly distributed to the brain. Half-life of cocaine is only 20–45 min. Cocaine plus alcohol produces cocaethylene, a psychoactive chemical that has a much longer half-life and is more likely to cause cardiac conduction abnormalities than either cocaine or alcohol alone. Cocaine increases biogenic amines by acting as an inhibitor of the reuptake mechanisms. In particular, cocaine binds to the dopamine transporter and induces a structural change that reduces the capacity to bind neurotransmitters (Leshner 1996). Cocaine can also act as a competitive inhibitor of dopamine. Unlike amfetamines, the large cocaine molecule cannot be transported across the neuronal membrane and biogenic amine release does not occur (Carvey 1998). Acute central nervous system effects of cocaine include anxiety, paranoia, hallucinations, emotional lability, irritability, stereotypic behaviour, tremor and seizures. Cocaine increases alertness and attention. In those individuals with a genetic susceptibility to affective illness, cocaine use can result in a state of mania.

There are several external markers of intense and repeated cocaine abuse and the presence of these external markers is a strong confirmatory sign of cocaine abuse. These markers include: perforated nasal septum, cocaine 'tracks' (salmon-coloured bruises that turn blue and yellow over time), 'crack keratitis' (damage to the cornea where the abuser has rubbed his or her anaesthetized eyes too roughly), enamel erosion of the teeth, calloused thumb from lighters, superficial burns and blackened, hyperkeratotic lesions on the palmar aspect of the hand (from handling crack pipes) and, in some cases, bite marks on the lips and tongue from seizure activity (Karch 1996).

Mittleman *et al.* (1999) analysed data from 3946 patients who were interviewed an average of 4 days after myocardial infarction (MI), of whom 38 reported using cocaine in the year preceding their myocardial infarction. Of these 38, nine reported using cocaine within 1 h of onset of MI symptoms; another two had used it within 1–3 h. Cocaine users were younger than non-users and were more likely to be males, current smokers or members of minority groups. Analysis showed that the risk for MI increased more than 20-fold within 1 h of using cocaine but the risk declined to levels that were not statistically significant after 1 h. Death from cardiovascular causes is more common with crack.

Cocaine abuse during pregnancy may cause vascular injury to the fetus. This effect seems to be related to the level of prenatal cocaine exposure (Frank *et al.* 1999). This has led certain states in the USA to regard cocaine during pregnancy as a criminal act. Cocaine smoke, just like cigarette smoke, can be passively absorbed and can lead to positive urine, blood and hair tests in those who have been in the environment while cocaine is being smoked.

In young adult homosexual males, cocaine abuse has been reported to be a significant independent predictor of the failure to

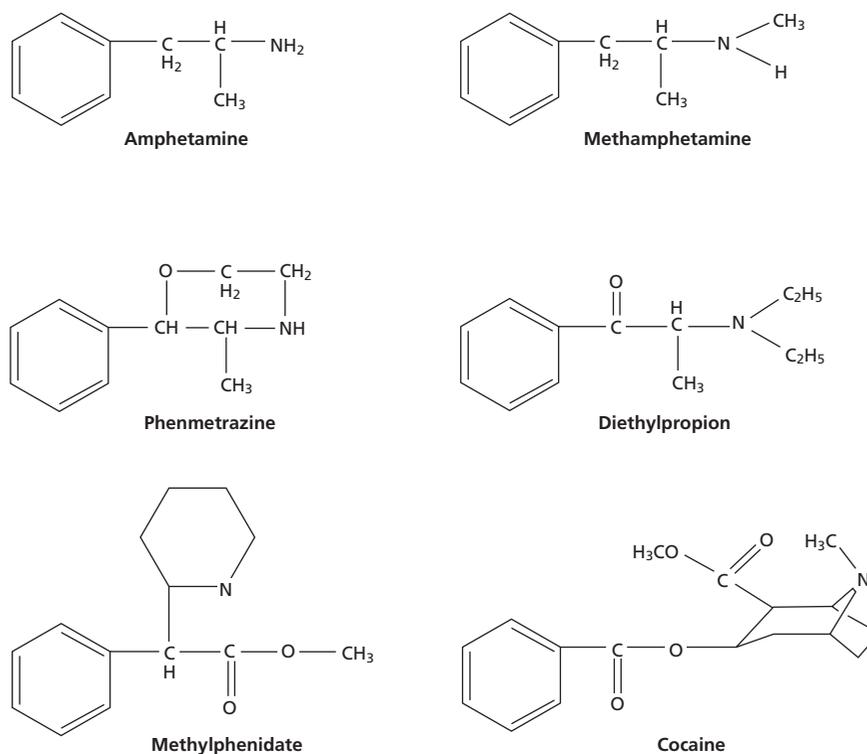

Fig. 27.2 The chemical structures of common psychostimulants. Used with permission from: Carvey, P.M. (1998) *Drug Action in the Central Nervous System*, p. 325. Oxford University Press.

use condoms during anal intercourse. Why this group (rather than those abusing amphetamines and other substances) chooses not to practice 'safe sex' remains unknown (McNall & Remafedi 1999).

Stimulants (Karch 1996; Carvey 1998; Siegel *et al.* 1999)

The psychostimulants are a structurally diverse group of drugs (Fig. 27.2). The most commonly used psychostimulants are dexamphetamine, methamphetamine, 3,4-methylenedioxymethamphetamine (MDMA or 'ecstasy'), phenmetrazine and diethylpropion (Carvey 1998). When amphetamine or methamphetamine is injected intravenously it is called 'speed'. Methamphetamine is called 'ice' when its free base is extracted into an organic solvent, such as ether, and smoked (Carvey 1998), similar to the technique of producing crack cocaine. The stimulants are indirect-acting agonists of catecholamines (dopamine and norepinephrine), and competitively inhibit the biogenic amine transporters (reuptake pump) for dopamine, norepinephrine and serotonin, cause calcium-independent release (release independent of nerve terminal depolarization) of the biogenic amines from nerve terminals in the brain, and competitively inhibit monoamine oxidase (Carvey 1998). Half-life is 8–12 h and these drugs are mostly excreted unchanged in the

urine (Karch 1996). Effects on biogenic amines also occur in the peripheral nervous system, resulting in hypertension, cardiac dysrhythmias, vasculitis, arterial thrombosis and cardiac failure (Schuckit 1979). High-dose abuse can also produce severe vasoconstrictive effects, resulting in intracranial ischaemia or haemorrhage, myoglobinuria and renal failure. Chronic use promotes—particularly in those with a genetic susceptibility to affective illness—agitation, irritability and homicidal ideation.

Downers (Stahl 1996; Carvey 1998)

Downers include sleeping pills, barbiturates, other sedatives and minor tranquillizers such as the benzodiazepines: diazepam and chlordiazepoxide. The prototype sedative-hypnotic are the barbiturates (phenobarbital, secobarbital) and the prototype tranquillizers are diazepam (Valium) and chlordiazepoxide (Librium). These central nervous system depressants reduce the electrical activity of the brain, facilitate sleep, promote muscle relaxation, treat seizures, produce anaesthesia and reduce anxiety. The liver metabolizes many of these drugs but some are excreted unchanged in the urine. Half-lives vary from hours to days (Cooper *et al.* 1991, 1996; Stahl 1996; Carvey 1998).

The barbiturates increase chloride conductance by binding to one of the GABA (A) receptor subunits, increasing the amount of time that the chloride channel remains open (Cooper *et al.* 1996; Stahl 1996). The increase in chloride conductance occurs even in the absence of GABA (Stahl 1996; Carvey 1998). Barbiturates depress respiration in a dose-dependent fashion, inducing coma and fatal respiratory depression at high doses (Carvey 1998). Death caused by a barbiturate overdose can be the result of drug autonomism rather than an intentional act (Carvey 1998). Drug autonomism is a behavioural pattern in which the patient takes drugs unnecessarily because the drugs have interfered with the individual's ability to determine if doses are really needed (Stahl 1996; Carvey 1998). Because barbiturates continue to open the chloride channel in the absence of GABA, a ceiling effect will not occur and can lead to fatal respiratory depression (Carvey 1998). Both pharmacokinetic and physiological tolerances develop during the use of barbiturates. Barbiturates (especially the longer acting agents, such as phenobarbital) induce the P-450 system, making increased doses necessary to maintain steady state plasma levels. Continued use results in dependence, especially if used for euphoria or sleep.

Benzodiazepines bind to a specific receptor site (or benzodiazepine receptor site) on the GABA (A) receptor (Carvey 1998). In the presence of benzodiazepine receptor binding, GABA more frequently activates the chloride channel, thus producing a greater degree of GABA-mediated inhibition (Stahl 1996; Carvey 1998). Because GABA (A) receptors are widely distributed in the brain, the benzodiazepines produce an overall reduction in brain electrical activity (Carvey 1998). Benzodiazepines also inhibit the reuptake of adenosine, promoting vasodilatation (including coronary artery dilation) and reducing acetylcholine release from the terminals of certain reticular formation neurones, thereby lowering the state of arousal. Some of the benzodiazepines (e.g. oxazepam and lorazepam) are conjugated extrahepatically (Carvey 1998). The degree of lipid solubility of the benzodiazepines varies > 50-fold and accounts in great part for the differences in rates of absorption, onset of action and redistribution (Carvey 1998). The benzodiazepines are generally completely absorbed following oral administration. Chlorzepate is decarboxylated in gastric juice to the active agent *N*-desmethyldiazepam, while the other benzodiazepines are biotransformed into active metabolites by the liver (Carvey 1998). The benzodiazepines are classified as short- (triazolam), intermediate- (lorazepam), or long-acting (diazepam, chlordiazepoxide) based upon the method of biotransformation, the lipid solubility and the half-lives (Schuckit 1979; Carvey 1998). Enterohepatic recirculation of conjugated benzodiazepine metabolites also increases their duration of action, and deposition in muscle and fat with subsequent delayed release over a long period of time produces some of the 'hangover effects' (Carvey 1998). Tolerance results in part from receptor alterations that decrease the amount of enhanced chloride conductance (Yu *et al.* 1988).

Although withdrawal symptoms occur, compulsive drug-seeking behaviour (addiction) to downers is considered unlikely

(Carvey 1998). In our experience, these drugs may lower anxiety at the expense of inducing or promoting dysphoria symptomatic of depression in those vulnerable to depression.

Hallucinogens (Carvey 1998)

The hallucinogenic (or psychedelic) drugs produce hallucinations without delirium in the presence of intact cognitive functioning and intact orientation to the environment (Carvey 1998). Hallucinations are perceptions that result from disruption of brain systems responsible for the recognition and interpretation of external events and may be visual, auditory, tactile, olfactory, gustatory or kinetic. The hallucinogens can also produce pleasurable moods or frightening experiences with sympathetic arousal. It has been suggested that nearly 8% of the population over age 12 years has used these drugs at least once (Carvey 1998).

The hallucinogens fall into three major classes: lysergic acid diethylamide (LSD), phenylalkylamines (mescaline) and indolealkylamines (psilocybin). In addition to these chemical groups, designer drugs (substituted amphetamines or phenylethylamine derivatives) with hallucinogen-like effects have been developed (Table 27.4; Carvey 1998). The hallucinogens generally act on 5-hydroxytryptamine (5-HT or serotonin) receptors but also act as dopamine agonists, although dopamine antagonists do not block hallucinations induced by these drugs (Carvey 1998).

LSD-induced hallucinations often occur in a temporal sequence as unformed bursts of light, then as geometric forms and finally as complex images which involve faces, scenes and movement within those scenes. This suggests that the hallucinogenic drugs reduce the threshold for activation of neurones along sequential sensory pathways, and once these thresholds have been reduced, neurones fire in response to background activity in the absence of an external event, thereby producing the hallucination. LSD is one of the most potent drugs known, with 50 µg being the threshold dose. LSD is a powder ingested orally either with sugar cubes or dissolved in a liquid, but it is unstable to heating which prevents inhalation in smoke (Carvey 1998).

The psilocybins and mescaline-like drugs are much less potent than LSD (Carvey 1998). The psilocybins are found in 'magic mushrooms' indigenous to Mexico, Texas, Florida, Hawaii and the Pacific Northwest USA. They are eaten raw or dry, brewed in tea or eaten in a stew (Carvey 1998). Mescaline, the least potent hallucinogenic, comes from the peyote cactus found in North and South America. The sun-dried crowns of these cacti are consumed either dry or in various recipes (Karch 1996; Carvey 1998). Mescaline is associated with nausea and vomiting and the hallucinogenic experience reflects its potent dopamine agonist properties (Carvey 1998).

LSD, mescaline and psilocybins are absorbed by oral ingestion with the hallucination beginning within 1 h and persisting for 6–12 h. Tolerance to these compounds is rapid and develops within 24 h, making dependence unlikely (Carvey 1998). These

Table 27.4 Designer drugs. From Carvey (1998).

Drug	Distinguishing characteristics
2,4,5-Trimethoxyamphetamine (TMA)	Structurally resembles both mescaline and amphetamine Effects are similar to those of mescaline
4-Methyl-2,5-dimethoxyamphetamine (DOM)	Also known as Serenity, Tranquillity and Peace (STP) Hallucinations occur with significant sympathetic autonomic nervous system activation
Paramethoxyamphetamine (PMA)	Very potent hallucinogen associated with excessive sympathetic autonomic nervous system stimulation and fatalities Most frequently used as a contaminant to enhance psychic effects of other drugs
Brom-DOM	The most potent phenylethylamine compound, distributed in a microdot formulation Effects last for 10 h Overdose is rarely fatal
3,4-Methylenedioxyamphetamine (MDA)	Mild intoxication without hallucination Produces feelings of empathy and euphoria Higher doses produce hallucinations with delirium
3-4-Methylenedioxymethamphetamine (MDMA)	Also known as 'ecstasy', Adam, and M&M Initially synthesized as an appetite suppressant Used in conjunction with group therapy because of its ability to produce empathy Known to have induced several deaths secondary to cardiac dysrhythmias
3-4-Methylenedioxyethamphetamine (MDEA)	Also known as Eve, with effects similar to those of MDMA

drugs are excreted rapidly in the urine, are not lipophilic, and thus not stored in muscle and fat. Serious medical consequences are unusual and most often secondary to some type of trauma occurring while experiencing the hallucinations (Carvey 1998). Cardiovascular or other serious medical problems also can result from combined use of another substance, such as phencyclidine (PCP) or a designer drug.

Designer drugs are substituted amphetamines or phenylethylamine. These drugs do not produce clear-cut psychostimulant effects or true hallucinations, but they do deplete serotonin, dopamine and norepinephrine (Carvey 1998). These drugs enhance self-esteem that leads to increased use (Carvey 1998). The designer drugs have much lower therapeutic indices than LSD with resultant overdose associated with morbidity and even mortality (Carvey 1998). They produce more sympathomimetic effects, which complicates emergency treatment of overdose (Carvey 1998). Signs and symptoms of sympathetic activation represent states of toxicity requiring immediate treatment, similar to amphetamine toxicity (Karch 1996).

Anabolic steroids (Karch 1996; Carvey 1998)

The anabolic steroids are all derivatives of the androgenic hormone testosterone: cypionate, nandrolone decanoate, methandrostenolone and boldenone undecylenate (Carvey 1998). These chemical modifications increase oral absorption and prolong the half-life. Their effects are to alter nitrogen balance and muscle growth and they are used with the goals of in-

creasing lean body mass, increasing strength, reducing recovery time between athletic activities and increasing aggressiveness. Anabolic steroid use was introduced during the Second World War to improve healing and speed recoveries in wounded soldiers and improve symptoms of depression (Karch 1996). Anabolic steroids can be taken orally or injected intramuscularly. Use occurs as 'stacking' (use of several different preparations at once) which maximizes the 'anabolic effect' while minimizing any 'androgenic effect'; 'cycling' (using combinations in alternating 6–12-week cycles) which reduces tolerance; and 'pyramiding' (initial use of low doses progressing to large doses for several weeks, followed by tapering before an athletic contest) which reduces the chance of detection by drug-screening programmes (Karch 1996; Carvey 1998).

The anabolic steroids are metabolized in the liver and excreted in the bile (Karch 1996). Half-life and onset of action is minutes to days (Karch 1996). Muscle hypertrophy and increased strength following anabolic steroid use is the result of massive increase in the size of type 2 (fast twitch, anaerobic) muscle fibres. However, collagen in tendons and ligaments is altered and weakened, resulting in a mismatch such that the hypertrophic muscle fibres cause tears and other injuries (sprains and strains). Adverse effects of anabolic steroids on the liver include peliosis hepatis, cholestatic jaundice and hepatic neoplasms. Myocardial fibrosis and cardiomyopathy have also been reported. Other systemic symptoms include testicular atrophy, hyperpigmentation of the skin, acne on the extremities and hirsutism. Metabolic conversion of anabolic steroids to estradiols may be responsible for the gynaecomastia and reduced

sperm production. Anabolic steroids bind with the sigma opiate receptors in the brain (Karch 1996).

Widespread use of anabolic steroids by athletes has been associated with euphoria, aggression, depression, irritability, hallucinations, paranoid ideation, manic symptoms and violent crime (Pope & Katz 1988, 1990; Conacher & Workman 1989; Oliva & Middleton 1990; Cooper & Noakes 1994). One report described a 16-year-old boy with school and social phobia, increasing symptoms of depression as he reached puberty, and a passive temperament, who began using anabolic steroids when he started weight-lifting. He then became increasingly aggressive and violent and in a rage murdered his girlfriend. He was diagnosed with depression and treated successfully with medication while awaiting trial for murder (Pope *et al.* 1996). Evaluation of 133 male convicts in the same facility (mean age 30.7 ± 7.6 years) uncovered two other cases of apparent anabolic steroid-induced crimes, suggesting the induction of manic-type (homicidal) anger (Pope *et al.* 1996).

Opiates/heroin (Schuckit 1979; Karch 1996; Carvey 1998)

Opiates are among the oldest substances used for psychoactive effects, with ancient Greek literature referring to the use of poppies for sleep and pain relief. The Greek word for the poppy seed 'opion' is derived from 'opos' for juice. The smoking of opium developed in China during the sixteenth century and was abetted by the colonial powers. Also in the sixteenth century, the famous physician Paracelsus (Philippus Aureolus Theophrastus Bombast von Hohenheim) popularized opium-containing formulations as the treatment of choice for all diseases. His 'laudanum' consisted of 25% opium and was the most popular formulation for disease treatment. Sydenham shared this enthusiasm for opium as a panacea and influenced Thomas Dover to create a powdered opium formula known as 'Dover's Powder' as a home remedy for all types of ills and its use continued well into the twentieth century. In the 1850s, the Scottish physician Alexander Wood popularized the injection of opium preparations for pain. The US Civil War further popularized the injection of opiate formulations for war injuries or other painful conditions and many of these people became addicted. Sigmund Freud suggested that chewing cocaine antagonized the sedative effects of opiates and was a treatment for opium addiction, but instead this resulted in simultaneous addiction to both opiates and cocaine. In 1874, Wright first synthesized heroin from morphine, and in 1898 Strube showed its effectiveness in relieving severe tubercular coughs. The Bayer Company then began commercial production of heroin, thinking this to be a safe and effective cough suppressant. Thus, widespread opiate abuse, particularly in the middle class population (and mostly in women), developed in Europe and the USA in the early 1900s as the result of purchases of legally produced opiate formulations containing morphine, heroin, codeine and other compounds. This led to the banning of some manufacture and the non-prescription dispensing of opiate analogues in the 1920s. Also in the 1920s, the practice of intravenous injection of heroin (and

other opiates) to maintain addiction developed among addicts. Legal bans did result in a decline in opiate use until the 1960s and the Vietnam War (Karch 1996).

Currently, a wide variety of chemical substances used and abused fall into the category of opiates. This category includes the natural substance opium (the raw material derived from poppy seeds) and its purified derivatives such as morphine and codeine. It also includes semisynthetic agents produced by minor chemical alterations of the basic poppy-derived substances, e.g. heroin, hydromorphone (Dilaudid), oxycodone (Numorphan), hydrocodone (Tussend), oxycodone (Percodan) and methadone (Dolophine). There are also purely synthetic opiates, e.g. propoxyphene (Darvon), fentanyl (Actiq), meperidine (Demerol), pentazocine (Talwin) and diphenoxylate (Lomotil) (Schuckit 1979).

Opiates are well absorbed from all routes of administration including intravenously, subcutaneously, orally, rectally, intranasally (snorting), inhalation (smoking) and transcutaneously (patch) (Schuckit 1979). Once in the bloodstream, opiates are rapidly distributed throughout the body (Karch 1996). Various opiates undergo metabolism, although some are excreted with only minimal changes (Karch 1996). Morphine is quickly conjugated in the liver to morphine-3-glucuronide and morphine-6-glucuronide. The half-life of these glucuronides is 3–4 h and they are excreted in the urine in 24–48 h. There is also some enterohepatic recirculation of the glucuronides excreted in the bile with deconjugation by gut bacteria followed by reabsorption, prolonging the half-life. Within 10–15 min heroin is rapidly converted to morphine in the body. Over 80% of codeine is conjugated to codeine-6-glucuronide which, unlike the morphine conjugates, is an inactive metabolite, but codeine is converted by demethylation to active metabolites morphine and norcodeine. *N*-demethylation is the most common route of metabolism for the other opiates (Karch 1996).

The opiate agents are all lipid soluble, rapidly distributing throughout the body and crossing the blood–brain barrier. In the brain, opiates interact with membrane receptors on neurones. The opiate receptors are G-protein-coupled receptors (GPCRs) that have a variety of actions. The major receptor is the mu opiate receptor but there also are kappa and sigma opiate receptors, which are normally neurotransmitter receptors for the endogenous endorphin, enkephalin and dynorphin peptides. The behavioural effects of opiates appear to be mediated mainly by the mu opiate receptor, which on various neuronal populations produces alterations in potassium channels, calcium channels and adenylyl cyclase. The effect on adenylyl cyclase is upregulation of the cyclic adenosine monophosphate (cAMP) pathways (Karch 1996). The acute effect of mu opiate receptor stimulation and upregulation of cAMP in locus caeruleus neurones is inhibition of neuronal firing, but with chronic use the neuronal firing returns to normal (resulting in tolerance). After chronic stimulation, acute cessation (withdrawal) of mu opiate receptor stimulation causes a 7–10-fold increase above normal in neuronal firing. Such changes in neurones explain some of the physiological and behavioural symptoms experienced by

individuals using and abusing opiates (Busquets *et al.* 1995; Karch 1996; Carvey 1998).

Opiates increase the pain threshold, and produce sedation and motor inco-ordination. In adolescents with genetic susceptibility for affective illness, opiates can induce manic symptoms (euphoria, giddiness, racing thoughts) or depression (dysphoria, irritability). A variety of systemic effects are evident with opiate use. Some of these are specific to the route of administration, e.g. skin puncture wounds, scarring, abscesses, fasciitis and lymphoedema occur with administration by injection. Peripheral thrombophlebitis often follows intravenous administration. Pulmonary oedema is a common consequence of intravenous opiate administration. It is unclear whether this is a direct result of the opiates, a reaction to the various substances mixed with the agents, or a combination. Damage to the heart valves (particularly the tricuspid valve) from both drug contaminants (especially particulate) in the injected solution and any pulmonary oedema predispose to subsequent endocarditis (most commonly staphylococcal endocarditis). Acute opiate overdose produces coma with decreased respiration, cyanosis and pinpoint pupils, and can progress to pulmonary oedema, cardiac dysrhythmias and/or convulsions, with death resulting from a combination of respiratory depression and pulmonary and cerebral oedema (Schuckit 1979).

Use of other substances adds to the potential of a fatal outcome. Granulomas from embolized particulate materials (adulterants such as talc, cotton, starch or cellulose) in the intravenously injected opiates are common in the lungs and result in a progressive thromboembolic microarteriopathy with resulting pulmonary hypertension. Almost all individuals who have used intravenous opiates have at least some pathologic evidence of this microarteriopathy. Infections transmitted through contamination of needles, syringes or opiate mixtures are very common and can be bacterial or viral (particularly prominent are hepatitis B and C, and human immunodeficiency virus). Renal damage (focal segmental glomerulosclerosis) following chronic intravenous opiate use may be the result of immunological changes and can result in renal failure (Schuckit 1979; Karch 1996; Carvey 1998).

As a consequence of pulmonary problems and/or cardiac disease, strokes can be observed in opiate abusers. Transverse myelitis has also been observed in patients abusing opiates and this is thought to relate to either thromboembolism or toxicity from contaminants. One contaminant of amateur synthesis of meperidine-like opiates is 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) that destroys pigmented neurones in the zona compacta of the substantia nigra, resulting in the acute onset of severe parkinsonism (Karch 1996).

Because an addict purchasing drugs 'on the street' has no way of determining its purity or potency, a less potent drug (less than 3% purity) often results in withdrawal symptoms, while a more potent than usual sample can produce fatal respiratory depression, and a sample containing different contaminants may result in hypersensitivity reaction, toxicity from another component, or emboli to the lungs and retina (Karch 1996). There are certain

individuals who have abused heroin in the past but are no longer addicted and have an apparently stable lifestyle, yet, presumably when under stress, these individuals will use opiates. This has been termed 'chipping' and does not impair social functioning (Zinberg *et al.* 1975; Zinberg & Jacobson 1976; Zinberg *et al.* 1978; Schuckit 1979; Harding 1983–84; Harding *et al.* 1980; Harding & Zinberg 1984). In these individuals, variability in potency and purity can be lethal.

The withdrawal syndrome of the 'street abuser' is a combination of emotional, behavioural and physical symptoms (Schuckit 1979). The benign nature relates to the variability in the potency of heroin obtained on the street that ranges from 8 to 75%, mostly around 36% (Karch 1996). The psychological state includes a strong 'craving' with irritability and agitation (Schuckit 1979). The physical signs and symptoms of withdrawal can be generalized as follows (Schuckit 1979, pp. 91–92).

a Within 12 hours of the last dose, physical discomfort begins with tearing of the eyes, a runny nose, sweating, and yawning, followed by a restless sleep (a 'yen') which continues for 24–48 hours. Over the same time period, other symptoms include dilated pupils, loss of appetite, gooseflesh (hence, the term 'cold turkey'), back pain, and a tremor.

b Subsequently the individual develops insomnia, incessant yawning, a flu-like syndrome (consisting of weakness, gastrointestinal upset and chills fusing), muscle spasms, ejaculation (males), and abdominal pain.

c The symptoms then slowly decrease in intensity by the fifth day, and completely disappear by 7–10 days.

The acute withdrawal phase can be followed by a more protracted abstinence of two subtypes: during weeks 4–10, a mild increase in blood pressure, temperature, respiration and dilated pupils; then a later phase, lasting 30 weeks or more, characterized by a mild decrease in all of the above measures and a decrease in the respiratory centre response to carbon dioxide (Schuckit 1979).

Heroin overdose, both accidentally and intentionally, is not uncommon. In a recent study of 438 heroin-users recruited in non-clinical settings, mean age of first heroin use was 21 years, 98 (23%) reported at least one overdose (unconsciousness), mean number of overdoses being 3.6, and mean age of first heroin overdose was 24 years. Fifteen (16%) reported more than one overdose. Ninety-six of the 98 overdoses were by injected heroin, with 31% of the injectors of heroin reporting overdose, compared to 2% of the non-injectors. Users who had overdosed were more severely dependent upon heroin, older, and more likely to have been treated for a drug problem. Overdose was not related to gender or reported frequency or quantity of heroin use. In this study group both the overdose and non-overdose groups were using heroin 3–4 times per week with the average daily doses being about 0.5 g of illegal street heroin. Reasons for overdose included a higher than usual dose; stronger than usual quality of the heroin; alcohol use at the same time; and heroin use after abstinence. Up to 16% reported having taken overdose 'deliberately'. Interestingly, 48% had been present when someone else overdosed (Gossop *et al.* 1996).

Concerns have been raised that the use of opiate analgesics (morphine, fentanyl, oxycodone, hydromorphone and, less so, meperidine) to control, prevent and relieve patients of pain may promote opiate addiction and opiate abuse. A recent study negates this concern by showing that increasing medical use of opiate analgesics to treat pain 'does not appear' to be contributing to opiate analgesic abuse (Joranson *et al.* 2000).

Acute withdrawal symptoms occur in up to 90% of the newborns of heroin-dependent mothers and this carries a mortality of up to 30%. There is usually a low birth weight, and on the second day post-delivery withdrawal symptoms begin with irritability, crying, tremor, hyperreflexia, tachypnoea, diarrhoea, hyperactivity, vomiting and sneezing/hiccups. Treatment of the withdrawal syndrome in neonates involves the use of paregoric, methadone, phenobarbital or diazepam. Medication is given for 10–20 days, with tapering doses during days 14–20 (Schuckit 1979). A prospective study of such infants remains unavailable; however, a recent prospective study (5–6 years) of prematurely born children who received morphine as neonates to facilitate mechanical ventilation showed no adverse effects on intelligence, motor function or behaviour (MacGregor *et al.* 1998).

Self-medication

The high rate of affective disturbance in opiate addicts attending a treatment programme was noted by Rounsaville *et al.* (1982), and similar associations have been found with the use/abuse of other substances (Deykin *et al.* 1987, 1992; Bukstein *et al.* 1989; Greenbaum *et al.* 1991; Swadi 1992a,b; Hovens *et al.* 1994; Clark *et al.* 1995; Young *et al.* 1995). This could reflect factors leading to clinical referral (and, doubtless, to some extent it does) but epidemiological studies of the general population have also shown a substantial association between drug use/abuse and depression (see Rutter, Chapter 28). This association has also been noted among delinquent youths manifesting conduct disorder (Riggs *et al.* 1995). Accordingly, it has been suggested that individuals start using substances in an attempt to treat themselves (Deykin *et al.* 1987; Milin *et al.* 1991; Riggs *et al.* 1995).

The selection of the substance used for self-treatment of affective illness is not random but seems to be directed towards specific moods and feelings. Certain substances seem to be used to induce a state of euphoria (amfetamines, cocaine, alcohol) while other illicit drugs are used in a more relaxing, sedative, calming manner (marijuana, heroin, alcohol). The opiates appear to dampen feelings of rage and aggression and cocaine benefits the rapid cycling moods of depression and mania (Khantjian 1985). Some substances are used to promote impulsive primitive behaviours and others to dull unpleasant feelings/moods.

The limbic system (which includes, among others, the ventral tegmental area, nucleus accumbens, hypothalamus, cingulate cortex, prefrontal cortex, hippocampus and amygdala) is a circuitry prominent in fear, hunger, sexual desire and the emotions associated with impulsivity and memories, and seem-

ingly plays a prominent part in addiction and dependency. The primary neurotransmitter of the limbic system is dopamine but other neurotransmitters (serotonin, norepinephrine, acetylcholine, GABA) are also involved. Laboratory animal models for dependency have focused on the effects on the dopaminergic system (Gardner 1992; Bukstein & Kaminer 1993; Bukstein & Tarter 1998). A possible molecular mechanism of cocaine addiction involves changes in the dopamine-reuptake transporter to which cocaine binds strongly (Giros *et al.* 1996; Leshner 1996).

It has long been proposed that alcoholics, and especially binge drinkers, are trying to 'drown their blues'. Problem alcohol use to cope with depressive affect has been reported to be a significant risk factor in the development of alcohol dependence (Carpenter & Hasin 1999). Poor psychological well-being (poor self-esteem, anxiety, somatic symptoms, and eating concerns, most likely representing depression) in adolescents (mean age 17 years) is a significant risk factor for the development of later problem alcohol use at 22 years of age (Pitkanen 1999).

The relationship between affective disorders and problematic substance use can be explained as the interaction between genetic susceptibility for affective disorders and environmental factors, specifically exposure to the experimental use of substances as a developmental variant (American Academy of Pediatrics, Committee on Substance Abuse 1996). The families in which problematic substance use occurs tend to show a loading for a broad range of psychopathology (including sociopathy and alcohol and drug abuse) as well as affective disorder. Children and adolescents with this mixed family pattern often present early in life with multiple developmental behavioural and psychiatric symptoms (Weinberg & Emslie 1991; Weinberg & Brumback 1992). Nevertheless, if the underlying affective disorder is not recognized and appropriately managed, progression to substance dependence/abuse will often occur (Famularo *et al.* 1985; Geller *et al.* 1998; Weinberg & Glantz 1999). Winokur *et al.* (1998), studying a large cohort of adults with affective disorders and substance abuse, noted that the drug-abusing bipolar patients were significantly younger at entrance and had a higher incidence of family histories of mania or schizoaffective mania compared to the non-abusing bipolar patients. They suggested that drug abuse might precipitate an earlier onset of bipolar disorder in those who have a familial predisposition for mania.

Identification of substance use/abuse

The standard method for identifying alcohol use and abuse has long been the demonstration of ethanol in various body fluids (saliva, urine, blood) but has recently been expanded to include the demonstration of a number of oxidative and non-oxidative enzymes metabolizing ethanol to acetate (oxidative pathway) and to phosphatidylethanolamine (non-oxidative pathway). These are called ethanol 'state markers' and are possibly more quantitatively specific in gauging the severity of chronic use rather than acute toxicity (Laposata 1999).

The QED saliva test is a cost-effective method of screening for alcohol exposure in public health settings where intoxication is a common cause of a clinic visit (Bendtsen *et al.* 1999). Currently, the gold standard for identifying drug use in the previous 48 h is chemical analysis of a urine sample. Urine tests performed before an interview have been shown to be 93% accurate, but this accuracy decreased to 58% when urine testing was performed after the interview (Hamid *et al.* 1999). However, urine testing vastly underestimates the problem. The overwhelming majority of substance-using children and adolescents are unrecognized and do not seek the care of health professionals for substance use. One popular method for identifying substance use is the mandatory drug screening of children and adolescents involved in sports. Screening in other school settings is also taking place with the belief that such drug screening will lower substance use and its complications. Unfortunately, there are no data to confirm that such screening reduces the incidence of substance use, and it is possible that such screening actually increases the likelihood of school drop-out or lack of participation in activities.

A better tool for identifying substance use is the careful and detailed history-taking and examination of the child or adolescent (Weinberg W.A. *et al.* 1998). History should be obtained from a competent informed guardian (preferably the biological or adoptive mother). The physician should use a closed-end semistructured interview format to obtain information from the guardian (the child/adolescent should be present and can contribute additional information) about the present illness (concerns), developmental history (course): behaviour *in utero* (fetal hyperactivity), neonatal period and infancy (colic, irritable, little need for sleep, incessant crying or pleasant, good-natured), toddler years (hyperactive and could not be taken to the supermarket ['supermarket toddler']), 2–5 years of age (hyperactive, moody, irritable, provocative, sad, clingy, unable to separate), and each school year from kindergarten to present grade (adaptation, performance, behaviour and concerns) at school and outside of school, including home. It is particularly important to enquire about the dysphoric and vegetative symptoms of depression, hypomanic/manic behaviours, antisocial activities, bothersome compulsions and/or anxieties, sleep disturbance, diligence, volition (abiding by rules and regulations), the ability to cope with discomfort, the enjoyment of affection, development of verbal communication skills, reading ability, arithmetic skills, writing and non-verbal communication (including social interaction, competency, enjoyment) (Weinberg *et al.* 1995, 1998). A detailed three-generation family history must also be obtained. The child is often excused prior to discussing the family history but the adolescent is encouraged to remain if the parent/guardian agrees in order to learn of his or her family background. Information should be sought about affective illness, thought disorder (schizophrenia), Briquet syndrome, alcoholism (and drug and substance abuse) and sociopathy. Dynamic issues including separation, divorce (and reasons why), and problematic difficulties of finance, violence and abuse are discussed.

The examination of the child/adolescent should be conducted in a non-threatening manner using a detailed semistructured closed-end interview format, assessing moods and feelings, behaviour, substance use (including reasons for use, substances used and the sequence and frequency). The guardian may or may not be present during this examination depending upon the wishes of the child or adolescent. We have found young people to be reliable historians when not in a manic (euphoric/denial) state. Their reliability of reporting of their serious and sensitive feelings has been documented by others (Robbins & Alessi 1985). In substance-abusing adolescents, their reporting of depressive symptomatology may be more reliable than their guardians (Hovens *et al.* 1994). Information must also be obtained about physical abuse, sexual activity, attitudes towards the present problems and the desire to feel and do better. The examination must also include a detailed evaluation of higher brain functions (the Symbol Language and Communication Battery, SLCB; Weinberg W.A. *et al.* 1998) and neurological function including the evaluation of subtle motor findings (Emslie *et al.* 1998).

In most cases, substance use can be identified through this careful history-taking and examination, making routine urine drug screening unnecessary because it promotes distrust of the physician. However, there are some illicit drug abusing adolescents who find urine screening helpful towards promoting abstinence and it should be provided for that individual.

Course and treatment

The treatment of substance use/abuse disorders begins with prevention (Brook *et al.* 1999), and prevention begins with eliminating exposure and other risk factors in the environments (home, school, playground). Limiting factors are the recognition and prompt treatment of guardians manifesting affective illness with or without secondary substance use disorders. It is often the unrecognized affective illness of the caregiver that is promoting an unstable home environment with violence, physical abuse or neglect. An equally limiting variable is schools not recognizing, or meeting the needs of children and adolescents with learning disabilities. Equally significant is the recognition of affective illness in children and adolescents, thus preventing the progression to substance abuse in young people with a mixed-type family history (Weinberg *et al.* 1973; Brumback & Weinberg 1976, 1977).

Childhood or adolescent onset of problematic alcohol use seems to be persistent to late fifth decade of life. Individuals from the upper socioeconomic classes (with family and financial resources and adequate dietary intake) have a more favourable prognosis than individuals from a lower socioeconomic class who often have complications of neurological damage, family violence associated with a mood disorder, social failure and antisocial behaviour. Crack cocaine and heroin use are significantly more problematic with greater maladjustment in social/work functioning and more frequent fatality. Tobacco smoking, alco-

hol and/or marijuana use often precede the use of cocaine and heroin, and thus prevention of serious drug problems may not require preventing all substance use but just preventing progression during adolescence (Robins 1984) or until a predisposing affective illness is brought under control (Deykin *et al.* 1987; Clark & Neighbors 1996; Geller *et al.* 1998). The hallucinogens (psychedelic drugs) and amfetamines are generally not used regularly but are often associated with other illicit drugs in a select group of poly-substance abusing adolescents. It does appear that with cessation of substance abuse there can be remarkably improved functioning during the fourth decade of life, if the individual survives to that age. Initiation of substance abuse is uncommon in the later part of the third decade of life and problematic substance use seems to start in early rather than late adolescence (Robins 1984).

To date there are no well-controlled treatment studies in children or adolescents. Individual psychotherapy, family therapy and group education/supportive programmes including Narcotics Anonymous and Alcoholics Anonymous have anecdotal successes. A recent study of the treatment of adults with cocaine dependence, using a randomly assigned method, demonstrated benefit from intensive drug counselling plus group drug counselling as compared to two methods of professional psychotherapy (Crits-Christoph *et al.* 1999). Another study in adults with cocaine dependence noted the important variable being a longer stay in the drug treatment facility (Simpson *et al.* 1999). However, in methadone-treated opiate addicts, depression seemed to be the prominent variable in promoting the escalation to cocaine abuse (Kosten *et al.* 1987).

A variety of pharmacological treatments have been employed in adult substance abuse: drugs (disulfiram and multiple other agents) are used in treating alcoholism (Swift 1999); opiate analogues (methadone) have been used for heroin abuse; D1–D5 antagonists (ecopipam) have been tried in a small sample of cocaine-dependent abusers (Romach *et al.* 1999); opiate-dependent cocaine abusing adults maintained on buprenorphine and methadone have been successfully treated with desipramine (a norepinephrine tricyclic agonist) to facilitate opiate and cocaine abstinence (Oliveto *et al.* 1999); and lithium has been successful in treating cyclothymic (bipolar disorder) cocaine abusers (Gawin & Kleber 1984). Interestingly, opium addicts with depression who were successfully treated with methadone continued to use cocaine. More recently, one older adolescent and one young adult female with affective illness reported that their use of a synthetic amphetamine ('ecstasy'; MDMA) no longer produced euphoria when under the influence of either citalopram or paroxetine (both selective serotonin reuptake inhibitors; SSRIs) (Stein & Rink 1999). Many non-controlled and anecdotal reports have shown the usefulness of psychotropic medications in treating substance abuse.

In our experience, the most important part of management of the child or adolescent with problematic substance use is freedom from availability of illicit drugs, continued education about the social, economic and physical effects of illicit drugs ('social influence model') (Kleber 1994), and the proper diagnosis and

successful treatment of predisposing underlying affective disorder, when it is present. Once recognized, the affective illness must be vigorously treated using a multimodal approach of individual and family cognitive therapy (Wilkes *et al.* 1994) and appropriate pharmacotherapy with antidepressant medications, often in conjunction with lithium (Geller *et al.* 1998; Weinberg *et al.* 1998; Winokur *et al.* 1998).

It is also important to identify any specific learning disorder that may be contributing to school failure and social exclusion that are known to be high-risk variables for substance use (school drop-outs, gangs, etc). If a specific learning disorder is identified, the child or adolescent should be provided with multimedia for learning and performance, preferably in regular mainstream classes with ordinary peers as colleagues, avoiding excessive remediation, time on the skill-area deficit, grade retention or daily failure (Weinberg *et al.* 1971; Weinberg & McLean 1986; Levy *et al.* 1992; Weinberg *et al.* 1998).

Conclusions

Increasing substance use and abuse by young people is one of the major problems to be confronted by society in the twenty-first century. Depending on their sociocultural circumstances and the availability of drugs, up to half (or even more) use substances at some time. In some societies, experimental substance use might be said to be a normal developmental variant. Why and how some of these children and adolescents go on to become chronic users/abusers of substances is a key question. Careful assessment of these chronic substance using/abusing children and adolescents suggests that some of them have evidence of affective illness, sometimes before the onset of the chronic substance use/abuse. A family loading for psychopathology suggests a genetic liability in many which, coupled with availability of substances in the environment, and family adversity, results in the substance use problem. Multimodal intervention, which includes treatment of affective illness, may be the most effective way of preventing or controlling the substance use problem.

Substance Use and Abuse: Causal Pathways Considerations

Michael Rutter

Introduction

One of the crucial features of substance use and abuse is the very high frequency of occasional recreational use of drugs and the relative infrequency of drug abuse and dependency. Thus, in the Christchurch longitudinal study, nearly 70% of the study had used cannabis at some time but less than 7% showed substance abuse or dependence (Fergusson & Horwood 2000a). It is necessary to ask whether these represent opposite ends of the same continuum or whether the factors leading to one are somewhat different from those leading to the other. For example, in her study of Vietnam veterans, Robins (1993) found that prior heroin use was most frequent in inner city African-Americans but, of those using heroin in Vietnam, the likelihood of becoming and remaining dependent after return to the USA was greatest in rural whites. The question is by no means specific to drug abuse. Very comparable questions arise with respect to the possible connections between dieting in adolescent girls, which is exceedingly common, and anorexia nervosa, which is quite uncommon (see Steinhausen, Chapter 34), or between occasional delinquent acts in males, which are virtually normative, and life-course-persistent antisocial behaviour, which is both uncommon and handicapping (see Earls & Mezzacappa, Chapter 26), or between isolated brief episodes of depression and bipolar affective disorders (see Harrington, Chapter 29). In this chapter, possible causal influences are considered, mainly with reference to the findings of longitudinal studies, and with a particular focus on the meaning of associations between substance use/abuse and other forms of psychopathology or social malfunction.

Risk factors

A diverse range of risk factors for substance use and abuse have been identified through epidemiological studies, time series analyses, case-control comparisons and longitudinal studies (Hawkins *et al.* 1995; Silbereisen *et al.* 1995; Weinberg *et al.* 1998; Gilvarry 2000). They are likely to operate maximally at different stages in the progression from experimental recreational usage to dependence and abuse; they reflect a variety of possible risk mechanisms; and they vary in the degree to which the risks apply specifically to drug use and abuse. The last consideration is crucial because of the very high frequency with which drug users also show other forms of psychopathology.

Societal influences

The second half of the twentieth century saw a massive increase in both recreational illicit substance usage and alcoholism in most Western countries (Silbereisen *et al.* 1995; Rutter 1979; Gilvarry 2000). Time series analyses have shown a quite close connection between overall levels of population usage and rates of abuse disorders—for example, between alcohol consumption and deaths from cirrhosis or rates of very heavy drinking. It has also been found that time trends in both reflect accessibility and costs, as shown by the effects of changes in licensing, taxation, purchasing power and drug controls. Increased affluence tends to increase alcohol consumption, a severe sudden rise in taxation reduces consumption, and making usage illegal (as by raising the age for legal drinking) also has effects. Prohibitions on smoking have been similarly associated with changed public attitudes and a fall in the proportion of the population who smoke but, strikingly, much less so among young people than in older age groups. Effects are crucially dependent on social context. Thus, Mooney *et al.* (1992) found that the higher minimum age for drinking in North Carolina as compared to Louisiana was associated with a lower alcohol consumption by college students in controlled situations, but a *higher* rate in uncontrolled situations. Government actions to restrict importing, distribution and sales of amphetamines was followed by a marked decrease in their use (De Alarcon 1972; Wilson 1972). To be effective such steps need to have community approval and need to be accompanied by equally effective prevention of illegal production and distribution. The parallels with situational prevention of crime (Rutter *et al.* 1998) are close. Although it is evident that societal influences do affect substance use and abuse, it has not proved at all easy to use that knowledge to prevent substance abuse disorders.

Genetic influences

The evidence from both twin and adoptee studies indicates that there is a moderate genetic influence on the overall liability to substance use and abuse (van den Bree *et al.* 1998a–c; Kendler *et al.* 1999a, 2000; Vanyukov & Tarter 2000). In itself, that finding is not very informative because it applies to almost all forms of psychopathology (see McGuffin & Rutter, Chapter 12). What is more important is the light thrown on possible causal processes. Several pointers warrant emphasis. Genetic influences are much weaker on individual differences in initial experimental recre-

ational use of drugs than on established abuse or dependency, which has a quite strong heritability. Although there is substantial overlap between the two, the genetic influences on initiation are to some extent different from those on dependence (Kendler *et al.* 1999b). On the whole, the heritability of substance abuse is somewhat stronger in males than females, although this may reflect little more than gender differences in the severity/persistence of substance abuse problems.

The liabilities to use and abuse of different categories of drugs, alcohol and tobacco share over half their genetic variance—implying that most of the genetic influences are not drug-specific. This shared genetic variance includes that between nicotine and alcohol (True *et al.* 1999). Nevertheless, there are genetic influences on individual differences in sensitivity/tolerance to specific substances and these may well have a role in vulnerability to problems with specific substances. The best demonstrated example concerns the flushing reaction to alcohol seen in about half of Orientals, because of a deficiency in one of the key enzymes involved in alcohol oxidation. This unpleasant reaction to alcohol is quite a powerful protector against alcoholism. The genetic polymorphism does not occur in Caucasian and black populations, however, and therefore cannot account for individual differences in liability to alcoholism in these groups. On the other hand, there could be comparable genetic mechanisms that do so (Schuckit 1985; Comings *et al.* 1997; Koob & Le Moal 1997). Thus, Heath *et al.* (1999) found that, in males but not females, high sensitivity to alcohol was associated with a reduced risk of alcohol dependence.

There is a paucity of evidence on the role of genetic factors in the comorbidity between substance abuse and either antisocial behaviour or depression. A longitudinal twin study of adolescents, therefore dealing with initiation more than dependence, found that there was shared genetic liability for both types of comorbidity (Silberg, Rutter, D'Onofrio & Eaves, submitted). Family and adoptee studies are somewhat inconsistent (van den Bree *et al.* 1998b). Twin and adoptee studies have confirmed the environmentally mediated risk associated with early experiences such as parental loss or sexual abuse (Kendler *et al.* 1996, 2000), adverse rearing influences (Cadoret *et al.* 1986) and contemporaneous experiences such as unusually early puberty (Dick *et al.* 2000). There is also some indication that genetic liability operates both directly as a risk factor and indirectly in relation to susceptibility to environmental hazards (Cadoret *et al.* 1995). The second route implies that environmental risks may operate only or mainly on individuals who are genetically vulnerable.

Molecular genetic findings provide valuable leads but, so far, no solid findings (Vanyukov & Tarter 2000). The early reports that allelic variations in the dopamine D2 receptor gene were associated with alcoholism were probably largely a result of stratification biases (see McGuffin & Rutter, Chapter 12 for explanation). Currently, the main attention is being focused on genes that may have a role in temperamental features (such as novelty-seeking) implicated in the risk for substance abuse, but it remains to be seen whether this will pay off.

Individual characteristics

There is abundant evidence that antisocial behaviour in middle childhood and later, and its correlates, is strongly associated with an increased risk for substance abuse (see below) but little is known about other individual characteristics that carry risk (Weinberg *et al.* 1998; Gilvarry 2000). Attention deficit disorder with hyperactivity (ADHD) is associated with an increased risk for substance abuse but it seems that this risk is largely carried by its association with antisocial behaviour (Biederman *et al.* 1997; Mannuzza *et al.* 1991; Disney *et al.* 1999). ADHD in the absence of conduct problems probably does not increase the risk of substance abuse. It has been suggested that impaired behavioural regulation and self-monitoring, and lack of foresight/planning, are associated with an increased risk for both disruptive behaviour and substance abuse (Giancola *et al.* 1996). The same applies to sensation-seeking and difficulties with affect regulation (Pandina *et al.* 1992). There is growing evidence of the associations between temperamental measures of lack of control and impulsivity in the postinfancy, preschool years and later disruptive and antisocial behaviour (Caspi 1997; Rutter *et al.* 1998). The risks are likely to include substance abuse but whether there is any increase in risk that is independent of antisocial behaviour is quite uncertain. The same applies to poor scholastic attainment. Both risk-taking behaviour and a lack of commitment to social institutions and their values may be expected to predispose to taking illicit drugs, but the strength of their effects is not known.

In view of the evidence that substance abuse is associated with drug and alcohol problems in the parents, it is also necessary to consider the possibility that some risk may derive from fetal exposure to maternal alcohol and drugs (see Marks *et al.*, Chapter 51). In that such exposure has behavioural consequences, it could be implicated in the risk processes but evidence is lacking on whether that actually is the case.

Psychosocial risk factors

There is an abundance of evidence that young people attending clinic facilities for treatment of their substance abuse problems have a much increased rate of family adversity, but this may say as much about referral factors as the causes of substance abuse. Nevertheless, longitudinal studies of non-clinic samples suggest that the associations have some validity. Four key issues have only just begun to be addressed. First, there is the query of the extent to which the risks are environmentally, rather than genetically, mediated. The possibility needs to be taken seriously because so many of the psychosocial risks involve parental psychopathology. Nevertheless, as already noted, genetically sensitive designs have shown the reality of the psychosocial risks associated with parental loss as a result of family breakdown (Kendler *et al.* 1996), with sexual abuse (Kendler *et al.* 2000) and adverse rearing (Cadoret *et al.* 1986). The nature of these risk factors suggests that they are operating on psychological functioning in childhood before there has been

any involvement with either alcohol or illicit drugs. In short, the effects are likely to be on the overall liability rather than on substance use as such.

The second query is the extent to which the risks apply to the initial experimentation with drugs and how far to the progression from drug use to abuse and dependency. Surprisingly, this issue has received little attention up to now.

Thirdly, there is the question of the extent to which the risks apply specifically to substance use and abuse as distinct from socially disapproved behaviour and psychopathology more generally. It is obvious that the psychosocial risk factors closely parallel those for antisocial behaviour (see Earls & Mezzacappa, Chapter 26) and little is known about possible specificities. Lewinsohn *et al.* (1995) sought to differentiate shared and specific risk factors as they applied to depression and substance abuse. Both shared and specific risks were found.

The fourth query concerns the extent to which the psychosocial risks stem from the children's qualities as distinct from environmental features over which they have no control. Thus, Brook *et al.* (1999) found that a close parent-child identification was protective and involvement with a deviant peer group carried risk. Both are likely to have been influenced by the young people's own behaviour in shaping and selecting environments and by influencing their own personal interactions with other people. Situations brought about by the individuals themselves can undoubtedly influence the person's later behaviour—as shown, for example, by the effects of a harmonious marriage in making desistance from antisocial behaviour more likely (Zoccolillo *et al.* 1992; Laub *et al.* 1998). Nevertheless, in conceptualizing risk processes, it is necessary to consider the various ways in which persons interact with their environments.

Perhaps this applies especially to the possible influence of deviant peer groups. Fergusson & Horwood (1996, 2000a) showed that these did make an impact that was still evident after appropriate statistical control for other personal and experiential factors. Urberg *et al.* (1997) and Brook *et al.* (1999) found the same. However, few studies have used designs that could truly test the causal role of peer group influences (Rutter *et al.* 1998). Those that have done so have shown that the transitions into smoking and into alcohol use are significantly affected by the peer group's use of those substances.

Depression, antisocial behaviour and substance use/abuse

Although substance use/abuse can be associated with diverse forms of psychopathology (including schizophrenia), the most frequent comorbidity patterns involve either depression or antisocial behaviour or both. The key question is which leads to which? Does the co-occurrence reflect a shared liability, deriving from either genetic or environmental risks? Do conduct problems predispose to drug-taking—perhaps because they reflect risk-taking and novelty-seeking behaviour—or does drug-taking lead people into delinquent activities? Similarly, does depression cause a propensity to drug-taking—perhaps as a form

of self-medication to reduce the pain of negative emotions—or does the taking of drugs with effects on the brain lead to depression?

These questions have been tackled using several different research strategies. Thus, cross-sectional data from the epidemiological catchment area (ECA) were used by Robins & McEvoy (1990) to derive pathways over time. They found that conduct disturbance in childhood was a powerful predictor of drug use/abuse in adolescence and adult life, the effect being found to follow a dose-response relationship; the effects were *not* dependent on the conduct problems being above a clinical threshold. Longitudinal methods provide a stronger test of predictive power because they can deal with the possible role of comorbidity in childhood. Harrington *et al.* (1990), in a long-term follow-up into adult life of a clinical sample, found that depression in childhood/adolescence caused a substantial increase in the risk for recurrence of depression in adult life but no increase in other forms of psychopathology (including drug abuse) in adult life compared with the risks associated with non-depressive psychiatric disorders in childhood. The rates of any form of substance abuse were 15% in the depressed group and 21% in the non-depressed psychopathology comparison group. Fombonne *et al.* (2001, a,b), in a comparable long-term 20-year follow-up of another clinic sample from the same hospital, focused more explicitly on the effects of early comorbidity. They contrasted the adult outcome for 96 children/adolescents with non-comorbid major depressive disorders and 53 whose major depression was accompanied by a conduct disorder. There was a dramatic difference between these two groups in the rate of substance abuse disorders (excluding alcoholism): 1% in the 'pure' depression group vs. 28% in the comorbid group. The between-group difference for alcoholism followed the same pattern but the difference was much less: 28% vs. 40%. The implication is that the main risks for substance abuse come from conduct problems rather than depression. The apparent risk from depression stemmed from a prior comorbidity with conduct problems.

Weissman *et al.* (1999a), somewhat similarly, undertook a 10–15-year follow-up of 73 adolescents with a major depressive disorder who attended a US clinical centre and 37 volunteers without psychiatric disorders in adolescence. The two groups differed little with respect to alcohol dependence (27 vs. 22%) or drug abuse (12 vs. 11%) or drug dependence (18 vs. 8%, a non-significant difference). A comparable follow-up study of 83 prepubertal children with major depression contrasted their outcome with that of prepubertal children with an anxiety disorder and a randomly selected sample of 91 controls living in the same neighbourhood (Weissman *et al.* 1999b). Both the clinical groups had a raised rate of substance abuse/dependence in adult life (45 and 39%, respectively, vs. 18%). The number of depressed children with comorbid conduct disorder was small ($n=13$) but they did not account for the increased rate of drug problems.

Yet another strategy has been to use longitudinal data to examine the temporal sequence of patterns of comorbidity. Brook *et al.* (1995a,b, 1996, 1998, 1999) have pioneered this

approach using a longitudinal study of a general population sample followed from age 5–10 years to adolescence and then on to early adult life. They found that both childhood aggression (incorporating anger and impulsivity) and intrapsychic distress predicted adolescent illicit drug use. However, overt depression in adolescence did not predict either the initiation or continuation of drug usage in the early twenties. A multivariate analysis of marijuana initiation showed that although unconventionality (rebelliousness, deviance and sensation-seeking) was significantly predictive after taking account of other variables, emotional distress was not predictive.

Rao *et al.* (2000) examined the temporal association between depressive disorder and substance use disorder in a longitudinal study of 155 young women (aged 17–19 years). Depression had no significant risk effect on substance abuse but the effect of substance abuse in increasing the risk for further depression was substantial (an odds ratio of 2.95) and long-lasting. The findings are informative in indicating how the impression that depression predisposes to substance abuse comes about. Women with substance abuse had a rate of major depression that was nearly threefold that in women without substance abuse. This resulted in just over half of women with substance abuse (53%) having a comorbid major depressive disorder. Nevertheless, whereas substance abuse predicted the development of a major depressive disorder during the subsequent 5 years, the reverse did not occur.

Silberg, Rutter, D'Onofrio & Eaves (submitted) in a longitudinal study of a general population twin sample found that the predictive correlation over time (a cross-lagged correlation) from early conduct symptoms to later drug usage was greater than the reverse, but that the opposite was the case for depressive symptoms. That is, although early drug usage predicted later depressive symptomatology, early depression had little effect on later drug usage. However, the genetic analyses also showed that an important reason for both types of comorbidity was a shared genetic liability rather than the effect of one type of psychopathology in increasing the risk for the other.

Other investigators have tackled the issue through a focus on the extent to which comorbidity occurs as a result of shared risk factors, but again using longitudinal data (Newcomb & Bentler 1990; Henry *et al.* 1993; Fergusson *et al.* 1996a,b, 2000; Lynskey *et al.* 1998; Fergusson & Woodward 2000). The findings have been consistent in showing the importance of shared risk with respect to both the associations among the usages of different substances and the associations among depression, conduct problems and substance use and abuse. Newcomb & Bentler's (1990) findings, however, suggested that there might be some direct effects that varied across the course of development. Thus, whereas early drug usage reduced negative emotions, later drug usage increased the risk of depressive mood. Henry *et al.* (1993), using data from the Dunedin Longitudinal Study, found that neither depression nor conduct problems at 11 years predicted alcohol use at 15 years; depression at 11 years predicted multiple substance use at 15 years in males but not in females.

Much the strongest association, however, was found between contemporaneous conduct problems and multiple drug use in both sexes at age 15. Both conduct problems and depression at 15 years were associated with self-medication at the same age. However, the lack of association between depression and drug usage in females suggests that the influences on self-medication may not be the same as those on recreational drug usage. Fergusson & Horwood (2000b) found that there was evidence that alcohol abuse predisposed to crime, even after account was taken of the shared liability.

Achenbach *et al.* (1998) examined the predictive power of Child Behaviour Checklist (CBCL) scores in adolescence on alcohol and drug use at age 19–22 years in a general population sample. Delinquent subscale scores proved to be predictive in both sexes after taking account of other variables whereas 'anxious/depressive' scores were not predictive. Fergusson *et al.* (2000), in their New Zealand study, found that conduct problems at age 8 years predicted substance use at 16 years in both males and females.

Putting the findings together, it may be concluded that the predictive associations from early conduct problems to later substance use/abuse are substantially stronger than those from early depression. In childhood, it may well be that dysphoric mood predisposes to drug-taking in some individuals, but during adolescence and adult life the effects of substance usage in leading to depression are greater. However, the strongest influence on comorbidity is a shared liability that derives from both genetic and environmental influences. In considering the clinical implications of these findings, the following features warrant emphasis.

- 1** Conduct problems in middle childhood are common and have an early onset; therefore they could account for a substantial portion of the risk for substance use/abuse in adolescence and adult life.
- 2** Depressive disorders in childhood are uncommon, with a peak onset only in late adolescence; therefore it is unlikely that they could account for much of the risk for substance use/abuse.
- 3** The main role of dysphoric affect seems to be in childhood/early adolescence. Accordingly, although not tested systematically, presumably the main effects are on initial experimentation and self-medication, rather than on the later stages of the causal pathway concerned with abuse and dependence.
- 4** Substance abuse in adolescence has an important effect in increasing the risk for major depressive disorders in early adult life.
- 5** Much of the association between both conduct problems and depression, and later substance use/abuse, reflects a shared liability rather than a causal effect of one form of psychopathology on the other.
- 6** Although there is a very strong contemporaneous comorbidity between substance abuse and depression, this does not necessarily mean that one causes the other.

Drugs, alcohol and crime

Numerous studies have shown associations between drug/

alcohol use/abuse and crime (Rutter *et al.* 1998). To a substantial extent, that is bound to be because they share the same set of risk factors (Robins & Wish 1977; Jessor *et al.* 1991; Catalano & Hawkins 1997). On the other hand, that is unlikely to be the complete story if only because there is such a marked variation among crimes in the likelihood that they would be committed under the influence of alcohol (Kerner *et al.* 1997)—being lowest for fraud (2%) and simple theft (5%) and greatest for violent crimes (32%). You need to have a clear head to commit fraud successfully and it is a good idea not to be drunk as a cat burglar! The association with violence probably arises in large part because of disinhibition; experimental studies have shown that intoxication leads to aggression in the presence of frustration (Ito *et al.* 1996). However, the issue is not mainly one of the role of intoxication (by alcohol or other substances) in predisposing to a criminal act, but rather whether substance use/abuse makes crime more likely through non-situational mechanisms and, conversely, whether antisocial behaviour predisposes to the use or abuse of alcohol or illicit drugs. Longitudinal studies have been reasonably consistent in showing predictive dose–response relationships in both directions (Robins & McEvoy 1990; Hawkins *et al.* 1992; Brook *et al.* 1996; Dobkin *et al.* 1997). Fergusson & Horwood (2000b), using the Christchurch Longitudinal Study data, showed that alcohol abuse in late adolescence increased the involvement in crime (especially violent crime) and that this effect held up after control for both observed and non-observed risk factors. Brook *et al.* (1996) suggested that non-alcohol drug use predisposed to crime by reducing inhibitions, creating a need for money to purchase drugs, causing difficulty in family relationships, interfering with the development of social coping skills and establishing a peer group that supports both further drug use and antisocial activities.

'Gateway' effects

It is clear from numerous studies that young people tend to start with using just one substance and then progress to polysubstance usage, this progression being accompanied by increasing associated psychosocial problems and becoming dependent on drugs. This observation has led to various stage theories (Kandel & Faust 1975; Ellickson *et al.* 1992; Stenbacka *et al.* 1993), most of which make the assumption that the usage of one substance (the main focus has been on cannabis as a substance that is used particularly widely) has a causal effect in making it more likely that the person will go on to take other illicit, and potentially more harmful, drugs. This could come about through several rather different mechanisms. For example, the discovery that the use of cannabis may be pleasurable and seemingly without major perceived harmful effects might lead users to experiment with other drugs to see if they had similar properties (Fergusson *et al.* 1993). Alternatively, it could be that the use of cannabis brings young people into increased contact with substance-using peers and drug sellers, so that both enhanced access and a fostering social context predispose to further substance usage (Kandel 1985; Newcomb & Bentler 1989). However, the

apparent gateway effect could simply reflect a general liability and process of transition from non-deviant to deviant behaviours (Osgood *et al.* 1998). According to this concept, the many young people who use cannabis but do not progress to polysubstance usage and dependence simply have a lesser liability than those who do progress.

In order to test this last possibility, several investigators have used multivariate analyses of longitudinal data to determine if cannabis use predisposes to other illicit drug use, once adequate account has been taken of other risk factors (Yamaguchi & Kandel 1984; Fergusson & Horwood 2000a). The Christchurch study well illustrates the pattern of findings (Fergusson & Horwood 2000a). Virtually all (99%) users of other illicit drugs had used cannabis first, but nearly two-thirds of cannabis users did not progress to other drugs. There was a very strong dose–response relationship between extent of cannabis usage and progression, with the likelihood of progression being over 140 times as high in young people who used cannabis on at least 50 occasions in the year compared to non-users of cannabis; the risk was 12 times higher in those using cannabis 3–11 times, and 41 times in those using cannabis on 12–49 occasions. To an important extent, this progression was a consequence of an accumulation of personal and experiential risk factors but, even after account of those had been taken, the risk for very heavy users of cannabis was still 59 times higher than for non-users (with the same linear dose–response relationship). It is possible that this risk was a function of unmeasured genetic liability, which could not be assessed in the study, but the findings supported the view that cannabis could act as a gateway drug that encouraged other forms of illicit drug use.

Implications for prevention and treatment

The first implication of causal pathways considerations is that prevention policies should begin with steps to constrain access to substances that carry major risks of abuse or dependence. That presupposes agreement on which substances carry such risks. Controversy mainly focuses on cannabis. Certainly, it is no more dangerous than alcohol, but whether it is desirable to add another drug to those legally available, given that some risks are involved (Ashton 2001; Hall & Solowij 1998; Johns 2001; see also Weinberg *et al.*, Chapter 27) and that it seems to serve a gateway function to other more harmful drugs (see above) is the question. Proponents of legalization argue that it is the very fact that cannabis is illicit that makes it have a gateway function. It is to be hoped that if it is decriminalized, the effects of the legal change will be monitored systematically, so that we may learn from the experience. With respect to alcohol, it is evident that, although taxation, laws on the drinking age and the introduction of breathalysers and blood alcohol laws (to reduce drunken driving) can all have effects, their benefits are crucially dependent on people's acceptance of the constraints. Nevertheless, attitudes can be changed by imposing rules, as

evident by antismoking legislation. However, there are powerful commercial misinformation campaigns, as instanced by the actions of tobacco companies (Glantz *et al.* 1996; Ong & Glantz 2000).

A rather different prevention approach is to focus on the secondary effects of drug abuse in predisposing to crime. The controlled prescribing of methadone for heroin addicts was introduced as an attempt to avoid criminalizing the problem. It has had some success in that connection (Farrell & Taylor 1994; Ward *et al.* 1998) although concerns have been expressed regarding its appropriateness in adolescence (O'Brien 1996). In terms of predisposing factors in childhood, it is evident that the main focus needs to be on the prevention and alleviation of disruptive behaviour and conduct problems, as these constitute the strongest risk factor for substance use/abuse. What can be achieved is discussed by Offord & Bennett (Chapter 52) and by Earls & Mezzacappa (Chapter 26). In addition there have been various school-based programmes specifically targeted at drug abuse prevention (Gilvarry 2000). Some successes have been reported (Botvin *et al.* 1995a,b) but there are few systematic evaluations and firm conclusions on the approaches that are effective are not possible (White & Pitts 1998), except that experiential programmes seem more effective than educationally didactic ones (Tobler & Stratton 1997).

Adequate evaluations of the efficacy of individual targeted interventions are similarly few. Family therapies seem promising (Stanton & Shadish 1997) and comprehensive approaches, such as multisystemic therapy (Henggeler *et al.* 1998) that combine family and community methods, are particularly so. Those who are most in need of treatment are often the hardest to engage and retain; this is perhaps especially the case with street youths (Smart & Ogborne 1994; Kipke *et al.* 1997).

In some respects, decisions on how to deal with the very frequent comorbidity with both antisocial behaviour and depressive disorders are some of the most difficult. That is especially the case in view of the evidence that some of these are secondary to the substance abuse, rather than the other way round. Nevertheless, in most cases causal effects are likely to be bidirectional and good clinical care requires attention to the whole pattern of psychopathology.

A final point is that the high frequency of substance use and abuse means that, if referred, most children and adolescents with these problems will be seen in general clinics rather than specialized services for children with substance use disorders. The implication is that routine diagnostic assessment should include enquiry about substance usage and general child and adolescent psychiatrists should be aware of the issues concerned with the diagnosis and treatment of drug problems.

There have been important gains in the development of prevention and intervention programmes over the last decade (Weinberg *et al.* 1998; Gilvarry 2000) but much remains to be done. Most of all, there is a need for a better integration of the findings from epidemiological/longitudinal studies tackling causal questions, experimental investigations of basic mechanisms, and prevention/intervention initiatives leading on to

randomized controlled trials designed to determine, not just whether something 'works', but also what are the crucial mediating mechanisms of success, and why the intervention works with this individual but not with that one (Rutter 1982; Rutter *et al.*, 2001).

Depressive disorders

History

The concept of a depressive syndrome that is distinct from the broad class of childhood onset emotional disorders has a relatively short history. Until the 1970s it was believed that depressive disorders resembling adult depression were uncommon among the young. Pre-adolescent children were thought incapable of experiencing depression. Depression in adolescents was often seen as a normal feature of development, so-called 'adolescent turmoil'. However, in the 1970s and early 1980s several investigators began to diagnose depression in children using adult criteria (Weinberg *et al.* 1973; Pearce 1978; Puig-Antich 1982). These studies showed that conditions resembling adult depression could occur in even young children. As a result, the features of depressive disorder were deemed the same for children, adolescents and adults (American Psychiatric Association 1980).

The next 15 years saw intensive research into the adult-like depressive conditions that were being diagnosed with increasing frequency among the young. These investigations have led to a reappraisal of the concept of childhood depression. It is apparent that a variety of different problems have been subsumed within the concept. Moreover, there seem to be important differences between child and adolescent depressions. In comparison with adolescent depression, pre-adolescent depression is less likely to lead to adult depression (Harrington *et al.* 1990; Weissman *et al.* 1999a,b), has more overlap with other disorders (Alpert *et al.* 1999), is less prevalent (Angold *et al.* 1998), shows a male preponderance (Angold *et al.* 1998), and is more strongly associated with family dysfunction (Harrington *et al.* 1997). Pre-adolescent depression may therefore be a different diagnostic entity (Harrington 2000). This chapter is concerned mainly with depressive disorders in adolescents but, when relevant, also deals with depressive problems that arise in younger age groups.

Concepts of depression

Depression can be conceptualized both as a dimension and as a category. Epidemiological studies suggest that juvenile depression is a continuum that is associated with problems at most levels of severity (Pickles *et al.*, in press). Indeed, it seems that there is no 'good' level of depression; it is better for an adolescent

to have no symptoms of depression at all than to be averagely depressed (Harrington & Clark 1998). Thus, in the Oregon Adolescent Depression Project the level of psychosocial impairment increased as a direct function of the number of depressive symptoms (Lewinsohn *et al.* 1998). Moreover, in line with studies of adults (Angst *et al.* 1997), much of the morbidity associated with depression occurred in the 'milder' but more numerous cases of minor depression. Even mild forms of adolescent depression are a risk factor for depression in early adulthood (Pine *et al.* 1999). The implication is that from the public health perspective of lowering the total burden of morbidity associated with depression, it might be better to regard depression as a continuum.

In clinical practice, however, depression is viewed not only as a dimension but also as a category. This is partly because many clinical decisions are dichotomous. For example, if a patient has a depressive disorder then a course of treatment is initiated; if not then the patient is reassured that all is well. Clinicians do not generally prescribe a little bit of antidepressant for a little bit of depression. To clinicians, then, depression usually means a diagnosis: something that a patient either does or does not have.

Nowadays most clinicians use one of the major schemes for diagnosis: ICD-10 (World Health Organization 1992) or DSM-IV (American Psychiatric Association 1994). The schemes differ in many ways, but at the core of both is the concept of an episodic disorder of varying degrees of severity that is characterized by depressed mood or loss of enjoyment that persists for several weeks. The individual must also experience other symptoms during the episode. These include *depressive thinking*, such as pessimism about the future or suicidal ideas, and *biological symptoms*, such as early waking, reduced appetite and weight loss. DSM-IV states that in children irritable mood may substitute for depressed mood, and that dysthymia (see below) need only last for 1 year (2 years in adults). It also notes that certain symptoms, such as somatic complaints and social withdrawal, are particularly common in children, while other symptoms, such as delusions, are rare. ICD-10 does not mention age differences.

Subcategories of depressive disorder

Subcategorizing depressive disorder by severity is widely accepted. Both DSM-IV and ICD-10 distinguish between mild, moderate and severe episodes of depression but differ in their definitions of severity. In ICD-10, severity is defined by symp-

toms, whereas in DSM-IV severity is defined in terms of symptoms and functional impairment. We shall see later that in clinical practice impairment is a useful guide both to choice of treatment and to prognosis. For example, adolescents with severe depression, defined as complete disability in one or more domains of social functioning (e.g. unable to go to school, does not see friends at all), are much less likely to respond to psychological treatment than those with mild or moderate depression (Jayson *et al.* 1998). Nevertheless, it can be difficult to link impairment to specific symptoms, and there are many cases whose impairment seems out of proportion to their symptoms (Angold *et al.* 1999c).

Both ICD-10 and DSM-IV distinguish between psychotic and non-psychotic episodes of depression. Psychotic depression is very uncommon before mid-adolescence, but the concept is useful in adults to the extent that it predicts a worse prognosis (Lee & Murray 1988). Psychotic symptoms also presage worse outcomes in adolescent depression (Strober *et al.* 1993).

Other subtypes are less well established. DSM-IV and ICD-10 have a category for chronic mild depression lasting 1 or more years—dysthymia. However, longitudinal studies have shown that in children there is much overlap of major depression and dysthymia (Kovacs *et al.* 1994) and it is likely that they are often part and parcel of the same problem.

Differential diagnosis

A problem with categorical approaches to diagnosis lies in differentiation from ‘normality’. As described earlier, there is no obvious point of inflection in the dimension of depressive symptoms. It is therefore not surprising to find that diagnostic systems that are based on numbers of symptoms only (such as DSM-III-R; American Psychiatric Association 1987) give implausibly high rates of so-called depressive disorder. Depressive disorder should therefore only be diagnosed when there is impairment of social role functioning, when symptoms of unequivocal psychopathological significance are present (such as severe suicidality), or when symptoms lead to significant suffering.

A further problem arises from the fact that all epidemiological studies conducted up to now have found that depressive disorder very commonly occurs in conjunction with other psychiatric problems (see below). Indeed, one of the best discriminators in community studies between children with any form of psychiatric disorder and children with no psychiatric disorder is the symptom of depression (Rutter *et al.* 1970). Moreover, some of the symptoms that are part of the depressive constellation may arise as a symptom of other disorders. Thus, restlessness is seen in agitated depression, hypomania and hyperkinetic syndrome. As a general rule, the double diagnosis should be made only when symptoms that are not simply part of another disorder clearly indicate the separate presence of a depressive disorder.

Depression can sometimes be the result of physical disorders. For example, Lewinsohn *et al.* (1998) found that adolescents who reported that they had had a physical illness causing functional impairment (e.g. glandular fever) were at increased risk of

subsequent depression. The diagnostic assessment should therefore establish whether a physical disorder may have caused the depression.

Rating scales and interviews

Many questionnaire measures are available to assess depression in children and adolescents (Costello & Angold 1988; Harrington & Shariff 1992). These can be divided into:

- 1 scales that were specifically designed for studies of juvenile depression, such as the Mood and Feelings Questionnaire (Angold *et al.* 1995a) and the Children’s Depression Inventory (Kovacs 1981);
- 2 scales that were originally devised for studies of depressed adults, but which have often been used in studies of adolescents, such as the Beck Depression Inventory (Beck 1967); and
- 3 general scales for assessing psychopathology in children that contain some depressive items, such as the Strengths and Difficulties Questionnaire (Goodman 1997).

The choice of scale depends on the purpose to which it will be put. As a general rule, depression specific scales tend to be better measures of change in depression than general scales. However, they are often lengthy and do not provide information about comorbid symptoms, such as anxiety or behavioural problems. Questionnaire measures are also used to screen for depressive disorder in community or high-risk samples (Roberts *et al.* 1991). It should be borne in mind, however, that at the cut-points that are often used on depression screening questionnaires, specificity and sensitivity seldom exceed 80%. This means that with a low prevalence problem, such as major depression in adolescence, it is a mathematical certainty that most cases with a ‘high’ score on a questionnaire will not have depressive disorder. Child mental health professionals are often unaware of this problem, assuming that a high score on a screening questionnaire means that the young person is very likely to have a depressive disorder (Clark & Harrington 1999).

Although pencil-and-paper questionnaires will often generate important information for the clinical assessment, an interview with the young person supplemented by an interview with the primary caregiver is usually considered the ‘gold standard’ for the diagnosis of depressive disorder. This is because careful interviewing is the only way of ensuring that the respondent is describing what the investigator is interested in. A number of standardized interviews of known reliability, such as the Child and Adolescent Psychiatric Assessment (Angold & Costello 1995; Angold *et al.* 1995b) have been developed (Hodges 1993). These are now widely used in research settings but they have some limitations: reliability is low in younger age groups; interviews can last for several hours; there is often a marked discrepancy between different sources of information; and outside of academic centres it can be difficult to obtain training.

The low reliability of the standardized interview as a means of measuring psychopathology in children aged less than 10 years has led to the development of several alternative methods of assessment in this age group (see Angold, Chapter 3). These

methods include a structured pictorial questionnaire based on the DSM (Valla *et al.* 1994) and puppet interviews. Early results from the use of puppet interviews with 4–8-year-old-children have been encouraging (Ablow *et al.* 1999).

Comorbidity

Most children and adolescents who are referred for treatment of depressive disorder meet the criteria for at least one other psychiatric diagnosis. Even in community samples, there is much overlap of depression and other forms of psychopathology. In a systematic review of around 20 epidemiological studies based on DSM, Angold *et al.* (1999a) found that the most common comorbid disorders were conduct disorder (occurring, on average, in 40% of depressed cases) and anxiety disorders (34%).

ICD-10 and DSM-IV take different approaches to comorbidity (see Taylor & Rutter, Chapter 1). In ICD-10 it is assumed that a mixed clinical picture is more likely to be the result of a single disorder with different manifestations than of two or more disorders that happen to occur in the same individual at the same time. ICD-10 therefore has a category for mixed disorders, Mixed Disorders of Conduct and Emotions (F92), which includes the subcategory Depressive Conduct Disorder (F92.0). DSM-IV, by contrast, usually allows the investigator to diagnose several supposedly separate disorders, with the result that in surveys based on DSM it is quite common to find individuals with three or more diagnoses (Caron & Rutter 1991).

Conduct disorders

There are several explanations for comorbidity of depression and conduct disorder. Comorbidity might be an artefact of methodology, measurement or current diagnostic systems. However, most reviewers have concluded that this is unlikely to be the case (Caron & Rutter 1991; Angold *et al.* 1999a). Another possibility is that depression is simply an integral part of conduct disorder. Zoccolillo (1992) suggested that conduct disorder is a problem of multiple dysfunction, with depression a dysfunction of affect regulation and conduct disorder a dysfunction of social regulation. Alternatively, it may be that conduct disorder causes depression. Children with conduct disorder sometimes behave in ways that increase their risk of the kinds of adverse events that cause depression, such as inconsistent parenting (O'Connor *et al.* 1998a). However, in an elegant analysis of longitudinal data from the Christchurch Health and Development Study, Fergusson *et al.* (1996) reported that direct causal pathways between depression and conduct disorder were weak. Much of the correlation between the two could be explained by shared risk factors, such as family dysfunction. Similarly, O'Connor *et al.* (1998b) found that nearly 50% of the association between depression and conduct disorder could be explained by a common genetic liability.

Comorbidity between depression and conduct disorder has implications for assessment and management. It is easy to miss depression when the clinical picture is dominated by problems

such as aggression. Comorbidity may also influence prognosis. The adult adjustment of children with depression and conduct disorder is as poor as that of children with conduct disorder alone (Harrington *et al.* 1991) and there may be an increased risk of suicide (Fombonne *et al.*, 2001b).

Anxiety disorders

Longitudinal and epidemiological studies suggest that anxiety tends to precede depression in both children (Kovacs *et al.* 1989) and adults (Merikangas *et al.* 1996), raising the possibility that depression is in some sense secondary to anxiety. It may be that they share a common temperamental basis, such as emotionality. Genetic studies suggest the possibility of a common genetic diathesis (Eley & Stevenson 1999).

Epidemiology

Prevalence

Rates of depressive disorder vary between studies. This is partly because of differences in definition and measurement (Roberts *et al.* 1998), and partly because of differences in the time period over which the rate of depression is calculated. For example, some studies report 3-month prevalence (Simonoff *et al.* 1997), others 6-month prevalence (Breton *et al.* 1999) and yet others cumulative incidence (Oldehinkel *et al.* 1999).

A review of early studies found prevalences among adolescents ranging from <1% to 6% (Fleming *et al.* 1989). Recent studies have produced similar findings, with a 1-year (or less) prevalence of major depressive disorder associated with impairment ranging from around 1% (Simonoff *et al.* 1997), through 3% (Cohen *et al.* 1993a; Lewinsohn *et al.* 1998) to 6% (Olsson & von Knorring 1999). When all kinds of depressive disorder are included, then the prevalence can be as high as 10% (Angold *et al.* 1998). The cumulative probability of having a depressive disorder by late adolescence seems to be between 10 and 20% (Lewinsohn *et al.* 1998; Oldehinkel *et al.* 1999; Olsson & von Knorring 1999). Depressive disorder is not, then, an uncommon problem in adolescence.

Developmental trends and gender differences

Almost all recent epidemiological research has found that depressive disorder is much less common among pre-adolescent children than among adolescents (Simonoff *et al.* 1997; Angold *et al.* 1998; Lewinsohn *et al.* 1998; Oldehinkel *et al.* 1999; Olsson & von Knorring 1999; Meltzer *et al.* 2000). For instance, in a large national survey in the UK the odds of having a depressive disorder for 11–15-year-olds compared to 5–10-year-olds was 8.5 (Meltzer *et al.* 2000). The origins of these reliable developmental differences are not well understood, but there are several pointers about possible causes. Age trends in depression are stronger in girls than in boys. Most studies have found that in prepubertal children there is either no gender

difference in the prevalence of depression or there is a small male preponderance. In contrast, by late adolescence the female preponderance found in adult depression is well established. However, there is some uncertainty about when the gender difference emerges. The New York and Greater Smoky Mountain studies (Cohen *et al.* 1993a; Angold *et al.* 1998) found that the difference was present by around the age of 13 years, but another study has reported that it emerges later (Hankin *et al.* 1998).

The finding that the gender difference seems to be linked more to some aspect of puberty itself than age (Angold *et al.* 1998) raises important questions about the mechanisms involved. It is possible that there is some direct vulnerability arising from changes in hormone levels, such as androgens (Angold *et al.* 1999b). However, puberty is accompanied by many other changes, such as in cognition and in stressful events. Moreover, even in large samples it can be very difficult to tease apart the effects of age and puberty. Probably there are several reasons for the greater vulnerability of girls. Before adolescence, girls are more likely than boys to have risk factors for depression, such as certain personality features (Nolen-Hoeksema & Girgus 1994; see below). However, these risk factors are not sufficient to cause depression until the person experiences the biological and social challenges of adolescence (Nolen-Hoeksema & Girgus 1994; Cyranowski *et al.* 2000).

Time trends

The prevalence of depressive disorders may be increasing among young people. Evidence of a secular trend comes mainly from retrospective reports of age at onset of depression in family and community studies of depressed adults. These studies have found that people in more recent birth cohorts report higher rates and an earlier onset of depressive disorder than those born earlier in the last century (Fombonne 1999). The results of these studies may have been biased by memory artefacts (Giuffra & Risch 1994). However, repeated cross-sectional surveys have also found an increase in levels of depression. It is likely, then, that there has been a real, though probably small, increase in depression.

Changes in the biological, familial and social context of adolescence provide clues about possible candidate mechanisms that could explain these time trends (Fombonne 1995). Adolescents enter puberty much earlier nowadays than they did 100 years ago. They may also be exposed to higher levels of family conflict. It is likely that combinations of these risk factors are particularly important. For example, earlier puberty probably means that adolescents experience the stresses of making and breaking intimate relationships at an earlier age.

Course

Short-term

Studies of clinical samples have reported that young people with a depressive disorder have a high risk of recurrence or persis-

tence (Emslie *et al.* 1997b; Goodyer *et al.* 1997a). Kovacs *et al.* (1984a) undertook a follow-up of child patients with a major depressive disorder, a dysthymic disorder, an adjustment disorder with depressed mood, and some other psychiatric disorder. The development of subsequent episodes of depression was virtually confined to children with major depressive disorders and dysthymic disorders. Surveys of community samples have generally also found that depressive disorders among young people tend to be recurrent (Fleming *et al.* 1993; Lewinsohn *et al.* 1993, 1994a; Garrison *et al.* 1997). Lewinsohn *et al.* (1993, 1994a) found that the 1-year relapse rate for unipolar depression (18.4%) was much higher than the relapse rate found in most other disorders.

Long-term

Adolescent depressive disorder shows significant continuity into adult life. Harrington *et al.* (1990) followed up 63 depressed children and adolescents on average 18 years after their initial contact. The depressed group had a substantially greater risk of depression after the age of 17 years than a control group who had been matched on a large number of variables. Other groups, too, have found high rates of recurrence of major depression in clinical samples of depressed adolescents who have been followed up into adulthood (Rao *et al.* 1995; Weissman *et al.* 1999a; Fombonne *et al.* 2001a).

Continuity from childhood into adult life has also been found in community surveys, such as the Dunedin Multidisciplinary Health and Development Study (DMHDS). Follow-back longitudinal analyses found that subjects with a mood disorder at age 21 years were much more likely to have a history of previous mood disorder than of non-depressive disorders earlier in life (Newman *et al.* 1996). Similarly, prospective longitudinal analyses from the Oregon Adolescent Depression Project (Lewinsohn *et al.* 1999) found significant continuity from late adolescence (age 17 years) into early adult life (age 24 years). About 45% of depressed adolescents developed a new episode of depression between the ages of 19 and 24. In the New York study (Cohen *et al.* 1993a,b), anxiety or depression in adolescence predicted anxiety or depression in early adult life (Pine *et al.* 1998). The British birth cohort follow-up of individuals born in 1946 found that evidence of affective disturbance at ages 13 and 15 years was a strong predictor of major affective disorder in middle life (Os *et al.* 1997).

Other outcomes

Early studies reported that depression can lead to subsequent problems in social adjustment, such as marital problems (Puig-Antich *et al.* 1985a,b; Kandel & Davies 1986; Garber *et al.* 1988). However, none of these studies excluded the effects that childhood conduct problems, which we saw earlier are commonly associated with adolescent depression, could have on these outcomes. Harrington *et al.* (1991) found that juvenile depression seemed to have little direct impact on social func-

tioning in adulthood once the association with conduct problems was controlled. Similar findings were reported by Renouf *et al.* (1997) who found that social dysfunction associated with comorbid depression and conduct disorder seemed to be mainly related to the effects of conduct disorder. The implication is that it is important to differentiate the course of depressive disorder from the course of other comorbid disorders.

Depressed young people very commonly have suicidal thoughts and some of them make suicidal attempts (Andrews & Lewinsohn 1992). Lewinsohn *et al.* (1994c) reported that depression was one of the strongest predictors of a subsequent suicidal attempt, even when the association with other risk factors was controlled. Conversely, it seems that suicidal children are at increased risk of depression. For example, Pfeffer *et al.* (1991) found that young people who had attempted suicide were 10 times more likely to have a mood disorder during the 6–8-year follow-up period than young people who had not made an attempt.

Three studies have reported increased rates of completed suicide in adolescent patients followed up into adulthood, with a cumulative risk of around 2–4% (Harrington *et al.* 1990; Rao *et al.* 1993; Weissman *et al.* 1999a; Fombonne *et al.* 2001b). This is around six times higher than in the general population of this age. Several psychological autopsy studies of suicide in young people have found high rates of affective disorders (Brent *et al.* 1988; Marttunen *et al.* 1991; Shaffer *et al.* 1996; Groholt *et al.* 1998; see also Shaffer & Gutstein, Chapter 33). The association between suicide and depression seems to be particularly strong in females (Marttunen *et al.* 1995). It is, however, important to note that other problems are also relevant in suicide. Marttunen *et al.* (1991) found that nearly one-fifth of suicides aged between 13 and 19 years had a conduct disorder, and that one-quarter abused alcohol or drugs.

Recovery

Although follow-up studies suggest that depressive disorders tend to recur, it should be borne in mind that the prospects of recovery from the episode are high. Indeed, the available data suggest that the majority of young people with major depression will recover within 2 years. Kovacs *et al.* (1984b) reported that the cumulative probability of recovery from major depression by 1 year after onset was 74% and by 2 years was 92%. The median time to recovery was about 28 weeks. This study included many subjects who had previous mental problems and some form of treatment. However, very similar results were reported by Keller *et al.* (1988) in a retrospective study of recovery from first episode of major depression in young people who had mostly not received treatment, and by Warner *et al.* (1992) in a study of the children of depressed parents. In a community survey, Garrison *et al.* (1997) found that only one-fifth of those with major depression at baseline continued to have it at 1 year. Recovery can be quite rapid. Harrington *et al.* (1998b) found that most cases of major depression following deliberate self-poisoning remitted within 6 weeks.

Patterns of relapse and remission

In summary, adolescent depression is a relapsing and remitting condition. Most adolescents will recover from major depression within a year, but a significant proportion will relapse. Persistence of depression is more likely if symptoms are severe (Pickles *et al.*, 2001) or if the young person experiences persisting adversity (Goodyer *et al.* 1997b), such as family problems (Birmaher *et al.* 2000). Depressed adolescents are at risk of a variety of other problems later in life, including poor social functioning and suicide. However, their risk of these outcomes stems at least in part from the conditions that are often associated with depression, such as behavioural problems and drug abuse.

Aetiology

The aetiology of depressive disorders among young people is not understood completely, but the available evidence suggests that the cause is a combination of: (i) predisposing constitutional factors arising from genetic endowment or earlier experience; and (ii) precipitating stressful events. These aetiological factors act through biochemical and psychological processes to produce the depressive syndrome. Once established, the syndrome is often prolonged by maintaining factors.

Predisposing factors

Genetic factors

The offspring of depressed parents are at increased risk of depression, especially in childhood and early adult life (Wickramaratne & Weissman 1998). Many other forms of psychopathology are increased among these children (Wickramaratne & Weissman 1998) and they are also at increased risk of medical problems (Kramer *et al.* 1998). Prospective longitudinal studies have suggested that these increased risks extend for many years (Hammen 1991; Beardslee *et al.* 1993a; Weissman *et al.* 1997). For example, Weissman *et al.* (1997) evaluated the effects of parental depression on offspring over a 10-year period. High rates of depression, panic disorder and alcoholism were found among the children.

There is evidence that affective disorders in adults have a genetic component. Genetic influences seem strongest for bipolar disorders (McGuffin & Katz 1986), but unipolar major depressions also show significant heritability (Kendler *et al.* 1995). There have thus far been no large systematic twin or adoption studies of depressive disorder in young people. However, family studies find increased rates of depression among relatives of young probands with depressive disorder (Harrington *et al.* 1993). Moreover, twin studies suggest modest genetic influences on depressive symptoms in adolescence (Thapar & McGuffin 1994; Eaves *et al.* 1997), although this has not been replicated in adoption studies (Eley *et al.* 1998). Twin studies also report that some of the stability in depressive symptoms arises from genetic factors (O'Connor *et al.* 1998c). The mode of inheritance is

uncertain, but genetic effects are likely to act through multiple mechanisms, many of which are indirect (Silberg *et al.* 1999). In some cases it seems that genetic factors act by increasing vulnerability to adverse life events (Silberg *et al.* 2001): an example of gene–environment interaction. In others, genes appear to increase the liability to experience depressing life events, such as falling out with friends, an example of active gene–environment correlation (Silberg *et al.* 1999).

Family environment

It is likely that family environment also plays an important part in predisposing to depression, although the relationship is likely to be bidirectional—children with problems may act as a stressor to the parents (Rutter 1997). Hammen *et al.* (1991) found a close temporal relationship between episodes of depression in children and episodes of depression in the mother. Fergusson *et al.* (1995) reported that maternal depression was only associated with depressive symptoms in adolescent offspring in so far as it was associated with social disadvantage or family adversity. Depression in parents is associated with many problems that could lead to depression in offspring, including impaired child management practices, personality problems, poor marital functioning and hostility towards the child (Goodman & Gotlib 1999). It is possible that the early relationship between the mother and the child partly mediates this association (Murray *et al.* 1999).

Temperament and personality

Genetic influences and family environment may also predispose to depression through the effects they have on the child's temperament and personality. Vulnerability to depression may start early in life (Sigurdsson *et al.* 1999); some temperamental features are associated with depression, particularly emotionality (Goodyer *et al.* 1993a). The child's cognitive or behavioural style, such as a tendency to blame oneself rather than other people, may also increase the risk of depression. Some of these behavioural styles are more common in girls from an early age, and may partly explain why girls are more likely to develop depression than boys (Nolen-Hoeksema & Girgus 1994). A longitudinal study in a community sample of adolescents showed that personality features predicted later development of depressive disorder (Daley *et al.* 1999).

Precipitating factors

Depressive disorders in young people often follow stressful life events (Goodyer *et al.* 1993b), such as parental discord, bullying, and physical, sexual or emotional abuse (Boney-McCoy & Finkelhor 1996; Kaplan *et al.* 1998). However, there is great variation in young people's responses to acute adversity. Most young people who experience such events do not develop mental disorder (Goodyer 1990; Silberg *et al.* 2001). Conversely, a significant minority of depressed young people show no obvious

acute precipitant for their episode (Goodyer *et al.* 1993b). Moreover, many stressors are chronic (Rutter, 2000). The adolescent's experiences of adversity over time may therefore be just as important as the precipitants of a single episode (Rueter *et al.* 1999). Indeed, isolated events, such as death of a parent, seem to carry little increased risk of subsequent depression (Harrington & Harrison 1999). Much depends on the context of the event, its meaning for the young person, on what happens before it and, perhaps most importantly, on what happens after it.

Biochemical and psychological processes

Monoamine neurotransmitters

The amine hypothesis proposes that depression arises from hypoactivity in monoamine reward systems. Research has concentrated on two monoamine neurotransmitters: 5-hydroxytryptamine (5-HT) and norepinephrine. The findings have not been very robust, but two lines of evidence support an abnormality of 5-HT in juvenile depression:

- 1 reduced 5-HT transporter protein in platelets from the blood of children and adolescents with major depression (Salee *et al.* 1998); and
- 2 the positive response of some young depressed patients to the serotonin-specific reuptake inhibitor, fluoxetine (Emslie *et al.* 1997a).

It will be appreciated, however, that 5-HT metabolism in the blood may be very different from in the brain. Moreover, other drugs that enhance the functioning of 5-HT pathways, such as the tricyclic antidepressants and sertraline, do not seem to be effective antidepressants in young people (Hazell *et al.* 1995; Mandoki *et al.* 1997). Thus, while it is likely that the amine hypothesis will continue to influence biological research, in this age group it is far from proven.

Endocrine abnormalities

Many investigations have examined the links between juvenile depression and endocrine abnormalities that are not associated with obvious endocrine disease. Possible candidate hormones include melatonin (Shafii *et al.* 1996), thyroid hormone (Kutcher *et al.* 1991; Dorn *et al.* 1996), prolactin (Hardan *et al.* 1999), growth hormone (Ryan *et al.* 1994) and cortisol. Interest has focused on cortisol. Several studies have shown that in comparison with non-depressed patients, depressed young people are less likely to show suppression of cortisol secretion when the exogenous corticosteroid dexamethasone is administered (Casat & Powell 1988). There is also evidence that cortisol levels predict the course of juvenile depression. Goodyer *et al.* (1998) found that higher cortisol levels at night predicted persistence of major depression. Susman *et al.* (1997) reported that adolescents who showed increased cortisol levels in a challenging situation had higher levels of depressive symptoms a year later than adolescents whose cortisol did not change or de-

creased. It could be, then, that cortisol mediates the links between adversity and depression, perhaps through direct effects on some parts of the brain. However, abnormalities of cortisol metabolism are not specific. They are seen in other child psychiatric disorders (Tyrer *et al.* 1991), as well as in stressful situations such as admission to hospital. Their role as an important mechanism in juvenile depression remains to be conclusively demonstrated and the cortisol findings have not as yet had many therapeutic implications.

Cognitive processes

In cognitive theory, depression is not simply triggered by adversity but rather by the perception and processing of adverse events. Research has shown that depressed young people have a variety of cognitive deficits and distortions. They often have low self-esteem and cognitive distortions, such as selectively attending to negative features of an event (McCauley *et al.* 1988; Kendall *et al.* 1990; Hammen 1991). In addition, depressed youngsters are more likely than their non-depressed peers to develop negative attributions. For instance, they tend to attribute the cause of positive events to unstable external causes rather than to their own endeavours (Cole & Turner 1993). Depressed young people also have low perceived academic and social competence (Cole 1990) and this sense of competency predicts subsequent depression (Cole *et al.* 1997).

Although many studies have documented an association between childhood depression and various cognitive distortions, there are many unresolved questions. In particular, it is unclear whether these negative cognitions are a cause or consequence of depression (Harrington *et al.* 1998d). Dalglish *et al.* (1998) reported that performance on information-processing tasks returned to normal when depression remitted. It is also uncertain whether some cognitive processes are more important than others. Nevertheless, research on cognitive processes in depressed children has provided a useful theoretical basis for planning treatment strategies.

Maintaining factors

Direct persistence of disorder

At first sight, the finding that most cases of major depression remit within a few months (see above) would seem to suggest that direct persistence is uncommon. However, a detailed 12-year prospective study of adults who had presented with major depression found that while only 15% had major depressive disorder during the follow-up, 43% had subthreshold depression (Judd *et al.* 1998). The same may apply to depression in young people; major depression and dysthymia often overlap and one can lead to the other (Kovacs *et al.* 1994). The symptomatic course of depression seems to be malleable, and symptoms of major depression, dysthymia and minor depression alternate over time in the same patients. Direct persistence of subthreshold symptoms is probably quite common.

Scarring or sensitization

Another potential mechanism of continuity is that individuals are changed by their first episode in such a way that they become more likely to have subsequent episodes. This notion, sometimes referred to as 'scarring' has attracted much attention from investigators of the neurobiological (Post & Weiss 1998) and psychological (Rohde *et al.* 1990) processes that may be involved in the relapsing and remitting course of depression in adults. Post *et al.* (Post 1992; Post & Weiss 1998) have suggested that the first depressive episode may sensitize people to further episodes. They hypothesized that such sensitization may help to explain three characteristics of depression in adults: the tendency to recur, the decreasing length of interval between episodes and the greater role of psychosocial stress at the first episode. The idea is that the first episode of depression, which can often be linked to a psychosocial stressor, is associated with long-lasting changes in biology and responsivity to stressors. There may be biochemical and microstructural changes in the central nervous system (such as electrophysiological kindling) that puts the individual at risk of further episodes (Post *et al.* 1996).

The idea of scarring may also be relevant to depression in young people. Lewinsohn *et al.* (1994b) found in cross-sectional comparisons that formerly depressed individuals shared many psychosocial characteristics with depressed individuals. A subsequent prospective study by the same research group identified 45 adolescents who experienced and recovered from a first episode of depression between two assessment points (Rohde *et al.* 1994). Psychosocial scars (characteristics evident after but not before the episode) included excessive emotional reliance on others and subsyndromal depressive symptoms.

Persistence of biological or cognitive vulnerability

Scarring should be distinguished from the concept of vulnerability, in which the predisposition to depression both precedes and follows the acute episode. As noted above, there are many personality, temperamental, biological and cognitive features that could act to increase vulnerability to subsequent episodes. However, the available data suggest that some of these features, such as depressive cognitions (see above), return to normal following apparent recovery from depression.

Persisting adversity

Depressive disorders are also maintained by continuing stressors. Asarnow *et al.* (1993) reported that relapse of depression after discharge from a psychiatric inpatient sample was virtually confined to children who returned to a home environment characterized by high expressed emotion and hostility. Goodyer *et al.* (1997b) found that family dysfunction and lack of a confiding relationship with the mother predicted persistent psychiatric disorder in a sample with major depression. Poor peer

relationships are also associated with persistence of depression (Goodyer *et al.* 1997b).

Comorbidity

Several studies have reported that comorbidity with non-depressive disorders predicts a worse outcome for juvenile depressive disorder (Sandford *et al.* 1995; Goodyer *et al.* 1997a; Kovacs *et al.* 1997). Kovacs *et al.* (1997) found that comorbid externalizing disorder predicted a much more protracted recovery from dysthymic disorder. Goodyer *et al.* (1997a) reported that comorbid obsessive-compulsive disorder was associated with persistence of major depression at 36 weeks follow-up.

Multifactorial aetiology

It seems, then, that the onset and persistence of depression are associated with many factors. It is likely that it is the combination of several of these factors that poses the greatest risk. Beardslee *et al.* (1996a) examined risk factors for affective disorder within a random sample of 139 adolescents. Single risk factors, such as parental major depression, parental non-affective diagnosis or a previous child psychiatric diagnosis, increased the risk of subsequent affective disorder from 7 to 18%. However, when all three risk factors were present the risk jumped to 50%.

In some instances, risk factors simply 'add up' to increase the risk of depression; but more often there is some kind of interaction between them. Two common patterns are found. In the first, the one risk factor causes another; Daley *et al.* (1998) found that personality disorder features seemed to generate chronic interpersonal stress, which increased vulnerability to depression. In the second, one risk factor increases vulnerability to another, as when acute life events only lead to depression when the child is made vulnerable by pre-existing relationship problems (Goodyer 1990).

Management of the acute episode

Initial management

The initial management of depressed young people depends greatly on the nature of the problems identified during the assessment procedure. The assessment may indicate that the reaction of the child is appropriate for the situation. In such a case, and if the depression is mild, an early approach can consist of a few sympathetic discussions with the child and the parents, simple measures to reduce stress, and encouraging support. Around one-third of mild or moderately depressed adolescents will remit following this kind of brief non-specific intervention (Harrington *et al.* 1998a).

Cases that persist will require more specific and lengthy forms of treatment. However, the clinician should initially consider a number of issues. The first is whether the depression is severe enough to warrant admission to hospital. Indications for admission of depressed young people include severe suicidality, psy-

chotic symptoms or refusal to eat or drink. A related question is whether the child should remain at school. When the disorder is mild, school can be a valuable distraction from depressive thinking. When the disorder is more severe, symptoms such as poor concentration and motor retardation may add to feelings of hopelessness. It is quite common to find in such cases that ensuring that the child obtains tuition in the home, or perhaps in a sheltered school, improves mood considerably.

The second issue is whether the depression is complicated by other disorders, such as behavioural problems. If it is, then measures to deal with these other problems must be included in the treatment programme. In some cases it is best to try to deal with comorbid problems before embarking on therapy for depression. For instance, it is difficult to conduct psychological therapies for depression when a patient is very underweight because of comorbid anorexia nervosa. In other cases it may be possible to treat the comorbid problem at the same time as the depression.

Managing the social context of depression

The third issue concerns the management of the stresses that are associated with many cases of major depression (Hammen *et al.* 1999). It is sometimes possible to alleviate these stresses. For example, bullying at school may be reduced by a discreet phone-call to the head teacher or other intervention with the school (Olweus 1994). Maternal depression may resolve following treatment with an antidepressant. However, in many cases acute stressors are just one of a number of causes of the adolescent's depression. Moreover, such stressors commonly arise out of chronic difficulties, such as family discord, and may therefore be very hard to remedy. Symptomatic treatments for depression can therefore be helpful even when it is obvious that the depression occurs in the context of chronic adversity that is likely to persist.

Evidence base for psychosocial interventions

Depression is a problem with such pervasive features that one can find abnormalities in almost any domain (e.g. cognitive, interpersonal, familial, psychodynamic) to justify virtually any psychosocial intervention. The interventions reviewed here all have three features in common.

- 1 They are based on testable theories about the mechanisms of disorder and about how treatment reduces dysfunction.
- 2 They have been evaluated in randomized trials.
- 3 They are all relatively brief and therefore capable of implementation in clinical practice.

Table 29.1 summarizes the evidence base for the three psychosocial interventions that meet these criteria.

Cognitive-behaviour therapy

The best studied of the psychological interventions is cognitive-behaviour therapy (see Brent, Chapter 54). Cognitive-

Table 29.1 Psychosocial treatments for adolescent major depression.

Intervention	Strength of recommendation	Quality of evidence	Comments
Cognitive-behaviour therapy	✓✓	B+	Moderate MDD
Interpersonal psychotherapy	✓	B-	
Family therapy	XX	B	

Recommendation: ✓✓✓ (good supporting evidence) through ✓X (uncertain evidence) to XXX (good evidence to reject).

Quality: A (five independent systematic randomized trials with consistent results) through C (systematic open studies) to E (opinion of respected authority).

behavioural treatment (CBT) programmes were developed to address the cognitive distortions and deficits identified in depressed children (see above). Many varieties of CBT exist for childhood depression, but they all have the following common characteristics.

- 1 The child is the focus of treatment (although most CBT programmes involve parents).
- 2 The child and therapist collaborate to solve problems.
- 3 The therapist teaches the child to monitor and keep a record of thoughts and behaviour. There is therefore emphasis on diary-keeping and on homework assignments.
- 4 Treatment usually combines several different procedures, including behavioural techniques (such as activity scheduling) and cognitive strategies (such as cognitive restructuring).

CBT has been used in both school and clinical settings. There have been at least six randomized controlled studies of CBT in samples of children with depressive symptoms recruited through schools (Reynolds & Coats 1986; Stark *et al.* 1987; Kahn *et al.* 1990; Liddle & Spence 1990; Marcotte & Baron 1993; Weisz *et al.* 1997). The design has usually been to screen for depression with a questionnaire and then to invite those with a high score to a group CBT intervention. In three of the trials CBT was significantly superior to no treatment. Although these results are promising, they may not necessarily apply to cases with depressive disorder. However, a meta-analysis (Harrington *et al.* 1998a) of six randomized trials with clinically diagnosed cases of depressive disorder (Lewinsohn *et al.* 1990; Reed 1994; Vostanis *et al.* 1996b; Wood *et al.* 1996; Brent *et al.* 1997; Clarke *et al.* 1999) found that CBT was significantly superior to comparison conditions, such as remaining on a waiting list or having relaxation training (pooled odds ratio of 2.2).

Interpersonal psychotherapy

Two other psychological treatments have been evaluated in randomized trials with clinically depressed adolescents. Interpersonal psychotherapy (IPT) is based on the premise that depression occurs in the context of interpersonal relationships (Klerman & Weissman 1992). The empirical basis for treating adolescent depression with IPT comes from research showing a strong association between depression and problems with relationships (Goodyer *et al.* 1997b). Like CBT, IPT is a brief time-

limited therapy. The two main goals are to identify and treat, first, depressive symptoms and, secondly, the problems associated with the onset of depression (Moreau *et al.* 1991; Mufson *et al.* 1993). A randomized trial in a very disadvantaged sample has shown significant benefits over non-specific counselling (Mufson *et al.* 1999).

Family interventions

Family interventions are based on the reliable observation that adolescent depression often occurs in the context of family dysfunction (see above). There are widely differing definitions of family therapy, but most therapies have the following features in common (Gorell Barnes 1994).

- 1 They typically involve face-to-face work with more than one family member.
- 2 Therapeutic work focuses on altering the interactions among family members.
- 3 Practitioners think of improvement at two levels: that of the presenting problem and that of the relationship patterns associated with the problem.

Two kinds of work have been undertaken with the families of depressed children. The first, exemplified by the research of Lewinsohn *et al.* (1990) and Clarke *et al.* (1999), consists of parental attendance at a course run in parallel with the child's individual psychological treatment (Lewinsohn *et al.* 1996). The aim of the parents' course is to help them promote the adolescent's learning of new skills. Parents also learn problem-solving and communication skills and adolescents and parents rehearse these skills in joint sessions. The second approach involves joint family work. In this approach the primary focus is usually within the treatment sessions, which aim directly to change family communication patterns and methods of solving problems. The therapist may also help the family to see depression from the relational function it could have within the family.

There have been at least four randomized controlled trials of family therapy in adolescent depressive disorder. Two involved a family intervention only (Brent *et al.* 1997; Harrington *et al.* 1998b) and two examined the value of parental sessions given in parallel with individual CBT (Lewinsohn *et al.* 1990; Clarke *et al.* 1999). None has found a significant benefit of the family

Table 29.2 Biological treatments for adolescent major depression.

Intervention	Strength of recommendation	Quality of evidence	Comments
Serotonin-specific reuptake inhibitors	✓	B	Three randomized controlled trials thus far
Tricyclic antidepressants	XX	A-	Second line in older adolescents
Venlafaxine	X✓	B-	One randomized controlled trial to date
Electroconvulsive therapy	X✓	D	Very severe cases

Recommendation: ✓✓✓ (good supporting evidence) through ✓X (uncertain evidence) to XXX (good evidence to reject).

Quality: A (five independent, systematic randomized trials with consistent results) through C (systematic open studies) to E (opinion of respected authority).

treatment. However, it would be premature to conclude that family interventions have no place in managing juvenile depression. The association between juvenile depression and family dysfunction is so strong that further studies of family interventions are indicated. None the less, the failure of the early family therapy studies suggests that future research will need to reconsider the target of the intervention. For example, because juvenile depression is often associated with family negativity (Harrington *et al.* 1997), trials of therapies that seek to reduce this negativity are needed. Until there is a firmer empirical basis for family therapy, however, other interventions will be the treatment of choice.

Limitations of psychosocial treatments

Individual focused 'here-and-now' psychological interventions, such as CBT and IPT, are promising treatments for adolescent depression but they have the following limitations.

1 Adolescents with severe depressive disorders respond less well than those with mild or moderately severe conditions (Clarke *et al.* 1992; Brent *et al.* 1998; Jayson *et al.* 1998; Brent *et al.* 1999).

2 Although proponents of psychosocial treatments often claim long-term benefits for the adolescent's psychological development, this has yet to be conclusively demonstrated. Few trials have provided follow-up data for more than a few months, and those that do have not generally found long-term effects (Vostanis *et al.* 1996a; Wood *et al.* 1996; Birmaher *et al.* 2000).

3 It is unclear what psychological processes correlate with a better outcome. The therapeutic basis for change is therefore uncertain.

4 Although both CBT and IPT have been described in detailed manuals (Clarke *et al.* 1990; Mufson *et al.* 1993), few centres offer training for therapists wishing to work with this age group.

Evidence base for biological treatments

Table 29.2 summarizes the evidence base for biological treatments. Most of the research on pharmacotherapy has been with the tricyclic antidepressants (TCAs), especially imipramine and

nortriptyline. The results from early open trials were encouraging. However, with the exception of Preskorn *et al.* (1987), the randomized controlled double-blind trials have found no significant differences between oral tricyclics and placebo (Kramer & Feiguine 1981; Petti & Law 1982; Kashani *et al.* 1984; Puig-Antich *et al.* 1987; Geller *et al.* 1989, 1990; Hughes *et al.* 1990; Kutcher *et al.* 1994; Kye *et al.* 1996; Birmaher *et al.* 1998). A meta-analysis of the tricyclic trials (Hazell *et al.* 1995) found that the pooled response rate was around one-third, less than that generally found when tricyclics are given to depressed adults.

There is evidence that TCAs are an effective treatment for adult depression (Boyce & Judd 1999), raising the question as to the possible explanations of the failure of clinical trials among the young. The first possibility is that the failure is more apparent than real, and stems from some of the methodological issues involved in conducting trials in this age group. Consent must in practice be obtained from two people, and many parents are reluctant to allow their children into a study in which one of the treatments is medication. This may be especially difficult in studies involving TCAs, where regular monitoring of cardiac function is required. The result may have been that particularly severe, and perhaps less responsive, cases of depression have been admitted to the tricyclic trials. There have also been technical problems with some of the trials (Hazell *et al.* 1995), of which perhaps the most striking is their relatively small sample sizes. Significant drug effects within subgroups could easily have been missed. In addition, some trials have had very high response rates in the group given placebo (Puig-Antich *et al.* 1987), making it even more difficult to detect an effect of active drug.

The second set of explanations concern that possibility that juvenile depressions differ from adult depression in ways that make it less likely they will respond to TCAs. There are important differences between pre-adolescent and adult depression in respect of comorbidity and epidemiology (see above). It has also been suggested that young people differ from adults both in the relative balance of the cerebral neurotransmitters on which TCAs are thought to act (Strober *et al.* 1999) and in the hormonal milieu of the brain (Ryan *et al.* 1986). Finally, it could be that it is harder to get drug dosage right in children than it is in

adults. There may be developmental variations in the metabolism of TCAs, such as their rate of elimination from the body (Geller 1991).

Two randomized trials have found that SSRIs may be of benefit in children and adolescents with major depression (Emslie *et al.* 1997b; Keller *et al.* 2001). It is too early to say whether this finding is robust—a small trial with fluoxetine produced a negative result (Simeon *et al.* 1990). Nevertheless, it clearly raises the possibility that young people may be more responsive to antidepressants than previously thought, perhaps especially to drugs that act more on serotonergic rather than noradrenergic systems (Ryan & Varma 1998). Negative results have been reported in a trial with the mixed serotonergic/noradrenergic antidepressant venlafaxine (Mandoki *et al.* 1997).

Electroconvulsive therapy (ECT) is very seldom used with adolescents, and then only for the most severe life-threatening depressions that have failed to respond to other treatments. It is usually best to obtain a second opinion from another psychiatrist before ECT is considered (for a review see Walter *et al.* 1999).

Limitations of biological treatments

The main limitation is side-effects. These are potentially severe with the TCAs (see Heyman & Santosh, Chapter 59), which can be cardiotoxic in overdose and which have been linked to sudden cardiac death even in therapeutic doses (Geller *et al.* 1999). SSRIs seem to have fewer side-effects (Ambrosini *et al.* 1999; Strober *et al.* 1999) and, unlike the TCAs, do not usually require specific cardiovascular monitoring (Gutgesell *et al.* 1999). However, symptoms such as dry mouth and gastrointestinal upset can be a problem (Emslie *et al.* 1999) and there has been concern about the so-called ‘serotonin syndrome’. This ‘syndrome’, which is probably better regarded as the extreme end of the continuum of toxicity, is characterized by alterations in cognition, behaviour, autonomic and central nervous system function as a result of increased post-synaptic serotonin receptor agonism (Gillman 1999). Abrupt discontinuation of SSRIs can lead to symptoms such as dizziness, nausea and lethargy (Drug and Therapeutics Bulletin 1999), which may raise parental concerns about ‘addiction’.

Another important limitation is that, as with psychosocial treatments, a significant minority fail to respond. It is unclear who is most likely to respond to drugs such as fluoxetine (Kowatch *et al.* 1999). Drug levels are unlikely to be helpful as there is tremendous interindividual variability in the metabolism of SSRIs (Findling *et al.* 1999), as there is with the TCAs.

An evidence-based treatment algorithm for moderate depression

Although the evidence base is not yet as comprehensive as one would wish, it is now possible to construct simple evidence-based algorithms for the management of juvenile depression (Fig. 29.1).

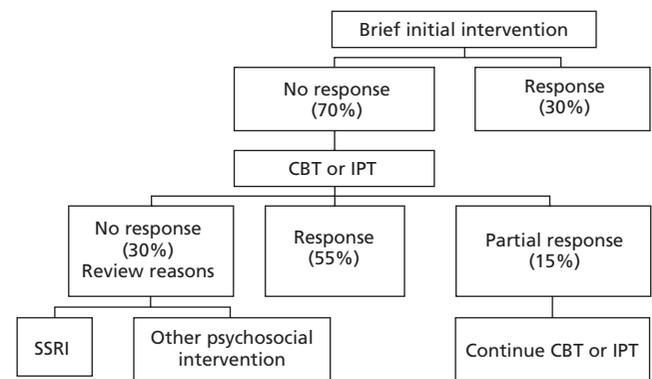

Fig. 29.1 Management of moderately severe depression.

Steps 1 and 2. Moderately severe depression of just a few months' duration remits after a brief intervention in around one-third of cases. This suggests that a sensible initial approach can consist of a thorough assessment, encouraging support and efforts to alleviate any obvious precipitating stressors (see above).

Step 3. The best treatment for persistent major depression in adolescence is not yet firmly established. SSRIs are probably cheaper than psychosocial treatments but their benefits have not yet been established in more than two published trials. This suggests that, if available, either CBT or IPT is probably the first choice treatment for moderate depression (Renaud *et al.* 1999).

Step 4. A meta-analysis (Harrington *et al.* 1998a) of CBT studies found that around one-third of clinically depressed adolescents had not improved by the end of the CBT course. Therefore, patients should be re-assessed after about 6–8 weeks to determine whether there has been a response or not. By this stage, there are likely to be two groups who still need help: those who have failed to respond or are getting worse and those who have partially improved but are still symptomatic. If an adolescent is resistant to the effects of CBT then the reasons for this should be reviewed. It may be that other problems besides depression are present. Review may also indicate some specific reasons for the failure of CBT. For example, CBT is less effective when given by an inexperienced therapist who tells the adolescent what to do (Scott 1998).

Step 5. If the review does not show a simple way of improving the adolescent's mental state, then a different line in treatment should be pursued. In some instances, this means starting an antidepressant, such as an SSRI. In other cases it may be necessary to provide treatments such as family therapy.

Less is known about the management of severe depression. Clinical experience suggests that combination of medication and individual treatment is often necessary. Antidepressants may be augmented with lithium in cases who fail to respond.

Promoting remission and preventing relapse

Young people with depressive disorders are likely to have another episode and so it is important to consider the need for prophylactic treatments. Research with depressed adults distinguishes between continuation and maintenance treatments.

Continuation treatments

The idea behind continuation treatments is that although treatment may suppress the acute symptoms of depression, the treatment should continue until the hypothesized underlying episode has finished. There have been no randomized trials of continuation treatments for juvenile depressive disorders. However, data from a non-randomized trial with depressed adolescents suggest that continuing psychological treatment for 6 months after remission is feasible and may be effective in preventing relapse (Kroll *et al.* 1996). The treatment given during the acute episode of adolescent depression should therefore be continued until the patient has been free of depression for around 6 months.

Maintenance treatments

Maintenance treatments have a different objective, which is to prevent the development of a new episode of depression. Research with adult patients suggests that both pharmacotherapy and psychotherapy may reduce the risk of relapse if maintained for several years after the index depressive episode (Frank *et al.* 1992; Kupfer 1992). Clearly, such treatments will be very time-consuming and expensive. They cannot therefore be contemplated for more than a small minority of patients. Clinical experience suggests that indications for maintenance treatment in depressed young people include a history of highly recurrent depressive disorder, severely handicapping episodes of depression and chronic major depression (for a review of maintenance treatments with adults see Keller (1999)).

Possibilities of primary prevention

The case for primary prevention

There is a strong case, at least in theory, for preventing depression in young people (Harrington & Clark 1998). Although the evidence reviewed earlier suggests that some effective psychological treatments are available, many patients fail to respond. Moreover, only a minority of depressed youngsters ever come to clinical services (Oldehinkel *et al.* 1999), possibly because parents perceive greater need for mental health services for children with disruptive disorders than for those with depression (Wu *et al.* 1999).

Strategies for primary prevention

There has been a great deal of work on general strategies for preventing child psychiatric disorders (Durlak & Wells 1997)

and some of these strategies could be effective in preventing depression (e.g. reducing bullying in classrooms, improving access to special education, and maternal befriending). As many of these interventions are discussed in other parts of this book, the present section only deals with strategies in which reducing depression in young people is an important potential outcome.

It is customary to distinguish between two types of primary preventive strategy. *Universal programmes* involve all individuals in a population regardless of their level of risk. Typically, such programmes involve either attempts to change levels of depression directly (Clarke *et al.* 1993) or efforts to develop strengths that might protect against depression (King & Kirschenbaum 1990). The latter have usually consisted of educational sessions and cognitive-behavioural techniques, particularly techniques to develop social skills.

Targeted programmes aim to prevent depression in a population known to be at risk. The best-established risk factors for depressive disorder in young people are earlier depressive symptoms or a family history of depression (Harrington & Vostanis 1995). Treatments for depressive symptoms are described above. The rationale behind family interventions is that improving problems such as parenting difficulties or maternal depression should reduce the risk of depression among offspring. Preventive family interventions have been devised both for the depressed mothers of young infants (Cooper & Murray 1997) and for the families of older children in which at least one parent has an affective disorder (Beardslee *et al.* 1993b). Interventions for depressed mothers have targeted maternal depression alone (Cooper & Murray 1997), toddler-parent attachment (Cicchetti *et al.* 2000), deficits in maternal social support (Brugha *et al.* 1999) and mother-infant interactions (Field 1997).

Effectiveness of universal prevention programmes

Clarke *et al.* (1993) have conducted two randomized trials of universal interventions designed to reduce depressive symptoms in the general population of children, regardless of their levels of depression. Neither has shown significant benefits.

Effectiveness of targeting young people with high levels of depression

Interventions that target individuals with high levels of depressive symptoms have produced more promising results. King & Kirschenbaum (1990) studied primary school children with a high score on a screening questionnaire. They found that a programme of social skills training and consultation with parents and teachers was significantly better than consultation alone in reducing depressive symptoms. Clarke *et al.* (1995) randomly allocated schoolchildren with a high score on a depression questionnaire to CBT or to no treatment. The CBT group had a significantly reduced risk of depressive disorder during the following year.

Effectiveness of targeting family risk factors

There is evidence from randomized trials that some (Wickberg & Hwang 1996; Cooper & Murray 1997), but not all (Brugha *et al.* 1999), forms of brief psychological treatment are effective in reducing depression in postpartum women. Antidepressant medication also appears to be beneficial (Appelby *et al.* 1997). Nevertheless, it seems that treatment of maternal depression does not necessarily improve the infant's outcome. Cooper & Murray (1997) found no significant benefits for the parent–infant relationship, even though maternal depression had improved considerably. Similar findings were reported by Gelfand *et al.* (1996) in a non-randomized design. However, intensive interventions that help depressed mothers to parent more effectively may lead to better infant outcomes (Field 1997; Cicchetti *et al.* 2000). It remains to be seen whether these interventions will prevent depression in these infants as they grow up.

Several randomized studies have examined the efficacy of intervening with the families of older children at risk for depression. In a study of bereaved families, Sandler *et al.* (1992) found that a programme of help for the whole family reduced depressive symptoms in the child. Beardslee *et al.* (1993b, 1996b) conducted a randomized trial with families in which at least one parent had an affective disorder. They compared a clinician-facilitated educational preventive programme with a lecture group. No data are yet available on rates of depressive disorders in the offspring but early findings indicate that there are useful changes in the family's knowledge about depression and in intrafamilial communication.

Conclusions on effectiveness of prevention strategies

In summary, the preliminary evidence suggests that universal programmes that aim to reduce depression across the whole population may not be effective. Universal programmes have a number of advantages over targeted interventions (Graham 1994) but it may be better for such programmes to concentrate on increasing factors that could protect against depression (Clarke *et al.* 1993).

Targeted interventions seem more promising, particularly those that focus on youngsters with high levels of depressive symptoms. A strength of these studies is that preventive programmes have huge potential to reduce the burden of suffering arising from depression. A challenge for targeted approaches is to increase the proportion of individuals who are willing to take part. The uptake of psychological treatments offered to individuals identified as at risk has often been low (Harrington *et al.* 1998c). Future studies must also pay greater attention to the possible harmful effects that might result from targeting at risk children or their parents for treatment (Harrington & Clark 1998).

Other affective disorders

Bipolar disorder

Classification and clinical features

Bipolar disorder is characterized by the combination of depressive disorder and distinct episodes of manic disorder. By convention, all patients with mania are classified in the bipolar group, whether or not they have had depression. The central features of mania are elation or irritability, increased activity and self-important ideas. When mania is *severe* there may be grandiose delusions, hallucinations and frenzied overactivity. When mania is moderate there is sustained overactivity and pressure of speech, euphoric mood and inflated self-esteem. In mild forms of mania (*hypomania*) there is some elevated mood, increased sociability and excessive involvement in pleasurable activities.

Diagnostic uncertainties

The concept of bipolar disorder in adult life has received substantial validation, but the same cannot be said for the concept of bipolar disorder among the young. There has been particular concern about the validity of the concept of mania in pre-adolescent children.

Until relatively recently, typical 'adult-like' manic states were widely regarded as extremely uncommon among prepubertal children. However, several investigations have identified substantial numbers of children with symptoms similar to mania. Wozniak *et al.* (1995) found 43 children aged 12 years or younger who met DSM criteria for mania. Geller *et al.* (1994) found that bipolarity developed in 25 of 79 children with major depression, the majority of whom were prepubertal.

Attempts to validate these mania-like states are necessarily at an early stage, but there are at least five reasons for doubting the links between prepubertal 'mania' and mania in adulthood.

1 Although the diagnosis of mania in young people should be based on the same criteria as adults (American Academy of Child and Adolescent Psychiatry 1997), some studies seem to have applied the criteria differently (Klein *et al.* 1998). For instance, mania in adults is usually a relapsing and remitting condition, yet studies of prepubertal mania find that it is often chronic without distinct manic episodes (Geller & Luby 1997).

2 There is huge overlap between the criteria for mania and those for attention deficit disorder. Core symptoms of both conditions include reduced attention, racing thoughts, distractibility, motor overactivity and impulsive behaviour. Both are also strongly associated with irritability. Indeed, around one-half of adolescents diagnosed with bipolar disorder also meet the criteria for attention deficit hyperactivity disorder (West *et al.* 1995). There must be concern that the two are being confused.

3 All epidemiological studies find that mania is very rare or non-existent in pre-adolescent children. For example, in the Smoky Mountain study in the USA (Costello *et al.* 1996) and in the Office of National Statistics survey in the UK (Meltzer *et al.* 2000) no cases of mania were found.

4 In contrast to the study of Geller *et al.* (1994), most other longitudinal studies find that among children the rate of conversion from major depression to mania is very low (Harrington *et al.* 1990; Weissman *et al.* 1999b; Fombonne *et al.* 2001a). Conversely, studies of children diagnosed with attention deficit disorder do not generally find increased risks of bipolar disorder in adult life.

5 Studies of the school-aged children of parents with bipolar disorder (Hammen *et al.* 1990; Radke-Yarrow *et al.* 1992) do not report cases of mania.

Differential diagnosis

Mild forms of mania are easily confused with problems such as conduct disorder and attention deficit disorder (Kovacs & Pollock 1995). Severe psychotic manic states can be difficult to distinguish from schizophrenia (Carlson *et al.* 1994). Manic symptoms can also occur when susceptible subjects have been prescribed antidepressants (Briscoe *et al.* 1995).

Epidemiology and aetiology

Severe 'typical' bipolar disorder appears to be uncommon in adolescence. In the first two waves of the Oregon study only 2 of the 1500 adolescents who were evaluated met full diagnostic criteria for bipolar disorder (Lewinsohn & Klein 1995). Nevertheless, bipolar disorder may be on the increase. Possible explanations include the genetic process of anticipation, more sensitive diagnostic methods and substance or alcohol abuse (Goodwin & Ghaemi 1998).

Little is known about the aetiology of juvenile bipolar disorder. There have been no large genetically informative studies of bipolar disorders in young people. However, there is no reason for thinking that juvenile bipolar disorder is any less genetic than it seems to be in adults. Adolescent bipolar disorder is familial (Strober *et al.* 1988) and shows a distribution of affective illness in relatives that is compatible with genetic factors (Todd *et al.* 1996).

Course

Bipolar disorders that occur in adolescence tend to follow the remitting and relapsing course of adult cases. Strober *et al.* (1995) followed up 54 consecutive admissions of adolescents with bipolar illness to a university inpatient service. At the time of admission, 20 were manic and the remainder depressed or in mixed states. Nearly 50% of the sample had a relapse during the 5-year follow-up. However, the prognosis of early onset bipolar disorder is probably better than of early onset schizophrenia (Werry *et al.* 1991). A small proportion of adolescent patients who pre-

sent with depression will go on to develop mania. Strober *et al.* (1993) found that 5 out of 58 adolescents with major depression developed manic or hypomanic episodes during the 24-month follow-up period. Many of these cases had psychotic features during their depressive episode. Other predictors of outcome include premorbid personality (Werry & McClellan 1992) and family history. Milder forms of bipolar disorder in adolescents also show moderate short-term stability (Lewinsohn & Klein 1995) and may be a manifestation of a temperamental vulnerability to typical manic depression (Akiskal 1995).

Treatment

In adults, lithium has been shown to be effective for both the prevention of manic and depressive episodes and the treatment of the acute episode of depression or mania. Much less is known about its use in children or adolescents but there is some evidence it is effective (Geller *et al.* 1998). As in adults, the lithium range for the acute phase should range from 0.6 to 1.2 mEq/L, with somewhat lower levels for effective prophylaxis (American Academy of Child and Adolescent Psychiatry 1997). Lithium has some significant side-effects, including hypothyroidism and neurological symptoms. Anticonvulsants may also be used in the treatment and prophylaxis of bipolar disorder among the young, perhaps especially when it is rapid cycling (Ryan *et al.* 1999).

Seasonal affective disorder

Retrospective studies suggest that adolescents report high rates of seasonal variation in affective symptoms such as energy level and mood (Sourander *et al.* 1999). Seasonal affective disorder (SAD) is characterized by depressions that occur at certain times of the year. Most often, the episodes begin in autumn or winter and remit in spring. Prominent symptoms include loss of energy, sleep disturbance and craving for carbohydrates. Carskadon & Acebo (1993) estimated a 3–5% prevalence for seasonal depression among children. Giedd *et al.* (1998) followed up six children (aged from 6 to 17 years) with a diagnosis of SAD. Subjects were followed for 7 years and outcomes were assessed using standardized methods. All subjects had persistent seasonal symptoms, which remained relatively severe. However, in most light therapy was of some benefit.

Future challenges

The past decade has seen important advances in research into the epidemiology, aetiology and treatment of depressive disorders among the young. We are beginning to understand how risk factors combine to precipitate and maintain depression. Progress has also been made in the development of effective treatments. This concluding section will consider some of the challenges that remain.

Methods

There are several outstanding methodological issues. First, better measures are needed of psychosocial risk factors for depression. Up to now, most of the research on juvenile depressive disorder has focused on acute life events. However, it is becoming clear that many cases of depression are recurrent and so we need to know how psychosocial factors contribute to long-term liability. This will mean developing measures that are better able to assess long-term psychosocial problems. Secondly, there is a need for greater use of intensive longitudinal designs that measure depression and its risk factors over several time-points. Much of what is currently known about the course of juvenile depression comes from studies with just a single follow-up. This makes it difficult to study covariation of depression and its risk factors over time.

How do genes and environment combine to produce depression?

Although many important predisposing factors for adolescent depressive disorder are familial (see above), it is still not clear how far this association is a reflection of genes, environment or both. At first sight, then, it seems obvious that the next step should be large genetically informative studies of samples with depressive disorder. Such studies could be useful. However, the data from studies carried out thus far indicate that genetic effects on depression are often indirect; they seem to operate more by making it likely that young people will experience risk environments, or be susceptible to such environments, than by direct effects on depression itself (Silberg *et al.* 1999). The implication is that further genetic studies should be concerned as much with factors that predispose to depression, such as personality dimensions, as with depression *per se*.

How can depression be prevented?

Identification of the complex gene–environment pathways leading to juvenile depression also has implications for preventive programmes. Much of the psychopathological risk to the children of depressed mothers seems to stem from factors other than maternal depression, such as chronic parenting problems. Future preventive studies probably need to target these factors at least as much as they do parental depression.

How should established depression be treated?

For the foreseeable future, however, it will not be possible to prevent more than a small number of cases of juvenile depression. Many challenges remain in the development of effective treatments for established depressive disorders, of which four stand out.

1 Although several promising treatments have been developed for the acute episode, we know very little about their relative

demerits and merits. A key question for future research is how individual psychological treatments compare with the SSRIs.

2 There needs to be greater appreciation of the limitations of current designs for clinical practice. Much extant research has been based on selected samples of cases with only moderately severe depression and without the comorbid problems that often complicate the cases that are seen in everyday practice. ‘Pragmatic’ studies (Hotopf *et al.* 1999) with large samples of the kinds of patients who present in routine clinical practice are also required. In particular, information is needed on the efficacy of treatments within severely impaired samples.

3 There needs to be a continuation of efforts to develop and test the kinds of clinical algorithms described earlier. Treatment researchers have, up to now, tended to conceptualize an intervention as just one treatment modality given for a short time. This strategy has been a necessary first step in the development of coherent theory-driven interventions. The complexity of factors that precipitate and maintain juvenile depression suggests, however, that it is unlikely that any single treatment will be effective in all cases. ‘Treatment’ in research studies needs to be conceptualized more often as a programme of interventions used singly or in combination that will often follow one after the other, depending on the likely causes of the young person’s problems and response to treatment.

4 There has been little attention so far to ways of preventing relapse or other complications, such as suicidal behaviour. Perhaps the most daunting challenge for the future will be to develop better ways of identifying and helping the significant minority of depressed young people in whom their first episode of depression presages further serious psychopathology.

Diagnosis of anxiety disorders in children

Distinction between normal and pathological childhood anxiety

Defining the boundaries between extremes of normal behaviour and psychopathology is a dilemma that pervades all psychiatry. In the very extreme, diagnostic decisions are straightforward (as in mental retardation, for example), but with milder forms, the defining point for caseness is often ambiguous. A few symptoms escape this definitional conundrum by virtue of being deviant no matter what their severity, such as delusional beliefs or hallucinations. Even in these cases, some childlike fantasies may resemble these symptoms. It is especially problematic to establish the limits between normal behaviour and pathology in the case of anxiety because many childhood anxieties are not only common but also have an adaptive role in human development, signalling that self-protective action is required to ensure safety. Because anxiety can be rated on a continuum, it is often believed that the extremes represent only a severe expression of the trait, rather than a distinct or pathological state. However, distributions may be comprised of distinct entities (Alpert *et al.* 1994), and the mere fact that anxiety falls on a continuum of severity does not preclude the presence of qualitatively distinct disorders at any point in the distribution.

Anxiety may become symptomatic at any age when it prevents or limits developmentally appropriate adaptive behaviour. A useful rule of thumb for determining diagnostic threshold is the child's ability to recover from anxiety and to remain anxiety-free when the provoking situation is absent. For example, it is not necessarily deviant for a young child to respond with distress to the parent's departure. However, such reactions reach clinical levels when the child is unable to recover after the separation is effected (assuming proper care is available), when the child cannot function normally during normal separation experiences, and when the child also develops concerns about future separations and vigilance, or even avoidance of activities that require separation. Therefore, the child's lack of flexibility in affective adaptation is an important pathological indicator. In addition, the degree of distress and dysfunction influences diagnostic decisions, which vary with the child's age, as well as with cultural and familial standards. When anxiety symptoms are developmentally inappropriate, subjective distress is relatively more informative. In brief, three clinical features impinge on the

definition of pathological anxiety. Two of these, distress and dysfunction, vary in importance as a function of developmental stage. The third, symptomatic inflexibility, is diagnostically relevant regardless of age (Klein 1978).

As long as signs and symptoms are the exclusive basis for establishing the presence of psychiatric disorders, it is unlikely that we will reach completely satisfactory criteria for diagnosis. Longitudinal research can provide answers by identifying specific symptom patterns and thresholds that have long-term significance. Such evidence is informative, but rarely conclusive. Even if recovery were a common ultimate outcome, it would not follow that the syndrome in question did not represent a discrete disorder or a pathological state.

Diagnosis of childhood anxiety disorders

The past two decades have witnessed great expansion in the study of childhood anxiety disorders. Until recently, determination of children's fears and anxiety largely relied on rating scales, or interviews that inquired about a multitude of unrelated fears and worries which generated a count without clear clinical meaning (Lapouse & Monk 1958). These approaches have virtually vanished as the sole strategies for documenting and quantifying childhood anxiety. The emphasis has shifted to the study of diagnostic groups that reflect explicit clinical criteria. This strategy makes sense for several reasons. The number of childhood fears is potentially very large. It is cumbersome to assess them all for their occurrence and impact on children's well-being, and the task of determining their clinical relevance would be a daunting endeavour. Generating syndromes provides a more parsimonious estimate of pathological anxiety than scales with a plethora of items. Besides their practical advantages, clinical diagnoses are intended to represent distinct forms of pathological anxiety and foster the hope that they provide a more accurate reflection of pathology than scale measures. Scale ratings can be grouped to generate overall scores of anxiety, or what has come to be called 'internalizing' symptoms, such as in the widely used Child Behaviour Checklist (CBCL; Achenbach 1991) but, as the evidence shows, these scale ratings correspond poorly to clinical entities. Except for the section concerning assessment of childhood anxiety, where the role of anxiety scales in children is discussed, we restrict this chapter to reports that have formulated diagnoses of anxiety disorders, based on interviews with children and/or parents.

ICD-10 and DSM-IV

The two nomenclatures have similar diagnoses for childhood anxiety disorders. The major difference is that the ICD-10 provides a single diagnosis for cases who have both anxiety and behaviour disorders, whereas the DSM-IV (American Psychiatric Association 1994) requires the use of several diagnoses for such children. In addition, obsessive-compulsive disorder and post-traumatic stress disorder are under the rubric of the anxiety disorders in the DSM-IV, but not in ICD-10. Longitudinal and family studies report a weak relationship between these disorders and other anxiety disorders; therefore, their coverage elsewhere is justified. The most important anxiety disorders, and the most studied, consist of phobic disorder (specific phobia in DSM-IV), separation anxiety disorder, social phobia, generalized anxiety disorder and panic disorder. This ranking approximates their modal developmental sequence. It may be that, as knowledge is accumulated, some or all anxiety disorders will be shown to have specific biological features or causes, and will warrant their own examination.

Some differences exist in the definitions of childhood anxiety disorders between ICD-10 and DSM-IV (Klein 1994); however, this summary focuses on common clinical features.

Phobic disorder

The diagnosis of phobic disorder is defined as marked unreasonable fear of a specific object (e.g. animals) or situation (e.g. heights), that is invariable (it occurs whenever the person encounters the feared object). In addition, the phobia must be of such severity that it impairs the person's well-being by causing clinically significant distress or affects normal activities through avoidance of the feared situations. Although phobic disorders may begin at any age, their typical onset is in early childhood, but it is not restricted to it.

Although there are multiple sources of phobias, the majority of children with phobic disorders share a limited number of feared situations. Attempts to differentiate among various phobias in adults have not yielded clearly differentiating features (Fyer 1998). An exception is blood phobia which has a distinct physiological profile, consisting of a sudden drop in blood pressure and heart rate, and possibly fainting (Rachman 1990). These somatic symptoms do not characterize phobic reactions to other specific stimuli.

Separation anxiety disorder

This anxiety diagnosis is the only one that must begin before adulthood (age 18). The onset is frequently in late childhood, before adolescence. As the name connotes, it reflects anxiety at separation from home or caregivers that is beyond reason and to the point of interfering with the person's well-being or age-appropriate function. It is often accompanied by resisting activities that require separation from caregivers, such as play dates in friends' home but not in their own home. In younger

children, what is referred to as school phobia is usually avoidant behaviour secondary to separation anxiety. (The diagnostic underpinning of school phobia in adolescence is more varied, because social phobia may also lead to school refusal.) There is no logical content to the specific situations children with separation anxiety disorder avoid; for example, a child may have no difficulty going to school, but be very uncomfortable during play dates in thoroughly familiar settings.

Social phobia

This condition is sometimes referred to as social anxiety disorder because its key clinical feature is anxiety in social situations because of fear of scrutiny, ridicule, humiliation or embarrassment. Some children may not articulate the latter concerns, but feel self-conscious and uncomfortable in social settings. Children must experience discomfort with peers, not only with adults, and anxiety cannot be caused by impaired capacity for socialization, as evidenced by the fact that the children relate well in social interactions with those who are familiar to them.

Individuals with social anxiety disorder avoid situations which require social interactions. In severe instances, there may be avoidance even of familiar people. The diagnostic qualifier, generalized social phobia, denotes whether social anxiety occurs in most social settings. Unfortunately, no definition of the non-generalized form is provided, and it has been interpreted in divergent ways. Some apply it to individuals who experience social anxiety in only one or two situations, such as parties; others use the diagnosis of non-generalized social phobia for patients who experience performance anxiety, such as public speaking or performance, eating in front of people, as well as test anxiety, but who do not have anxiety during social interactions.

Epidemiological evidence supports the notion that the two forms of social phobia are distinct, because the generalized form has been reported to have an earlier onset, more chronicity and comorbidity, and more psychopathology in relatives (Wittchen *et al.* 1999). This work exemplifies how epidemiological studies can inform diagnostic validity.

Generalized anxiety disorder

This diagnosis encompasses multiple worries about a variety of life circumstances, such as school work, appearance, money problems, the future, etc., to the point of interference with the person's comfort and functioning. The age of onset of this disorder is poorly understood, but typically is not in early childhood. Relative to other anxiety disorders, generalized anxiety disorder, unlike other anxieties, is more likely to occur with other psychopathology, and is not typically found on its own. Also, because the symptoms consist mostly of worries, the disorder is not usually characterized by avoidant behaviour, although there are exceptions. For example, children with extreme worries about academic performance may be absent from school on testing days.

Panic disorder

The essential clinical feature of panic disorder is the repeated experience of unprovoked spontaneous panic attacks, which may lead to limited independent travel or agoraphobia. The panic attacks are characterized by intense fear of impending doom or danger, accompanied by physical symptoms, such as rapid heartbeat, shortness of breath, choking sensation, sweating, depersonalization or derealization. The onset is usually in late adolescence and early adulthood.

Young children may display panic reactions, but whether they experience spontaneous unprovoked panic attacks—the hallmark of panic disorder—is controversial. Case reports have described panic disorder in pre-adolescents (Herskowitz 1986; Biederman 1987; Alessi & Magen 1988; Ballenger *et al.* 1989; Last & Strauss 1989; Black & Robbins 1990; Klein *et al.* 1992), but several are based on retrospective reports (Herskowitz 1986; Last & Strauss 1989; Black & Robbins 1990; Klein *et al.* 1992). These are certainly suggestive, but they fall short of being conclusive as they may be subject to retrospective distortions. Further, it is not easy to establish spontaneity of panic attacks retrospectively, or to distinguish other forms of severe anxiety-related panic attacks. A child psychiatry clinic series of 12 cases with panic disorder included only one pre-adolescent, who had the additional diagnosis of separation anxiety disorder (Renaud *et al.* 1999). Whether panic disorder occurs at all in pre-adolescents is still an unresolved issue but, if it does, it must be very rare. This makes it difficult to study the condition systematically. It has been suggested that, in keeping with the cognitive model of anxiety, children may lack the cognitive resources for misinterpreting somatic experiences in a catastrophic fashion and therefore do not have panic attacks (Nelles & Barlow 1988). This conjecture seems unlikely, because panic reactions associated with terror occur in children. It is the sudden unprovoked aspect of panic that seems to be missing in childhood, not the catastrophic reaction. At the same time, it is possible that true panic attacks have age-related clinical variants.

Comorbidity of childhood anxiety disorders

Comorbidity is an important clinical feature because it has been shown repeatedly to entail relatively greater dysfunction (Newman *et al.* 1998). Two forms of diagnostic overlap are considered: comorbidity of anxiety disorders with each other; and comorbidity of anxiety disorders with other diagnoses.

Studies of children referred for treatment report very high comorbidity among the anxiety disorders. In the largest treatment study to date of children and adolescents with anxiety disorders, social phobia, separation anxiety and generalized anxiety disorder were each diagnosed in about 60% of the children (RUPP Anxiety Study Group 2001). Comorbidity was particularly elevated in children with generalized anxiety disorder who, in 90% of the cases, also had another anxiety disorder, a finding consistent with clinical studies that also have noted the

greatest comorbidity for overanxious disorder (reclassified as generalized anxiety disorder).

In epidemiological studies, comorbidity across anxiety disorders has been a highly consistent finding (Anderson *et al.* 1987; Bird *et al.* 1988; McGee *et al.* 1990; Fergusson *et al.* 1993; Costello *et al.* 1996; Simonoff *et al.* 1997; Verhulst *et al.* 1997; Essau *et al.* 1999; Wittchen *et al.* 1999). An examination of Table 30.1 provides a broad estimate of comorbidity, as the total prevalence of anxiety disorders exceeds the number of children with any anxiety disorder. It also indicates that comorbidity occurs in all geographical sites, and is not a variable phenomenon.

As to comorbidity between anxiety and other types of psychopathology, there is unanimous agreement that major depression is highly comorbid with anxiety disorders. As depression is much less frequent than anxiety disorders, especially in pre-adolescents, it follows that among those with anxiety disorders the overlap with depression is not as striking as when one selects those with diagnoses of depression, and that comorbidity increases with age. Although some clinical reports have indicated marked comorbidity between anxiety and attention deficit hyperactivity disorder, this relationship has not been confirmed in population studies, whereas there is some evidence of comorbidity between anxiety disorders and substance abuse and conduct disorder. At the same time, as noted in the section on long-term outcome, children with conduct and anxiety disorders may represent a distinct subgroup of conduct disorder because their longitudinal course seems relatively favourable (Pine *et al.* 2000a).

Historical developments

ICD-10 and DSM-IV implemented some changes in the diagnosis of anxiety disorders in children. As the literature mostly derives from the DSM-III-R classification (American Psychiatric Association 1987), these revisions are noted. The first and obvious proviso of a nomenclature is that clinical diagnoses should reflect distinct phenomenology. This elementary desideratum was felt to be lacking in the case of avoidant and overanxious disorders in the DSM-III (American Psychiatric Association 1980) and DSM-III-R, because their symptomatic content overlapped with several other anxiety disorders, especially with social phobia. This peculiar situation was not too surprising for overanxious disorder because it was introduced in the diagnostic manual in spite of there being no literature whatever on such a clinical syndrome, much less study, and it was essentially fabricated (Klein 1994). In view of these limitations, the DSM-IV does not include overanxious disorder. Avoidant disorder has a different history (Klein 1994)—it was felt that it was encompassed adequately by the diagnosis of social phobia.

Differentiated syndromes of anxiety facilitate communication among professionals, which is not a trivial goal, but it represents a very minimum requirement as a standard for the nomenclature. The DSM-IV and ICD-10 have met the minimal goal of providing anxiety diagnoses with distinct if not unique

clinical content. However, do specific anxiety disorders reflect valid distinct conditions, as defined by different natural histories, different correlates and risk factors, whether environmental, genetic or biological (Robins & Guze 1970), and different treatment responses? As far as possible, we examine research findings in this light to assess whether they support the validity of the current classification of anxiety disorders in children and adolescents.

Conclusions

The specific anxiety disorders in ICD-10 and DSM-IV, separation anxiety disorder, specific phobia, social phobia, panic disorder and generalized anxiety disorder, contain sufficiently distinguishing clinical features to assure their discreteness at the descriptive level. Comorbidity among anxiety disorders is well documented. Comorbidity of anxiety disorders with other disorders has also been demonstrated, but is not universally supported, except for the association with depressive disorders.

Assessment of childhood anxiety

There has been a proliferation of instruments to quantify levels of anxiety or determine the presence of anxiety disorders in children. Assessments include paper-and-pencil scales for children, parents and teachers, as well as child and parent interviews specifically designed to assess anxiety symptoms. Several reviews have appeared of self, parent and teacher rated anxiety scales for children (Klein 1994; March & Albano 1998; Silverman & Rabian 1999). Therefore an overview is provided, rather than a detailed report.

Rating scales

Rating scales serve diverse purposes. They may be useful for screening large groups to identify children likely to have anxiety at a symptomatic level, in order to provide economical means of targeting these individuals. At times, this strategy is used in prevention programmes (Dadds *et al.* 1997), or in epidemiological studies, to maximize efficacy of costly treatment or interview procedures. Rating scales have also been used in very large studies to examine the relative contribution of genetics and environment on dimensions of anxiety (Topolski *et al.* 1997, 1999). In clinical studies, scales may serve as indices of severity and as outcome measures of treatment efficacy.

Rating scales that anteceded the nosology of anxiety disorders introduced in the DSM-III (American Psychiatric Association 1980) and ICD-10 were not designed to reflect anxiety syndromes but, rather, consisted of factors such as worry, physiological anxiety, fear of bodily harm, etc. These scales include the Revised Children's Manifest Anxiety Scale (RCMA; Reynolds & Richmond 1985), the State Trait Anxiety Inventory for Children (STAIC; Spielberg 1973) and the Revised Fear Survey

Schedule for Children (FSSC-R; Scherer & Nakamura 1968; Ollendick 1983). In addition, the CBCL (Achenbach 1991) generates a non-specific factor of emotional disturbance, called 'internalizing' factor.

A major clinical challenge is to differentiate between anxiety and depression, and there would be great value to instruments capable of doing so. However, anxiety scales do not distinguish adequately between children with anxiety disorders and those with other diagnoses (Klein 1994). The Negative Affect Self-Statement Questionnaire (Ronan *et al.* 1994) has been reported to discriminate anxious from depressed affect (Lerner *et al.* 1999), but scale factors reflecting these two affects are highly correlated (Hodges 1990; Brady & Kendall 1992; DiBartolo *et al.* 1998; Lerner *et al.* 1999). The meaning of self-ratings of anxiety is further complicated by the finding that they do not correlate with symptoms of anxiety obtained from clinical interviews. Anxiety scales may provide overall estimates of anxiety levels, but they cannot be viewed as contributing to the diagnosis of anxiety disorders, and clinicians would be unwise to rely on them for differential diagnostic decisions.

A discussion of psychometric requirements for enabling usage of scales for diagnostic purposes is beyond the purview of this chapter. Nevertheless, it is useful to recall that if a measure differentiates statistically between two groups, such as depressed vs. anxious children, the difference is not an indicator of the utility of the measure as a clinical or diagnostic tool. Many other conditions must be met before assessments can contribute to diagnostic assignment.

The limitations of the older anxiety rating scales, and renewed interest in the study of childhood anxiety disorders, have spurred the development of more sensitive and diagnostically relevant measures of childhood anxiety. Recent efforts reflect the shift in the classification of anxiety disorders, and there has been a move toward specificity of content, with relevance to diagnostic groupings. In this vein, several scales have been devised, such as the Social Anxiety Scale for Children (La Greca *et al.* 1988; La Greca & Stone 1993) and for adolescents (La Greca & Lopez 1998), the Multidimensional Anxiety Scale for Children (MASC; March *et al.* 1997; March & Albano 1998) and the Screen for Child Anxiety Related Emotional Disorders (SCARED), which has a parent version (Birmaher *et al.* 1997; Monga *et al.* 2000). The MASC and SCARED stand out as promising for clinical purposes, because they were sensitive to the effects of fluvoxamine, a serotonin-specific reuptake inhibitor (SSRI), in a placebo controlled trial in children and adolescents with anxiety disorders (Research Units on Paediatric Psychopharmacology Anxiety Group, in press).

The Hamilton Anxiety Scale (HAS; Hamilton 1959, 1969), a clinician-based assessment, was developed for use in adults. It has had limited application in younger populations (Clark & Donovan 1994), maybe because it is weighted heavily with somatic symptoms, which are not believed to be clinically relevant to young patients. Unlike other scales in the RUPP Anxiety Study Group (2001), the HAS score was not significantly

affected by fluvoxamine relative to placebo at all sites, suggesting limited utility for the measure.

Diagnostic interviews

There are several systematic diagnostic interviews for children, and for parents as informants about their child (Shaffer *et al.* 1999). They have been devised to meet different purposes, and vary accordingly. The Diagnostic Interview Schedule for Children (DISC; Shaffer *et al.* 1996) was developed for use in epidemiological studies, to be administered by individuals without clinical training. It is therefore highly structured, and the interviewer has the sole function of reading the interview content. The DISC provides a computer-administered version that eliminates the interviewer. As one study reported fair agreement among clinic patients, between standard DISC diagnoses and clinicians who administered the DISC, as well as a clinical interview, it has been claimed that the interview has a role in clinical settings (Schwab-Stone *et al.* 1996). That non-clinicians can provide valid clinical diagnoses in referred groups requires better documentation, especially because diagnostic rates are relatively elevated in epidemiological studies that have relied on the DISC (see Table 30.1).

The Child and Adolescent Psychiatric Assessment (CAPA; Angold & Costello 1995), also devised for epidemiological studies, is less structured than the DISC, requires some appreciation of clinical syndromes, and allows for clarification of questions by the interviewer. As a result, it entails extensive training for proper implementation. The CAPA resembles more closely usual clinical interview procedures than other diagnostic instruments by inquiring about areas of function, such as school, social relationships, etc., as well as specific symptoms, whereas most other instruments focus on symptoms exclusively.

The Kiddie Schedule for Affective Disorder and Schizophrenia (K-SADS) was developed for use by clinicians and allows full latitude of inquiry (Chambers *et al.* 1985). Multiple versions exist (Kaufman *et al.* 1997), including a highly structured version administered by lay interviewers (Orvaschel *et al.* 1982).

The Diagnostic Interview for Children and Adolescents (DICA) (Herjanic & Reich 1982; Reich *et al.* 1991) is also highly structured, but at times has been used in semistructured format.

The Anxiety Disorders Interview Schedule for Children (ADIS) was designed originally to provide detailed information on child and adolescent anxiety disorders obtained in flexible clinical fashion (Silverman & Albano 1996). It has been expanded to provide diagnoses for other major disorders.

There is little to guide the selection of one instrument over another, in terms of better reliability or validity. All have demonstrated modest to adequate test–retest reliability, with the anxiety disorders faring no better or worse than most other diagnoses. The DISC, developed under contract from the National Institute of Mental Health (NIMH) for use in epidemiological research, has provided more information on its psychometric properties than any other interview. It is the most widely used

worldwide, perhaps because of its source, which has resulted in major dissemination efforts. It has been used in large multisite clinical studies developed under the aegis of the NIMH (MTA Cooperative Group 1999). The few direct comparisons between diagnostic interviews do not support the expectation that they yield similar rates of anxiety disorders, and therefore are interchangeable (Carlson *et al.* 1987; Cohen *et al.* 1987). The finding that method variance affects rates of psychiatric disorders complicates straightforward interpretation of the disparate rates of anxiety disorders across studies.

Although conceived for research purposes, diagnostic interviews may be useful to clinicians because they provide comprehensive coverage of symptomatic status. Also, they are excellent teaching tools for training in clinical diagnosis by providing a systematic means of ensuring that no important symptom domain has been overlooked.

The key issue is whether anxiety disorders generated by structured interviews are valid. Evidence points to the validity of diagnoses of social phobia, through consistent demonstration of onsets in adolescence, and the specificity of its longitudinal course (Pine *et al.* 1998a), which is discussed below. Inconsistent findings concerning the predictive significance of childhood anxiety disorders in girls and boys (McGee *et al.* 1992; Pine *et al.* 1998a; Costello *et al.* 1999) raise questions about the validity of diagnoses in childhood. If the findings from Pine *et al.* (1998a) are replicated, showing that overanxious disorder (now generalized anxiety disorder) has no specific longitudinal course, the syndromal distinctness and significance of the disorder will be questionable. Rather, overanxious disorder might be a marker of severity in a range of pathology. It is difficult to estimate the validity of anxiety disorders based on results from any one study, because interviews are not interchangeable and findings may be specific to the measure used. As a result, each interview schedule has to have demonstrated diagnostic validity—a costly enterprise.

Conclusions

Rating scales of anxiety have not been shown to distinguish between: various anxiety disorders; anxiety disorders and other child psychiatric disorders; or anxiety and depression symptoms. As such, they have not reached a sufficient level of precision for diagnostic classification. Two scales have been found to reflect treatment effects, and can contribute to the assessment of therapeutic efficacy in children with anxiety disorders. Several diagnostic interviews have been developed, with reliability estimates for anxiety disorders that do not differ from the reliability of most other diagnoses. There is evidence of validity for social phobia diagnoses derived from systematic interviews.

Epidemiology of anxiety disorders of childhood

Across several continents, well-executed epidemiological stud-

ies have informed on the prevalence, comorbidity, possible risk factors and, to a limited extent, course of anxiety disorders. These studies have the great advantage of avoiding the confounds of self-selection and other features that bias the information obtained from clinical studies.

Prevalence of childhood anxiety disorders

Population studies that report on anxiety disorders are presented in Table 30.1. As noted, focus is on investigations that have obtained direct information from children and/or parents. Epidemiological studies that antedate such practices have been reviewed previously (Links 1983).

Problematically, an overview of the prevalence of anxiety disorders is complicated by shifts in diagnostic convention. For example, avoidant and overanxious disorders that were in the DSM-III and DSM-III-R were removed from the classification with the advent of the DSM-IV. Social phobia now encompasses what was previously avoidant disorder, and generalized anxiety disorder substitutes for overanxious disorder. These disorders are not completely equivalent; especially in the case of overanxious disorder for which it is unclear whether it is captured by generalized anxiety disorder. One study (Pine *et al.* 1998a) formulated diagnoses of generalized anxiety and overanxious disorder in the same cases, and either or both disorders could be given. Modest concordance between the two diagnoses was found, suggesting that they do not reflect the same syndrome. Ongoing epidemiological studies are obtaining DSM-IV and ICD-10 diagnoses, but the published literature antedates them. However, the diagnoses of separation anxiety disorder, and simple as well as social phobia, have remained virtually unchanged in the DSM-IV, so that previous studies are relevant to the current nomenclature.

Table 30.1 is limited to prevalence of anxiety diagnoses; other syndromes are discussed in other chapters. Most epidemiological studies have found that anxiety disorders are the most common mental disorders in children and adolescents. Similar results have been obtained in adults (Christie *et al.* 1988). Epidemiological studies do not report on panic disorder in preadolescents. The few population-based studies that have reported the disorder's frequency in adolescents have found low rates, below 1% for lifetime (Whittaker *et al.* 1990; Pine *et al.* 1998a; Reed & Wittchen 1998), and lower frequencies for the past 6 or 12 months (Verhulst *et al.* 1997; Reed & Wittchen 1998). In preadolescents (below age 13), separation anxiety disorder is more prevalent than overanxious disorder (Anderson *et al.* 1987; Costello *et al.* 1988, 1996; Velez *et al.* 1989; Gurley *et al.* 1996). This ranking is reversed in adolescents in some reports (McGee *et al.* 1990; Fergusson *et al.* 1993; Verhulst *et al.* 1997), but not all (Velez *et al.* 1989). In DSM-III-R, the diagnosis of overanxious disorder was heavily weighted by symptoms of social anxiety; therefore, the pattern of relative frequency of separation anxiety and overanxious disorders in childhood and adolescence fits well the developmental literature on vulnerabilities to various types of anxiety disorders at different ages.

Rates of any anxiety disorder in children or adolescents within the past 6 or 12 months, range from 1.8% in New Zealand (Anderson *et al.* 1987) to 23.5% in Holland (Verhulst *et al.* 1997). It follows that there are also large differences in the prevalence of individual anxiety disorders. These striking discrepancies point to factors that may be important in affecting the diagnosis of anxiety disorders in children.

For one, age is a key issue. The modal age of onset of anxiety disorders varies. A consistent finding of epidemiological studies is that social phobia is relatively more common in adolescence. This finding gives indirect support to the validity of the assessments of social phobia in non-clinical populations. Longitudinal epidemiological studies would be informative, but they are scarce. Exceptions, such as the New York Study (Pine *et al.* 1998a) and the Dunedin studies (Anderson *et al.* 1987; McGee *et al.* 1990), indicate an increase in social phobia from childhood to adolescence in the same children, confirming that the disorder occurs more frequently in adolescence than childhood.

At the same time, there is marked variation in prevalence among similar aged groups across different studies. Some of this variation may reflect true differences because it has been argued that there may be geographical discrepancies in rates of anxiety disorders, at least in adults. However, disparate rates emerge even when site differences seem minimal. Two well-executed studies of adolescents, using similar interviews and both conducted in urban sites in Germany—Bremen (Essau *et al.* 1999) and Munich (Wittchen *et al.* 1999)—report lifetime rates for social phobia of 1.6 and 4%, respectively. A greater than twofold difference in prevalence is not inconsiderable. The 1.6% prevalence for social phobia in Bremen is for 12–17-year-olds, whereas the 4% rate in Munich is for 14–17-year-olds. This age difference could be key to the divergent rates, but it is not. The Bremen study indeed found that 12–14-year-olds had a significantly lower rate of social phobia than 14–17-year-olds (0.5 vs. 2.0%) (Essau *et al.* 1999). However, the 14–17-year-olds in the Bremen study had half as much social phobia as a similar aged group in the Munich study (Wittchen *et al.* 1999). As evident in Table 30.1, another case in point are the New Zealand studies from Dunedin (McGee *et al.* 1990) and Christchurch (Fergusson *et al.* 1993) which, in spite of applying similar assessments in similar aged cohorts, report a fourfold difference in rates of separation anxiety disorder (2.0 and 0.5%, respectively). No anxiety disorder is spared discrepancies in prevalence even when diagnostic definitions are identical and sites appear indistinguishable.

Thus, in spite of applying a uniform definitional standard for diagnoses, in the hope of limiting inconsistencies because of variable means of assessment, there is considerable divergence across rates of anxiety disorders. Variability in prevalence occurs in all child psychiatric disorders, but different factors may be at play in various conditions. In determining the presence of anxiety disorders, one relies on children's and parents' judgments, often lacking corroboration through objective observations by the informant. Given the highly subjective nature of

informant judgements, it is likely that the method used for eliciting anxiety symptoms affects reporting.

In addition, there is no consensus about diagnostic thresholds and what rules diagnoses in or out, so that rates vary greatly depending on the convention applied. For example, rates are relatively high if diagnoses of anxiety disorders do not require that symptoms impact function. Some ignore the issue of impairment; others require it. Yet others use an overall index of impairment which is interpreted as documenting the diagnostic importance of all symptoms reported. Table 30.1 illustrates clearly that diagnostic rates are reduced sharply if diagnoses are made only when impairment is present. Problematically, an overall index of impairment, such as that obtained from the Children's Global Assessment Scale (C-GAS; Shaffer *et al.* 1983), a commonly used impairment scale, may not reflect impairment caused by a specific diagnosis. Also, when several disorders exist, each may not incur the same impairment. The use of a single global judgement of impairment is likely to exaggerate the frequency of comorbidity, because no distinction can be made among diagnosed disorders as to their respective contribution to impairment. Only one study has compared prevalence rates as a function of diagnostic definitions (Shaffer *et al.* 1996). The overall rate of anxiety disorders was considerably lower when diagnosis-specific rather than global impairment measures were applied (13.9 vs. 20.5%). A key problem for judging impairment is the lack of any standard definition. How much or little is enough? Moreover, because global impairment measures are not designed for dysfunctions characteristic of specific disorders, they are amenable to local interpretation, and hardly represent thermometers of functional status in children. Divergent rates may reflect, in part, different local concepts of impairment. This problem is much less likely to occur in interviews that provide specific impairment definitions for each class of symptoms (e.g. the CAPA; Angold & Costello 1995). At the same time, serious overall impairment has been found to contribute to the stability of some anxiety disorders in children (Cohen *et al.* 1993; Costello *et al.* 1999). Although requiring impairment for diagnosis has a great deal of clinical and common sense appeal, and now has empirical support, it is not known whether the standard is appropriate in all cases. For example, adolescents with social fears (Essau *et al.* 1999), and with panic attacks (Reed & Wittchen 1998), who did not qualify for a diagnosis of social phobia or panic disorder, had high comorbidity with other disorders. It may be that impairment is relatively more critical to diagnostic validity in younger children, whose conditions are likely to be of relatively recent origin and transient. Impairment can be especially difficult to determine for the anxiety disorders in cases where the environment accommodates the child's anxious concerns. Some families, at times without deliberate planning, eliminate activities that cause distress to the child, and avoid making demands on the child. When this pattern occurs, impairment may be masked and not obviously apparent.

Not all studies are conducted during the same time period. Could it be that there are secular changes that affect rates of

anxiety disorders? This possibility cannot be ruled out, but does not seem to account for discrepancies across studies, because results do not suggest time-dependent rates of anxiety disorders in young people (see Table 30.1).

Another problem for consistent diagnosis of anxiety disorders is that informant agreement is poor. It is commonplace to interview parents about their children. Depending on their age, children also contribute valuable information about themselves, especially about internal states, such as worries and fears. Studies that specify rates of anxiety disorders reported by children and parents, separately as well as jointly, reveal very different rates for each source, with little overlap between the two sources (see Table 30.1). Whether the same discrepancies occur to a similar extent in clinical cases is not known, but seems unlikely. At the very least, there is no dilemma about the issue of impairment in children brought for treatment because children with trivial dysfunction rarely come to clinical attention. How should multiple sources be used or combined? Some consider symptoms present when endorsed either by the child or parent. Others identify an optimal informant and disregard the others. These two strategies are essentially what clinicians do, depending on the individual case, based on their opinion of each informant's ability to provide accurate information. A more sophisticated approach has been to derive a statistical estimate of the diagnosis or latent class (Fergusson *et al.* 1993). This strategy has generated rates that closely parallel those generated by the 'optimal informant' method, but it has not been compared to the 'either parent or child' approach to diagnosis.

It is generally agreed that the answer regarding optimal approach to diagnosis will come from studies that examine the relative accuracy of diagnostic conventions in predicting course, as well as other features such as genetics and biological markers. There is some evidence that childhood anxiety disorders without impairment are not predictive of difficulties in adolescence, whereas the same is not true for disorders with impairment (Costello *et al.* 1999). At the same time, it is possible for impairment to occur in syndromes that are subthreshold for diagnosis (Reed & Wittchen 1998).

Conclusions

Based on the weight of the evidence in children, a fair estimate of current prevalence for any anxiety disorder accompanied by impairment appears to be between 5 and 10% (Anderson *et al.* 1987; Costello *et al.* 1996). Results suggest that similar rates apply to adolescents (Kashani *et al.* 1987; McGee *et al.* 1990; Fergusson *et al.* 1993; Kramer & Garralda 1998), with some exceptions in which rates exceed 20% (Shaffer *et al.* 1996; Verhulst *et al.* 1997). Additionally, epidemiological studies have been important in confirming that child (Benjamin *et al.* 1990) and adolescent disorders (Wittchen *et al.* 1999) are associated with significant impairment in multiple functional domains.

Risk factors for childhood anxiety disorders

Epidemiological studies are potentially the most enlightening means of identifying factors associated with illness. The most consistent finding has been that, at all ages, girls are overrepresented among individuals with anxiety disorders of all ages. This sex difference is virtually universal across studies. The twofold preponderance of girls among children with anxiety disorders has been claimed to occur as early as age 6 (Lewinsohn *et al.* 1998). Sex may also influence the stability of anxiety disorders because childhood anxiety disorders have been reported to have greater predictive impact for later anxiety in girls than boys (McGee *et al.* 1992; Costello *et al.* 1999), but findings are not unanimous (Pine *et al.* 1998a). In addition, some have reported headaches to be associated with anxiety disorders in girls but not boys (Egger *et al.* 1998), but others have not (Pine *et al.* 1996).

The documentation of a sex difference in childhood anxiety has influenced theories of psychopathology. It has been conjectured that vulnerability to depression in women may be partly caused by the greater prevalence of early anxiety disorders in women (Breslau *et al.* 2000). Indeed, in a prospective epidemiological study, Breslau *et al.* (2000) found, as expected, that women were twice as likely as men to have had an anxiety disorder and to become depressed in adulthood. However, men and women with histories of anxiety were equally vulnerable to the development of depression, and early anxiety disorders accounted to a large degree for the sex difference in adult depression. Problematically, studies of adults rely on retrospective reports of anxiety whose accuracy may differ by sex. Moreover, the role of early anxiety as a risk factor for adult depression needs to be reconciled with the fact that rates of depression escalate markedly after puberty (Angold *et al.* 1998), but rates of anxiety, in general, do not. However, as noted further on in the review of the course of childhood anxiety disorders, there is support for the expectation that anxiety disorders in childhood are risk factors for depressive disorders in adulthood.

Although relationships between smoking and anxiety had been observed in cross-sectional and retrospective studies, it was not possible to disentangle their causal relationship. A recent prospective epidemiological survey of adults found that smoking predicted the onset of panic attacks, but not vice versa (Breslau & Klein 1999). A subsequent prospective epidemiological study of adolescents also found that daily smoking was a significant predictor of anxiety disorders in adulthood, including agoraphobia and panic disorder, but not social phobia (Johnson *et al.* 2000). Importantly, anxiety disorders in non-smoking adolescents did not predict smoking in adulthood. It has been suggested that it is through its dysregulation of respiratory function that smoking places individuals at risk for some forms of anxiety.

There is little consensus regarding other risk factors for anxiety disorders in children (Costello & Angold 1995). A variety of environmental and family features, including economic disadvantage, school failure, stressful life events, family dysfunction, single-parent households, parental emotional problems, and

low parental education have been related either to separation anxiety or overanxious disorder. However, unlike risk factors for conduct disorders, no consistent pattern has emerged.

In the Dunedin longitudinal study, risk factors were found for behaviour disorders, but no pattern emerged for anxiety disorders (McGee *et al.* 1992). Although epidemiological studies offer unique opportunities for assessing risk factors, they also have inherent limitations. Although anxiety disorders are common in the general population, each specific anxiety disorder is relatively scarce. Consequently, the number of affected children is small. As an example, among the 1035 adolescents studied by Essau *et al.* (1999), only 17 had social phobia. The Dunedin study examined risk factors for 'internalizing disorders' by combining all cases of anxiety and depressive disorders. In spite of its large sample of over 700 children, only 23 were identified with internalizing disorder (Williams *et al.* 1990). When addressing important questions, such as distinctions between girls and boys or between ages of onset, sample sizes become vanishingly small. The challenge will be to develop strong hypotheses that can be refuted without requiring large samples of affected individuals, as well as to identify the mechanisms that account for the contribution of anxiety disorders to young people's vulnerability for later depression. So far, epidemiological studies of risk factors have been fishing expeditions. The most heuristic observation is that disparate risk factors may be associated with different anxiety disorders. On the other hand, this suggestion is difficult to reconcile with claims of high overlap across anxiety disorders.

Conclusions

The lack of uniform standards for diagnosing anxiety disorders complicates estimates of prevalence in children and adolescents. There is inconsistency in sources of information, and in the requirement for impairment in symptomatic individuals. In spite of these methodological dilemmas, the evidence from epidemiological studies, with regard to anxiety disorders, provides support for:

- 1 relatively elevated rates, estimated to be between 5 and 10%;
- 2 their causing clinically significant impairment;
- 3 the significant longitudinal contribution of impairment in childhood to dysfunction into adolescence;
- 4 an approximate twofold preponderance of girls; and
- 5 the possibility that childhood anxiety disorders have different longitudinal consequences in girls and boys.

Recently, smoking has been identified as a risk factor for the development of anxiety. The identification of risk factors in childhood anxiety disorders has been hampered by a lack of cogent hypotheses.

Longitudinal course

The long-term consequences of childhood anxiety disorders take on special importance given the high proportion of affected

children. Although a considerable literature exists, interpretations of studies on the outcome of childhood anxiety disorders are complicated by methodological issues, such as the nature of the samples, procedures implemented to evaluate children, and definitions of outcome, including psychiatric diagnosis and indices of overall function.

Often, one cannot assume that the assessment of anxiety disorders has been established reliably. While recent approaches have fared relatively better, the longest follow-up studies necessarily relied on older measures, with questionable reliability. As reliability places an upper limit on associations, outcome findings may represent lower-bound estimates of the impact of anxiety disorders on later adjustment. Moreover, the information on outcome relies mostly on studies of clinical cases. As children with uncomplicated or pure anxiety disorders are less likely to present for treatment than those with comorbid psychopathology (Cohen *et al.* 1987; Costello *et al.* 1999), studies of children in clinical settings may not capture the broad course of childhood anxiety. Usually, no matter what the disorder, children in treatment centres experience a more sustained and impairing course than children ascertained in the community. Another strategy has been to examine children at high risk (Weissman *et al.* 1997). These studies follow the children of parents with anxiety disorders, for whom it is expected that comorbidity and outcome patterns are less influenced by referral biases than is the case in clinical patients. However, high-risk studies must grapple with referral biases among parents, and the effects of parental psychopathology on reports of psychopathology in their children (Breslau *et al.* 1988).

Some of the initial epidemiological data on outcome relied on retrospective reports from adults. Because of the influence of current emotional state on recall, it may be that adults with ongoing mood or anxiety disorders selectively report negative childhood experiences, thus exaggerating the contribution of early anxiety on later adjustment.

Two major sources of data have addressed the developmental progression of childhood anxiety disorders: studies of the relationships between early life temperament, especially behavioural inhibition, and later anxiety; and studies of the outcome of specific anxiety disorders.

Inhibited temperament and psychopathology

Kagan *et al.* (1988, 1995), in Boston, first called attention to the relationship between childhood temperament and later anxiety disorders. Kagan noted that a subset of young children react with apprehension in novel situations. These children are defined as highly reactive during infancy and as behaviourally inhibited during toddlerhood. Inhibited children are slow to speak and smile in social settings. Criteria for inhibited temperament have been set to identify approximately 15% of toddlers. Relying on different approaches but using similar criteria, at least five other groups have studied temperamentally inhibited or uninhibited children. Rubin (1993) and Calkins *et al.* (1996) used

observational methods similar to those of Kagan *et al.* (1988); Caspi *et al.* (1996) used psychologists' observations during testing of preschool-age children; Kerr *et al.* (1997) and Hayward *et al.* (1998) used rating scales in older children. Altogether, associations between inhibition and psychopathology have been examined in thousands of children. In all centres, results suggest an association between behavioural inhibition and later anxiety (Kagan *et al.* 1995), with distinct associations at different developmental periods. During school-age years, Kagan's inhibited toddlers were found to have elevated rates of various anxiety disorders, including separation anxiety disorder and various phobias (Biederman *et al.* 1995). Similarly, Rubin (1993) reported associations with a range of symptoms on anxiety rating scales in young children. Caspi *et al.* (1996) found that inhibition at age 3 was associated with measures of anxiety and depression at age 21. Across these cohorts, associations with anxiety vary in strength, but none approach the magnitude of stability found for conduct problems across similar ages. Correlations between inhibition and anxiety ratings over time fall in the 0.20–0.40 range. However, there appears to be a specific link between early behavioural inhibition and social phobia in adolescence (Hayward *et al.* 1998; Schwartz *et al.* 1999), with odds ratios in the 2.0–4.0 range.

In addition to its association with anxiety, behavioural inhibition has been reported to influence the development of later behaviour problems (Kagan *et al.* 1995). Results from the Boston group (Schwartz *et al.* 1999), and from Kerr *et al.* (1997) in Canada, indicate lower rates of behaviour disorders in inhibited compared to uninhibited children. However, it is unclear whether this difference reflects relatively low rates of behaviour problems in inhibited children or high rates in those who were uninhibited (Raine *et al.* 1998).

An Australian longitudinal study recently reported that shyness in early childhood was significantly associated with parent and self-rated anxiety in early adolescence (ages 13–14), with odds ratios around 2.0 (Prior *et al.* 2000). In addition, the *persistence* of shyness through development was a predictor of later anxiety. Among the adolescents, 11.7% of those with little or no childhood shyness were considered anxious, vs. 41.5% of those with consistent childhood shyness. However, most shy children did not have high anxiety levels later on, and most adolescents with anxiety had not been shy children. Yet, the relationships observed are impressive in so far as they relied on rating scales of shyness and of anxiety. These are likely to underestimate the extent of longitudinal relationships.

Stability of anxiety disorders

The study of diagnostic stability of anxiety disorders has been examined among community cases, high-risk children and clinical patients, using retrospective and prospective designs.

Despite limitations of retrospective studies, they may provide leads for further study. The ease with which retrospective data can be collected is a major advantage (Robins 1978). Retrospec-

tive studies of adult anxiety disorders have called attention to the possible role of childhood anxiety disorders over time. Two large epidemiological studies in the USA, the Epidemiological Catchment Area (ECA) study, and the National Comorbidity Survey (NCS) found that the majority of adults with specific and social phobia reported childhood onsets (Robins & Regier 1995; Curtis *et al.* 1998). In contrast, adults with panic disorder and generalized anxiety disorder reported onsets in early adulthood, although some anxiety symptoms during adolescence were common (Eaton *et al.* 1991; Robins & Regier 1995; Wittchen *et al.* 1998). Also, self-reports of childhood generalized anxiety disorder in the NCS were associated with major depression in adulthood (Kessler & Walters 1998). These large community-based observations are generally consistent with retrospective clinical studies of adults, which have found that a large proportion of adults with panic disorder report childhood anxiety (Alpert *et al.* 1994; Labbate *et al.* 1994; Otto & Whittall 1995; Manfro *et al.* 1996).

Five community-based studies have examined the course of specific anxiety disorders. Although the first, from Dunedin (Anderson *et al.* 1987), did not specify outcome for individual anxiety disorders, some conclusions may be inferred (McGee *et al.* 1992; Feehan *et al.* 1993; Newman *et al.* 1998). In the initial follow-up, from age 11–15, a composite index of any mood or anxiety disorder predicted later anxiety for girls, but not boys (McGee *et al.* 1992). Comparable sex differences were obtained in prospective studies (Costello *et al.* 1999; Rueter *et al.* 1999). The latter also found that internalizing symptoms predicted a diagnosis of major depression.

These studies suggest that early broad indicators of anxiety disorders at one age predict risk for mood or anxiety disorders at a later age. However, they provide limited information on the course of specific anxiety disorders. Using a school-based cohort, Hayward *et al.* (1998) reported some degree of specificity in the course of social phobia across adolescence, but they did not find an association between self-ratings of past separation anxiety disorder and later panic disorder in adolescents. Lewinsohn *et al.* (1998) found that early adolescents with an anxiety disorder faced a threefold risk for anxiety disorders in late adolescence. Consistent with other family data (Wickramaratne & Weissman 1998), Lewinsohn *et al.* (1997) also noted that adolescents with both anxiety and depression were especially likely to have poor outcomes. This study did not find significant specificity in the short-term course of individual anxiety disorders.

Another longitudinal community-based study examined the outcome of specific anxiety disorders (Cohen *et al.* 1993; Pine *et al.* 1998a). There was relatively poor stability for overanxious disorder from early to late adolescence ($\kappa = 0.29$) (Cohen *et al.* 1993). A different longitudinal pattern characterized the course of anxiety disorders into early adulthood (Pine *et al.* 1998a). Specific phobia during childhood or adolescence predicted specific phobia exclusively in adulthood. Similarly, previous social phobia was predictive of social phobia in adult-

hood, and no other adult disorder. The two disorders yielded odd ratios in the 2.0–5.0 range. Separation anxiety disorder predicted no specific disorder, but tended to predict panic attacks, whereas overanxious disorder was associated with an array of adult disorders including any anxiety disorder and major depression.

Beyond these community-based studies, two prospective high-risk studies have followed children of parents with either major depression or panic disorder. Anxiety disorders early in life, particularly phobia and overanxious disorder, incurred a two- to fourfold increase of major depression at follow-up (Wickramaratne & Weissman 1998). Similarly, children ascertained through a family study of anxiety and substance use disorders had elevated rates of anxiety and depressive disorders (Merikangas *et al.* 1999).

The course of childhood anxiety disorders has also been reported for clinic samples. Two studies ascertained children with school refusal and prominent anxiety symptoms prior to the nosological standardization introduced in the early 1980s (Berg & Jackson 1985; Flakierska-Praquin *et al.* 1997). The majority of children experienced relatively benign clinical courses into adulthood. Two other studies (Klein 1995; Last *et al.* 1996) confirm the generally good outcome of children with anxiety disorders referred to a child psychiatric clinic. In the study by Klein (1995), separation anxiety disorder coupled with school phobia predicted panic disorder, as well as major depression, though panic disorder was uncommon.

Conclusions

Data from longitudinal studies lead to several conclusions. Childhood anxiety disorders show considerable stability, but most children with anxiety disorders do not have anxiety disorders in adulthood. However, most adults with anxiety as well as mood disorders are very likely to have suffered from a childhood anxiety disorder. Furthermore, anxiety disorders in childhood increase the risk for later depressive disorders. Specificity of course into adulthood has been found for specific phobias and social phobia and, to some extent, for separation anxiety disorder but not for overanxious disorder.

Family genetics of childhood anxiety

The sequencing of the human genome has stimulated great interest in the familial aggregation of psychiatric disorders, including childhood anxiety disorders. During the past 25 years, more than 20 studies have reported an association between various forms of parental psychopathology and childhood anxiety. A series of studies document an association between child anxiety disorders and various parental psychiatric disorders. These studies include so-called ‘top-down’ studies which evaluate the children of parents with anxiety disorders, as well as a handful of so-called ‘bottom-up’ studies, which ascertain the parents of

Table 30.2 Anxiety in children as a function of parental psychopathology.

		Odds ratio between parental psychopathology and anxiety disorders in offspring vs. normal controls
<i>Top-down studies</i>	<i>Parental diagnosis (number of offspring)</i>	
Weissman <i>et al.</i> (1984)	MDD and PD (19) (mothers)	10.4*
	MDD (23) (mothers)	2.3

	OAD and SAD (17)	10.7*

* 95% Confidence interval of odds ratio excludes 1.0 (statistically significant at $P < 0.05$).

Parental diagnoses: AGO, agoraphobia; MDD, major depressive disorder; OCD, obsessive-compulsive disorder; PD, panic disorder.

Offspring diagnoses: AD, anxiety disorder including PD, OCD or social phobia; GAD, generalized anxiety disorder; OAD, overanxious disorder;

SAD, separation anxiety disorder.

T1, time one; T2, 2-year follow-up.

children with anxiety disorders. In light of consistent cross-generational transmission, attempts have been made to decompose the familial transmission into environmental and genetic components, and some have attempted to delineate the process by which anxiety is transmitted from parent to child. This effort has involved studies of parent-child relationships, as well as studies of temperamental or biological profiles of children born to parents with anxiety disorders.

Anxiety and parental psychopathology

Multiple studies report higher rates of anxiety disorders in children of parents with anxiety disorders, relative to children of non-ill parents. As shown in Table 30.2, they include 'top-down' and 'bottom-up' studies. Two studies of adults also suggest that a childhood-onset anxiety disorder may identify a particularly heritable form of psychopathology. Specifically, Goldstein *et al.* (1994) found higher familial aggregation of panic disorder in relatives of adult patients with early onsets compared to families in which the patients had onsets in adulthood. Similarly, Battaglia *et al.* (1995) found higher loading for panic disorder in families where patients reported a history of childhood separation anxiety disorder.

Among adults, there is a growing literature on familial and ge-

netic aspects of conditions related to the anxiety disorders. In general, this literature parallels the literature on childhood disorders; there is evidence of specificity in familial transmission in some instances but not in others. Kendler *et al.*'s (1996, 1997) twin studies support strong associations in the genetic factors implicated in generalized anxiety disorder and major depressive disorder. These two conditions are thought to share an underlying genetic substrate, differing largely in contributions from non-shared environmental factors. In contrast, other anxiety disorders show more evidence of distinct genetic risk. For example, genetic risk for panic disorder appears distinct from the risk for phobias, for generalized anxiety disorder, as well as major depression (Kendler, 1997; Kendler *et al.*, 1999). Findings from twin studies and family studies are consistent (Goldstein *et al.* 1994). Family studies have found that 'pure' cases of panic disorder and major depression tend to 'breed true'; in other words, panic disorder in the absence of depression is not associated with major depression in relatives. Similarly, data from twin studies implicate distinct genetic factors in the phobias. These data are also consistent with family studies where phobias confer relatively specific risks among family members (Fyer *et al.* 1993; Fyer 1998). Nevertheless, firm conclusions do not readily emerge from these data on familial genetic aspects of adult anxiety disorders. The strongest evidence of specificity in

family studies derives from research on 'pure' cases (those with limited if any comorbidity). In cases with comorbidity, such as in adults with panic disorder and social phobia, evidence of non-specificity emerges (Horwath *et al.* 1995). Similarly, twin studies performed in the community may be less likely than clinic-based family studies to select cases with high rates of comorbidity, which may account for some evidence of specificity in family genetic risk. Moreover, not all twin studies support the view of specificity in genetic risk (Andrews 1990).

Ongoing twin studies are delineating the degree to which familial associations may result from genetic, and shared or unshared environmental factors. Only tentative conclusions can be drawn because twin studies have reported divergent estimates of heritability for rating scale scores of childhood anxiety (Topolski *et al.* 1997; Topolski 1998) and of interview-based symptom scale ratings (Silberg *et al.* 1999). As with data from adult twin studies, the twin data in children are consistent in suggesting a modest genetic component to most forms of childhood anxiety, with heritabilities generally less than 40–50%. These relatively low heritabilities across the age range have led to the suggestion that genes confer a broad diathesis towards anxiety as opposed to a predilection for one or another specific disorder. Consistent with this possibility, heritabilities for temperamental factors, such as behavioural inhibition, have been somewhat higher than those for specific anxiety symptoms or disorders. Non-shared environmental factors account for much of the remaining variance in child-based twin studies of anxiety symptoms, much as they do in adults. Nevertheless, the data in children show considerable variability across samples in genetic and environmental contributions to anxiety. Such variability may reflect distinct genetic and environmental effects across age, sex and specific forms of anxiety.

A key question arising from family and twin studies concerns the degree to which connections between parent and child anxiety represent specific diagnostic associations. Most studies report associations between parental panic disorder and a range of childhood anxiety disorders. However, several studies suggest a particular relationship between parental panic disorder and childhood separation anxiety disorder (Warner *et al.* 1995; Capps *et al.* 1996). Conversely, family studies of adults, as well as two family studies of children, suggest specificity in the transmission of social phobia (Fyer *et al.* 1993; Merikangas *et al.* 1998). However, the limited number of children and parents with 'pure' forms of specific anxiety disorders limits firm conclusions with respect to the diagnostic specificity of risk conferred to children by parental anxiety disorders.

Other questions related to diagnostic specificity concern the degree of overlap in risk for anxiety and depression. 'Top-down' studies document a strong association between parental major depression and childhood anxiety disorders, particularly specific phobia and overanxious disorder or generalized anxiety disorder (Warner *et al.* 1995; Beidel & Turner 1997; Weissman *et al.* 1997). These findings are consistent with twin and family studies of adults, in whom common genetic factors may predispose to depression and generalized anxiety disorder (Kendler

1996; Kendall & Flannery-Schroeder 1998). Based on these findings, Wickramaratne & Weissman (1998) suggest that childhood anxiety signals a particularly familial form of mood disorder.

A range of factors, including environmental, temperamental and psychophysiological, have been examined in efforts to identify mechanisms related to the tie between parental and child anxiety disorders. As in the area of twin research, the paucity of available data precludes conclusions in this area.

Conclusions

Findings from family studies clearly establish the cross-generational transmission of anxiety from parents to children. These data have stimulated the pursuit of key questions, one of which concerns the degree of specificity in familial associations among anxiety disorders. A second question concerns the mechanisms of intergenerational transmission.

Behavioural genetic studies in child and adolescents are extending work carried out in adult anxiety disorders. Twin studies, which are highly informative, suggest that there are moderate genetic components to anxiety in adults, and a relatively large contribution from non-shared environmental effects (Kendler 1996). Conclusions from twin studies in children have yet to emerge, given the ambiguities in the determination of childhood anxiety. For example, heritability estimates may vary for self as opposed to parent reports. Variability in heritability may also emerge as a function of gender or developmental level (Topolski *et al.* 1999). Despite these complications, efforts to resolve these issues may eventually clarify aetiological factors in childhood anxiety. For example, twin studies may identify mechanisms that influence comorbidity (Simonoff 2000), especially because studies in adults demonstrate the utility of twin designs in this regard.

Familial features of childhood anxiety disorders

Various aspects of parent–child interactions have been suggested as contributing to child anxiety disorders. Parental behaviours include:

- 1** modelling of avoidant or anxiety promoting behaviour through parental overprotectiveness;
- 2** direct production of anxiety through harsh rearing practices; and
- 3** facilitation of anxiety through failures to soothe children.

These aspects of the parent–child relationship are generally viewed from a transactional perspective, with possible contributions from parent behaviour, child behaviour, and their interaction. Based on these models, treatment approaches have been designed to alter parent–child interactions patterns and child anxiety (Barrett 1998).

Behavioural inhibition is thought to constrain variability in later behaviour and interact with parental behaviour ultimately to produce anxiety in the child. For example, behaviourally inhibited children raised by parents showing high levels of

emotional expressivity may be particularly vulnerable to high levels of anxiety later on (Hirshfeld *et al.* 1997).

Other transactional relationships between parent and child behaviour focus on attachment and reactions to separation. Bowlby originally hypothesized that attachment behaviours reflect interactions between evolutionarily derived genetic factors and environmental influences. Warren *et al.* (1997) found that toddlers who exhibited abnormal behaviours during separation faced an elevated risk for anxiety, particularly separation anxiety disorder, during adolescence. While these findings are consistent with prior data linking childhood separation anxiety disorder to later-life panic disorder, follow-up of children's responses to separation experiences and later anxiety have yielded inconsistent results (Rutter 1997).

Psychobiological features of childhood anxiety disorders

Based on the study of the brain substrates for anxiety in lower mammals (Davis 1998), children at risk for anxiety are hypothesized to have abnormalities in physiological systems implicated in adult anxiety disorders and animal models of anxiety. Animal models of anxiety have been facilitated by a high degree of cross-species conservation in brain circuitry among mammals as well as extensive cross-species data on the pharmacology of fear. Distinct forms of fear are regulated by interrelated brain systems involving various components of the limbic system. Learned fears can be modelled by fear conditioning experiments, where an aversive stimulus, such as a shock or air-puff, is paired with a neutral stimulus, such as a light or tone. Following such pairings, an organism exhibits fear-related behaviours towards the formerly neutral stimulus. Such forms of learned fear, known as 'fear conditioning', depend upon a neural circuit involving the central nucleus of the amygdala, located within the medial temporal lobes.

Other forms of fear develop without prior experience and are regulated by distinct but related neural circuits. For example, nocturnal organisms, such as rodents, display fearful behaviour in a well-lit environment. Unlike learned fears, this fear does not habituate and actually may increase in intensity with repeated exposure. The fear involves the basolateral as opposed to the central nucleus of the amygdala; the two circuits are regulated by distinct neurochemical systems (Davis 1998). For example, infusions with corticotrophin-releasing factor may potentiate light-enhanced fear but not conditioned fear. Innate fears of other stimuli may show similar distinctions from learned fears on pharmacological and anatomical grounds.

Functional aspects of brain circuits that regulate learned and innate fears can be quantified reliably in lower mammals as well as humans by examining changes in the startle reflex following presentations of mildly stressful stimuli. Adults with various forms of anxiety exhibit startle abnormalities. A study of asymptomatic children of parents with anxiety disorders pro-

vides evidence that risk for anxiety is associated with abnormalities in startle regulation (Merikangas *et al.* 1999). However, the precise conditions under which startle is most discriminatory of family history of anxiety are incompletely understood. Kagan *et al.* (1995) suggest that behavioural inhibition, a behavioural marker of risk for anxiety, also results from abnormalities in the same brain circuits. This view is based on peripheral physiological profiles in inhibited children, using physiological indices that are influenced by components of circuits that regulate fear in mammals. Data in children implicate the same abnormalities in brain circuits that regulate fear in lower mammals. Consistent with this view, behavioural and physiological signs of behavioural inhibition have been found in children of parents with panic disorder (Biederman *et al.* 1990). However, the finding is not specific to anxiety because similar relationships characterized the offspring of depressed parents.

While these data provide scientific leads, there are crucial pharmacological inconsistencies among humans and animal models in the regulation of fear conditioning and clinical signs of anxiety. For example, medications effective in panic disorder do not affect fear conditioning (Cassella & Davis 1985), though they appear to affect certain forms of unlearned fear (Blanchard *et al.* 1997). Accordingly, risk for anxiety disorders has been hypothesized to relate more closely to inherited tendency to respond to innate unlearned fearful stimuli than to the fear conditioning circuit. The most developed line of research examines the association between respiratory dysregulation and panic disorder (Klein 1993). Much like a well-lit room for a rodent, respiratory stimulants represent unlearned fear-inducing stimuli for air-breathing organisms, including humans. A wealth of studies suggests that sensitivity to respiratory stimulants identifies individuals with a diathesis for types of anxiety closely related to spontaneous panic attacks. For example, adults with panic disorder have enhanced responses to respiratory stimulants, such as CO₂, sodium lactate, cholecystokinin-cholecystokinin or doxapram (Klein 1993). Sensitivity to CO₂ has also been found in children with anxiety disorders compared to controls (Pine *et al.* 1998b), specifically among children with separation anxiety disorder (Pine *et al.* 2000b). Syndromes, such as subclinical panic disorder, that have strong familial associations with panic disorder are also characterized by enhanced responses to respiratory stimulants. Moreover, signs of respiratory abnormalities, such as sensitivity to CO₂, occur especially among panic patients with highly familial forms of panic (Perna *et al.* 1995; Horwath *et al.* 1998). In addition, healthy first-degree relatives of panic patients also exhibit enhanced responses to respiratory stimuli (Perna *et al.* 1995; Coryell 1997). These data suggest that children at risk for panic disorder may also be sensitive to respiratory stimulation.

In brief, abnormalities in underlying fear circuitry, as assessed using startle, may quantify a child's risk for later anxiety. However, learned fear, as assessed via fear-potentiated startle, has inconsistent relation to clinical anxiety disorders in adults, as well as to risk for anxiety disorders in children (Merikangas *et al.*

1999). There also is some evidence that startle under circumstances of innate threat may index risk for anxiety, based on temperamental or familial factors. However, as with work on fear-potentiated startle, there are inconsistencies across studies, sex and age groups. The level of basic science knowledge in this area is likely to foster research in the relationships between startle regulation and childhood anxiety.

Another area of research delineates the effects of fear on cognitive processes. Fear-relevant stimuli are processed more readily than neutral stimuli; this effect can be quantified using lesions or neurophysiological recordings in animals (Gallagher & Holland 1994), and using reaction time in humans (McNally 1996). In animals, the effect of fear on cognitive processes is thought to result from changes in amygdala-based circuits. Two procedures have been used in humans to probe changes in cognitive processes. One procedure, the so-called emotional Stroop test, increases the latency required to name colours during the presentation of coloured ‘threat’ words as opposed to ‘neutral’ words. Adults with various forms of anxiety show relatively prolonged latency to name colour words that are threat cues, such as ‘panic’, presumably because of enhanced vigilance to the meaning of ‘threat’ words (Williams *et al.* 1996). In another procedure, the so-called dot-probe test, reaction time to a spatial probe is quantified based on variations in the proximity of the probe to ‘threat’ words or pictures. Adults with anxiety show faster reaction times to probes appearing proximal to threatening stimuli, an effect that is also attributed to enhanced vigilance. For both tasks, there are relatively subtle but consistent effects of anxiety in adults’ reaction times during the presentation of threats (Williams *et al.* 1996). There is some evidence suggesting similar effects in childhood anxiety disorders (Vasey *et al.* 1995).

Two central questions emerge from work on cognitive bias. First, the cognitive bias for threat has been conceived as a risk factor for anxiety. However, among adults, enhanced cognitive bias for threat cues is related primarily to ongoing symptoms, and disappears with treatment. Similarly, asymptomatic children with behavioural inhibition do not show enhanced bias for threat cues on the emotional Stroop test. Although these negative results have been attributed to methodological factors, they raise questions about the degree to which cognitive biases are central to anxiety or represent epiphenomena. Questions also arise about the diagnostic specificity of cognitive biases, because they have been found in most forms of adult anxiety, as well as in adult depressive disorders.

Preliminary data from the only available child-based study of anxiety disorders found an enlarged amygdala volume among children with generalized anxiety disorder, as compared to healthy comparisons (De Bellis *et al.* 2000).

Clinical implications

There is evidence for non-shared environmental influences in the development of anxiety in children. However, their nature

is poorly understood, and the findings do not lend themselves to clinical applications. There have been attempts to identify parental features that may affect either the development or the maintenance of anxiety in children. This is a problematical task because it is difficult to identify the direction of the relationship. Do parents behave differently because their children are anxious, or has the parental behaviour led to anxiety in the child? Furthermore, the exact nature of parental behaviour is difficult to establish. For example, in a study of parental behaviour among adolescents with social phobia, parents of socially phobic children did not differ from parents of non-socially phobic children in their ratings of their child-rearing styles and the family environment (Caster *et al.* 1999). In contrast, the anxious adolescents, compared to the non-anxious adolescents, rated their parents worse on multiple measures relating to social phobia (concern about others’ opinion, etc.). The identification of parental influences on childhood anxiety will likely require a longitudinal approach among children at high risk for anxiety.

Although the evidence is hardly in, it is generally accepted, based on clinical lore (at times it may be accurate) that it is best not to accommodate the child’s fears, but rather to help the child experience anxiety-provoking situations to enable the development of mastery. Such parental behaviour may be quite relevant to preventing the maintenance of anxiety in children; it is less compelling that it prevents the onset of anxiety disorders.

Conclusions

The research summarized lays the groundwork for studying psychobiological bases of childhood anxiety. Data on cognitive biases and fear conditioning suggest a need for systematic brain imaging research on the structure and functioning of human limbic brain regions linked to animal models of anxiety. Research in other areas of medicine illustrate the strategic advantages afforded by genetic studies through the identification of physiological markers indicative of an endophenotype. Work on the associations among childhood anxiety, adult panic disorder, and respiratory dysfunction holds the hope of providing similar knowledge on the genetics of anxiety disorders across the life span.

Treatment of childhood anxiety disorders

The evidence that childhood anxiety disorders cause suffering and impairment, and findings that they may entail long-term liability, highlight the need for effective treatments. Some interventions, such as cognitive-behaviour therapy (CBT), are based on a theoretical model of anxiety; others, such as medications (e.g. SSRIs), follow from demonstrated efficacy in adult anxiety disorders.

The literature is replete with case studies reporting efficacy for treatments. Were there no systematic controlled trials, it

would be sensible to consider them. However, because controlled studies have been conducted, clinical reports are not contributory.

Psychotherapy

The most well-studied intervention is CBT (see Brent, Chapter 54), which is based on the notion that distorted cognitions about the dangerousness of the environment are the underlying mechanism for anxiety symptoms at all ages. Therefore, treatment focuses on the child's thought processes, aiming to replace negative beliefs with more realistic neutral cognitions. This theory implicates only the child, and some forms of CBT focus exclusively on the child (Kendall & Ronan 1990; Albano *et al.* 1995). Others systematically recruit the family's active involvement (Barrett *et al.* 1996; Barrett 1998). The contribution that parents can make to their child's progress in treatment is likely to vary as a function of the child's disorder and age. It is difficult to appreciate how a child with severe separation anxiety could receive optimal assistance without parental involvement. Also, if such a child resisted school attendance, why would one not involve the school? At times, theoretical allegiances may lead to practices that seem out of step with children's problems.

A major positive feature of CBT is the availability of treatment manuals that allow comparisons across studies. All the studies reported have used treatment manuals. The controlled studies of CBT can be classified as those that used a no-treatment waiting list control, and those that compared CBT to a non-specific control intervention. While often used in early psychotherapy trials, the use of waiting list controls is methodologically problematic when applied to clinic patients. This clinical disposition confirms to patients that they require treatment, but withholds it. Moreover, there is concern that, in some instances, waiting list controls may have a deleterious impact. Another limitation is that this control does not reveal the specific usefulness of an intervention, because there is no way of determining whether treatment was effective because of its particular nature, or because of non-specific treatment features, such as therapist's interest and concern, or the family mobilizing itself to bring the child for treatment.

The most informative studies are those that have relied on a comparison treatment that is reasonable and credible for the particular disorder. Even when a control psychotherapy is used, methodological problems remain. The treatments should be equivalently appreciated by the recipients, so that treatment effects are not a function of differences in treatment credibility. Finally, in studies of psychotherapy, it is essential that treatment outcome be evaluated by individuals who are not aware of the treatment delivered, rather than by the therapist. In this fashion, one ensures that biases introduced by treatment allegiances do not influence estimates of outcome. Thus, self-reports of patients who received psychotherapy compared to waiting list controls are not revealing of specific treatment efficacy and may reflect the wishes of the patient rather than actual improvement. These design features are very infrequently met in current

studies of psychotherapy in anxiety disorders. However, most studies have the merit of examining both the immediate and long-term effects of treatment. Long-term advantages of therapies are important, because there would be little point in investing costly efforts for transient clinical advantages.

CBT was examined in two systematic studies by Kendall (Kendall 1994; Kendall *et al.* 1997) in which anxious children were randomized to receive CBT for 16 weeks, or be on a waiting list for 8 weeks. In both trials, relative to the waiting list group, the group that received CBT was significantly improved after treatment, as well as 1 year, and 2–5 years later (Kendall & Southam-Gerow 1996). The treatment studies are weakened by the fact that there was a twofold difference in time between the two conditions. Controlled treatment studies are meant to control for time, especially when disorders are not regularly chronic, as is the case with anxiety disorders. (Understandably, there were concerns about the ethics of keeping patients on a waiting list for 4 months.) The sustained effect of CBT over several years is impressive, but it is difficult to understand because the children in the waiting list control received CBT after the 8-week wait, if they required it. Why should their status be different from children whose treatment was not delayed? Is this an example of the psychotoxic effects of waiting list controls in clinic patients? Waiting list controls have been used in other studies of CBT; as a result, their contribution to an estimate of efficacy is difficult to establish (King *et al.* 1998; Silverman *et al.* 1999).

Three studies have used 'attention' controls. Last (1998) treated a diagnostically mixed group of school phobic children with CBT or an established manualized control treatment. This is the only study that ensured that the two treatments had equivalent credibility to children as well as parents. No difference in efficacy was obtained between the two treatment conditions.

A study by Silverman *et al.* (1999) examined the specific effect of a cognitive treatment component by comparing an exposure-based behavioural contingency treatment with an exposure-based cognitive programme, and a family group intervention. No outcome differences were found across the three treatments.

A well-designed study compared a behavioural approach to a control intervention in children with social phobia (Beidel *et al.* 2000). This study is unique in restricting patients to a single anxiety disorder. Based on independent assessors, children in the behavioural intervention were significantly more improved than their peers in the control group. Unfortunately, the credibility of the treatments was not assessed.

Other studies have examined variations in treatment, such as parental involvement and group format. A study of parent involvement compared treatment of the child only, parent only, and parent with child treatment, in children with a variety of anxiety disorders (Mendlowitz *et al.* 1999). The parents who received treatment with their child reported greater improvement. In the absence of independent assessment, it is difficult to draw clear conclusions. Another controlled study found that there was significant advantage to having families participate in CBT, as assessed by independent evaluators and that the advantages

of family involvement were maintained over a 1-year follow-up (Barrett *et al.* 1996).

On the basis of a systematic trial of group CBT, group family CBT, and waiting list control, Barrett (1998) concluded that CBT could be implemented in a group format, but the children who received CBT were not better than the controls.

Pharmacotherapy

SSRIs have been studied extensively in adults with anxiety disorders, and have documented safety and efficacy in generalized anxiety disorder, obsessive-compulsive disorder, post-traumatic stress disorder, social phobia and panic disorder (Roy-Byrne & Cowley 1998). Although open clinical trials of SSRIs in children have appeared, only one placebo controlled study has been conducted to date (RUPP Anxiety Study Group, 2001). A large multisite 8-week study found that fluvoxamine was significantly superior to placebo in children with mixed anxiety disorders (social phobia, separation anxiety and generalized anxiety disorders), but without major depression. The advantage of the active compound was sizeable: 79% of children on the medication improved, compared to 28% on placebo. The superiority of the medication was detectable after 3 weeks of treatment, reached its peak after 6 weeks, and was maintained over the ensuing 2 weeks.

A previous literature review (Klein 1994) indicated that there was inconsistent support for the efficacy of tricyclic antidepressants in children with separation anxiety. A recent study found that imipramine was superior to placebo in adolescents with school refusal and anxiety disorders (Bernstein *et al.* 2000). Problematically, the patients also had major depression and therefore differed from previous samples. In spite of the fact that tricyclic antidepressants have not established efficacy in adolescent major depression (Klein *et al.* 1998), the possibility remains that the disorder contributed to the treatment results.

Although there have been some reports on the use of benzodiazepines in anxious children (Klein 1994), the safety profile of the SSRIs and recent evidence of their usefulness weaken consideration of benzodiazepines.

Conclusions

Although therapeutic research in anxiety disorders has progressed considerably, few studies of psychotherapy meet adequate methodological standards. Two of the three studies that have used a psychotherapy control condition failed to find an advantage for CBT in school phobic (Last *et al.* 1998) and phobic children (Silverman *et al.* 1999). Only one study, that focused on social phobia, found superiority for a behavioural intervention over a control treatment (Beidel *et al.* 2000). There is evidence supporting the merit of parental involvement in the child's treatment.

One large placebo controlled study obtained significant clinical superiority for an SSRI in children with anxiety disorders.

No investigations of the utility of combined treatments has been conducted.

Summary

A multiplicity of findings have contributed to a growing awareness of the possible importance of childhood anxiety disorders. These include findings of the common occurrence of child and adolescent anxiety disorders; the associated functional limitations they may incur; the fact that they put children at risk for later depression; and their moderate but significant continuity with anxiety disorders in adulthood.

Epidemiological studies of childhood anxiety disorders have generated divergent rates of current anxiety disorders. The overall evidence suggests a 5–10% prevalence in the general population, with girls being overrepresented. Gender also may influence course, in that some have found greater stability of anxiety in girls. Long-term stability has been found for social phobia, but less so for other specific childhood anxiety disorders. Childhood anxiety disorders have not been found to predict adult psychopathology other than anxiety and depression.

Identification of antecedents of childhood anxiety disorders would enable the identification of children at risk, and the development of appropriate treatment. Few antecedents have been established. Early temperament, specifically inhibited temperament, is weakly related to later anxiety, especially social phobia. A modest influence for genetic transmission has been found, with non-shared environmental factors playing a greater part in the occurrence of childhood anxiety disorders. Unfortunately, the nature of non-genetic factors in childhood anxiety disorders are poorly understood. As a result, they make little contribution to the clinical management of children with anxiety disorders.

Models of brain circuits that regulate fear in animals, and that have been studied in adults, are currently being applied to investigations of anxiety in children. Early studies suggest that children show the same abnormalities in underlying fear circuitry, as measured by startle responses to non-conditioned fear stimuli, and information processing of fear-related stimuli. However, it is difficult to determine which is cause and which is effect in the relationships between startle sensitivity and anxiety disorders. Neuroimaging studies of children are under way, focusing on the hypothesis that amygdala volume is positively related to anxiety disorders in children. At this time, the most well-documented biological feature of childhood anxiety is respiratory dysregulation, as indexed by hypersensitivity to CO₂ exposure, in children with anxiety disorders, especially those with separation anxiety disorder.

Treatment of anxiety disorders encompasses psychotherapeutic and psychopharmacological interventions. Treatment studies of anxious children, with one exception, have included a mixture of anxiety disorders, and have not distinguished among various anxiety disorders. Most psychotherapy studies have

methodological limitations, but there is evidence of sustained improvement over time. Comparisons of different therapeutic approaches do not demonstrate superior efficacy of any one psychotherapeutic approach over others. Fluvoxamine, an SSRI, has been found effective in reducing anxiety in a placebo controlled study of a diagnostically mixed group of anxiety disordered children and adolescents. There now are treatments based on empirical evidence that can be offered to children with anxiety disorders.

Introduction

Adjustment disorder has the curious distinction of being the only condition in the major classification schemes for psychiatric disorders, ICD-10 (World Health Organization 1992) and DSM-IV (American Psychiatric Association 1994) that has no characteristic psychopathological picture. Its nature is essentially defined by the exclusion of a major category axis I disorder, its relationship to a putative stressor, and its duration. It might, with reason, be regarded as a historical anachronism. Indeed, the history of the concept of adjustment reaction or disorder reflects the history of Western thought about childhood psychiatric disorder for most of the last century. In DSM-I (American Psychiatric Association 1952) it was one of only two categories of childhood psychiatric disorder listed, the other being childhood schizophrenia.

Early definitions and papers reviewing the concept reveal the extent to which earlier clinicians conceptualized childhood and adolescent psychiatric disorder as a reaction to both external stressors and to internal mental developmental processes. This approach appears to have been coupled with a prejudice against using psychiatric disorder categories when children were considered and an apparent assumption that psychiatric disorders in the young were transient and not serious (Weiner & Del Gaudio 1976). Certainly adjustment reaction or disorder were commonly used labels. In the USA, 'adjustment reaction' and 'transient situational disturbance' were the most common diagnoses in child and adolescent psychiatric practice in the early 1960s (Rosen *et al.* 1964). Originally these concepts seem to have been remarkably vague, as well as all-encompassing, and were criticized accordingly (Fard *et al.* 1978). This led to a tightening of criteria in subsequent editions of ICD and DSM, restricting the concept to a relatively brief abnormal psychological reaction (not amounting to a major psychiatric disorder) to an acute external event. Even so, criticism of the concept continued (Newcorn & Strain 1992; Hill 1994), albeit with recognition that some classificatory mechanism was required to accommodate abnormal psychological reactions to external adversity that did not amount to major psychiatric disorder.

Adjustment disorder is a popular term with many psychiatrists. Setterburg *et al.* (1991) surveyed US child psychiatrists and reported that the diagnosis was more frequently used by those who were psychodynamically trained, older, and in office rather than hospital practice. Some 55% of those surveyed stat-

ed that they employed the diagnosis specifically in order to avoid stigmatization of the patient. The authors also commented that the diagnosis retained its popularity because of the way in which its non-specific wording maintained a degree of confidentiality as to the exact nature of the psychopathology and did not prejudice subsequent life insurance application. Reviewing the published literature with this in mind, it is interesting how prevalent the term is in studies of adolescent psychiatric inpatient populations (e.g. 34% of the adolescents in Greenberg *et al.* 1995) given its supposed mildness and brevity. Its popularity is not entirely American, however; figures from Pelkonen *et al.*'s (2000) study indicate a prevalence of 29% among outpatients in a Finnish clinic.

The current approach taken in ICD-10 recognizes three main categories of reaction to acute stress, irrespective of age: acute stress reaction, post-traumatic stress disorder (PTSD) and adjustment disorder. The latter is divided further into six main sub-categories defined symptomatically (with respect to presence of depression, other emotional disturbance or conduct problems) and an 'other' category.

For the core diagnosis of adjustment disorder, 'subjective distress and emotional disturbance, usually interfering with social functioning and performance' needs to have arisen 'in the period of adaptation to a significant life change or to the consequences of a stressful life event'. 'None of the symptoms is of sufficient severity or prominence in its own right to justify a more specific diagnosis.' Stressors should be more than minor, and the onset of the disorder is said to be 'usually' within 1 month of the occurrence of the stressful event, 'significant life change leading to continued unpleasant life circumstances', or life crisis. A period of more than 3 months between stressor and symptom onset indicates that the disorder should be classified differently. For most reactions, the duration of symptoms will not normally exceed 6 months, although brief and prolonged depressive reactions have maximum limits of 1 month and 2 years, respectively, and, if it does, the diagnosis should be changed to a more specific category. The identified stressful event or situation can be coded with a separate Z code or, for children and adolescents, listed in axis V (associated abnormal psychosocial situations) of the multiaxial version of ICD-10. Subsection 6 of axis 5 (acute life events) is most likely to be invoked. For an experience to be included it must be 'significantly abnormal in the context of the child's level of development, past experiences and prevailing sociocultural circumstances'.

Although adjustment disorder is intended to be a category

that can be applied to all age groups, some comments in the diagnostic guidelines apply specifically to children. The subcategory 'with predominant disturbance of other emotions' 'should also be used for reactions in children in which regressive behaviour, such as bed-wetting or thumb-sucking, are also present'. Later in the guidelines an adolescent grief reaction resulting in aggressive or dissocial behaviour is given as an instance of the subcategory 'with predominant disturbance of conduct'. Separation anxiety disorder, which must have an onset in the preschool years, is specifically excluded, but 'hospitalism' in children is included.

The definition of adjustment disorder provided in DSM-IV is very similar: marked disproportionate distress coupled with significant impairment of social, occupational or academic functioning arising within 3 months of exposure to an identifiable stressor and lasting no more than 6 months after the stressor has ceased. The stressor can be of any severity, not necessarily extreme. Bereavement is excluded unless the reaction is excessive or protracted. Severity is mild: 'the stress-related disturbance does not meet the criteria for another specific axis I disorder'. There is provision for subtyping, very much as in ICD-10. A chronic variant can be invoked if the psychological disturbance lasts more than 6 months in response to 'a stressor that has enduring consequences'.

An original notion that there is a specific type of psychological distress or disturbed behaviour that is the result of a stressor, external or internal, and which can be recognized as a disorder has thus been modified. This is in response to a mounting volume of evidence that various adversities, acute and chronic, can contribute to the causation or maintenance of psychiatric disorder in the young (see Friedman & Chase-Lansdale, Chapter 15; Sandberg & Rutter, Chapter 17; Yule, Chapter 32). The impact of adverse circumstances is now recognized to be relevant to a number of other psychiatric conditions and the concept of adjustment disorder has shrunk to indicating a mild, short-lived and non-specific reaction to an adversity that is itself circumscribed in duration.

In the ICD-10 clinical description, the points are made that there is commonly a plurality of emotional symptoms and that there needs to be a careful evaluation of relationships among form, content and severity, previous personality and the stressor. This is the kernel of the concept, which in both classification schemes has four or possibly five components.

- 1 Distress or disturbance of functioning that is beyond the normal expected range or is maladaptive.
- 2 Psychopathology less severe than a major category diagnosis would require.
- 3 An identifiable stressor that is an event or onset of change in circumstances occurring within a maximum of 3 months prior to onset of the disorder. This must be of significant but not overwhelming severity, and it is a necessary condition for the disorder to be diagnosed.
- 4 Relatively short duration (usually a maximum of 6 months).
- 5 Not an exacerbation of previously identified psychopathology.

From this, some critical issues emerge that have to do with caseness and normality.

Threshold issues

To qualify as a disorder, a pattern of symptoms or signs has to be associated with clinically significant distress or impairment in social, occupational or other important areas of functioning. In DSM-IV and the Diagnostic Criteria for Research edition of ICD-10 (World Health Organization 1993) a minimum number of clinical features must be present for caseness. By definition, adjustment disorder can only be diagnosed when criteria for a major category disorder are not met. The impairment criteria specified in ICD-10 are vague: 'usually interfering with social functioning and performance'; 'some degree of disability in the performance of daily routine'. The duration of an adjustment disorder is brief, by definition.

There is not always a predictable correlation between the number of symptoms and the degree of impairment, yet the major classification schemes determine caseness by symptom counts. This can be criticized. Harrington's group (quoted in Harrington & Clark 1998) have demonstrated that one or two severe symptoms of adolescent depression can be associated with very substantial impairment yet be an insufficient number to qualify as a major category disorder. From data accumulated in the Great Smoky Mountains epidemiological study, Angold *et al.* (1999) were able to make a similar point. If caseness is restricted to those children whose psychopathology contains a given minimum number of symptoms or signs specified in a major category psychiatric disorder, some instances of what would otherwise be considered as illness or disorder and that represent a health care need will be missed.

Impairment appears to be a fundamental variable in determining prognosis, trumping symptom counts. Costello *et al.* (1999) examined the psychiatric status of adolescents 5–7 years after first assessment in childhood. Children with 'threshold' status (symptom count satisfying DSM criteria but of insufficient severity for clinical caseness) were subdivided into those with and without impairment. Threshold status might be thought comparable with the degree of clinical severity indicated by a diagnosis of adjustment disorder. Threshold children without impairment had the same long-term outlook as healthy children. The presence of impairment in conjunction with threshold status provided an intermediate prognosis compared with clinical-level impaired cases.

Nevertheless, functional impairment is not an all-or-none feature; it can fluctuate and be measured in its own right. Scales of personal functioning, such as the Children's Global Assessment Scale (C-GAS; Shaffer *et al.* 1983) or the Functional Impairment Scale for Children and Adolescents (FISCA; Frank & Paul 1995; Frank *et al.* 2000) do not indicate a clear cut-off for impairment, although a consensus as to the level below which *most* cases of agreed disorder fall can be established. In the Puerto Rican general population study (Bird *et al.* 1988), the prevalence of

adjustment disorder in children varied from 7.6% when a C-GAS cut-off score of 70 or less was employed, to 4.2% at the inferior level of functioning of 60 or below.

The situation with respect to caseness is thus less than clear-cut. The usefulness of an adjustment disorder concept is that it can accommodate some cases in which there is a clinical need but a major category disorder cannot be said to be present. It describes a subthreshold, or subsyndromal condition, something of potential importance in primary care practice. Clear assessment of associated impairment seems important, yet the time constraints on duration and the temporal relation with a stressor still limit its applicability in this respect. In the previous edition, this chapter was critical of the concept of adjustment disorder and suggested it be recast as a V code. In the same vein, Pincus *et al.* (1999) have suggested it be abolished and a subthreshold category created in each of the major disorder sections. This would free matters from the time constraints. A condition would be subthreshold if either the symptom count or impairment criterion were not met.

Establishing an aetiological link with the stressor

Reactions to acute stressors are already subclassified in the major classification systems. In an acute stress reaction, a state of mute disorientated bewilderment lasting only a few hours or days is typical and quite commonly seen in children subject to severe life-threatening experiences, such as road traffic accidents. Astute observation reveals them commonly to be highly aroused in autonomic terms. Clinically, it seems more likely to be evident when a child has no access to attachment figures, although their presence does not necessarily prevent its occurrence.

Post-traumatic stress disorder is a classic example of a pattern of more protracted symptoms that have a defined relationship to an extremely stressful event (see Yule, Chapter 32). It is well recognized that other psychological and psychiatric symptom patterns can follow such stress. Moreover, the classic pattern of formal PTSD is not absolute; rather, it is at the severe end of a spectrum of post-traumatic reactions displaying the same component symptoms.

Adjustment disorder is conceptualized as arising as a result of a less catastrophic but acute experience. This acute experience may not be as potent an aetiological factor as it seems. Indeed, Rutter & Sandberg (1992; see Sandberg & Rutter, Chapter 17) point out that an acute adverse experience occurring in isolation is usually not pathogenic and the interaction with chronic stressors is critical. In a particular case, the aetiological contribution of previously existing chronic stressors may be proportionally greater but masked by a recent dramatic acute event serving as the straw on the camel's back. Yet it is this event that forms the base from which are drawn the time limits specified in the diagnostic rules. Furthermore, the definition of adjustment disorder refers to a linear model of causation that does not square easily with what is known about the impact of adversities on children's

minds. For instance, the extent to which an individual's behaviour contributes to the likelihood of future adversity, even apparently independent life events, needs consideration (see Sandberg & Rutter, Chapter 17).

The association between apparent stressor and reaction will necessarily be based on *post hoc* reasoning. It will rest upon a clinical judgement as to how closely the stressor relates to the behaviour or emotional disorder in terms of form and content or in temporal proximity. Effectively, a *verstehende* concept applies in that the type of stressor and the extent and content of the psychopathology must be understood by the observer to be semantically related. However, when an attempt is made to link disorder with life events in childhood, it is apparent that the association between type of event and type of disorder is generally weak (Goodyer *et al.* 1985) and even extreme stressors do not consistently produce predictable types of reactions such as PTSD.

Timing

In the definition of adjustment disorder, the time elapsing between the putative stressor and the onset of the adjustment disorder is set at a maximum of 3 months. From the study of Kovacs *et al.* (1995) on children in whom the stressor was a first diagnosis of diabetes, this would seem appropriate. Thirty-one patients had developed an adjustment disorder in that period; extending the time frame to 6 months only identified another two.

Although not a study of adjustment disorder, it is interesting that Goodyer *et al.* (2000) found that when undesirable life events are considered in relation to major depression, only events in the preceding month before onset were relevant. However, only 53% of episodes of major depression were preceded by such an event. The other cases may have responded to the impact of daily hassles. Indeed, some reviewers have suggested that these are more likely to predict psychopathology than are major events (Leadbeater *et al.* 1995; see Sandberg & Rutter, Chapter 17). Timing obviously becomes more difficult when daily stressors rather than discrete events are considered.

Both classificatory schemes specify a 6-month maximum duration after which reclassification is required, although it is not explained why such a time was selected. Clearly, this constraint is often neglected, as admitted by the majority of those psychiatrists surveyed by Setterburg *et al.* (1991). Furthermore, there is the issue, not just of what the time course of understandable reactive distress might be, but whether this can be related to a definition of disorder. If one takes bereavement as the paradigm for a stressor that can lead to an adjustment reaction, then it is instructive to note that in Fristad *et al.*'s (1993) study, one-third of children were at their *most* distressed 6 months after the death, although by 13 months matters had subsided somewhat. However, duration of disorder may vary with stressor. Kovacs *et al.* (1995) found that the average episode length for adjustment disorder following an initial diagnosis of diabetes was 3 months. However, in that study 5 of 33

children had episodes lasting longer than 6 months, although all had recovered by 9 months. In the same group's related study of children with adjustment disorder in a psychiatric clinic, the mean duration of disorder was 9 months (range 3–24 months). In contrast to the notion of prolonged depressive reaction in ICD-10 (the only subtype to allow a 2-year duration), there was either no difference in duration between subtypes (Kovacs *et al.* 1995) or a trend for depressive subtypes to recover faster (Kovacs *et al.* 1995).

A key complicating issue is that children's response to a stressor is not just their own distress at the experience but mediated through the reactions of their carers, often exposed to the same stressor. For instance, Van Eerdewegh *et al.* (1985) and Downey *et al.* (1999) demonstrated a relationship between the amount of parental psychopathology and the child's emotional and behavioural status following parental bereavement. With this in mind, it is probable that the time limitations set for adults might not be appropriate for children dependent on carers who are also affected by similar life stresses.

Abnormality

There is an implicit assumption in the concept of an adjustment disorder that normal patterns of adjustment to stressors are sufficiently well defined for a normality to be identifiable by referring to:

- quality of response—a deviation from normal reaction patterns to the stressor in question;
- quantitative issues, such as number of symptoms or excessive duration; and
- adaptive vs. maladaptive response.

However, there is often no clear indication of what the limits of normality are. For instance, with respect to qualitative abnormalities in bereavement reactions (the example cited in ICD-10), Kranzler (1990) demonstrated that better studies of grief in children reveal that aspects of the bereavement response previously considered pathological may be seen in most bereaved children. This can result in normal bereavement being seen as abnormal and lead to unnecessary interventions (Harrington & Harrison 1999).

Frequency and intensity of symptoms, or chronicity would be a better indicator of abnormality rather than presence or absence of particular features. However, estimating the normal intensity or duration of responses to adverse events is not straightforward and may indeed be difficult for many psychiatrists (Malt 1986). Accurate judgement would involve an extensive knowledge of how the stressor impinges upon the individual child in terms of the child's attributions or previous sensitization, as well as being able to assess the contribution of associated chronic adversity. A more general appeal to empirical data may help but little because of the influence of development and context. With respect to children's reactions to divorce as an event, for instance, responses are known to alter by age and sex, according to the quality of previous family relationships, and to

continuing features of relationships between the parents and between parents and children (Kelly 2000).

It is also necessary to determine that the child's reaction is maladaptive, placing him or her at risk or at an avoidable disadvantage, as in repeated acts of deliberate self-harm. Clinicians seem especially likely to diagnose an adjustment reaction when an adolescent, for instance, takes an overdose (Martunnen *et al.* 1994; Greenberg *et al.* 1995; Nasser & Overholser 1999), yet such an action, although at first sight clearly maladaptive, may ultimately prove beneficial if it recruits help in resolving the child's predicament. There is a difficulty in moving beyond the descriptive to evaluating the cost to the child because this may alter according to whether short- or long-term benefits are considered. There may be potential in identifying deviation from normal patterns of coping and this is now considered further.

Coping strategies

The very term 'adjustment disorder' implies that the process of satisfactory adjustment to or coping with a stressor is awry or insufficient. The affected young person either uses a method of coping that is counterproductive and thus maladaptive, or their mind is overwhelmed and symptoms result which are not those of acute stress reaction or classical PTSD. In order to make a judgement about this, a knowledge of normal coping and normal responses to stress is necessary, but this field is young and much of what is known is provisional and culture-bound.

A major difficulty is that prediction of coping method depends upon several factors. Frydenberg (1997, p. 5), doubtless with tongue in cheek, suggested the quasi-mathematical formula:

$$C=f(P+S+pS),$$

where C is coping, P is the individual person, S the situational determinant, and pS the perceived situation).

It is possible to make some generalizations. The language and the conceptual models used in coping research are becoming useful for clinical approaches. Thus, in one model (Rice *et al.* 1993) stressors may be:

- *normative* or generic, experienced by all children during development (e.g. separation from parents in order to attend school, public examinations);
- *non-normative*, which is peculiar to the individual and may be subdivided into acute (e.g. bereavement) and chronic (e.g. bullying, parental discord) (Compas *et al.* 1993); and
- daily hassles, relatively minor but cumulative.

These become more or less stressful according to their *number*, *timing* and *synchronicity*.

A very similar position but using different terms was taken by Graber & Brooks-Gunn (1996) who suggested an interplay among *transitions* (universal experiences in development), *turning points* (unique experiences), and the ways in which the number, synchronicity and timing of these (e.g. in relation to age) govern their impact and the manner of coping. The idea that dif-

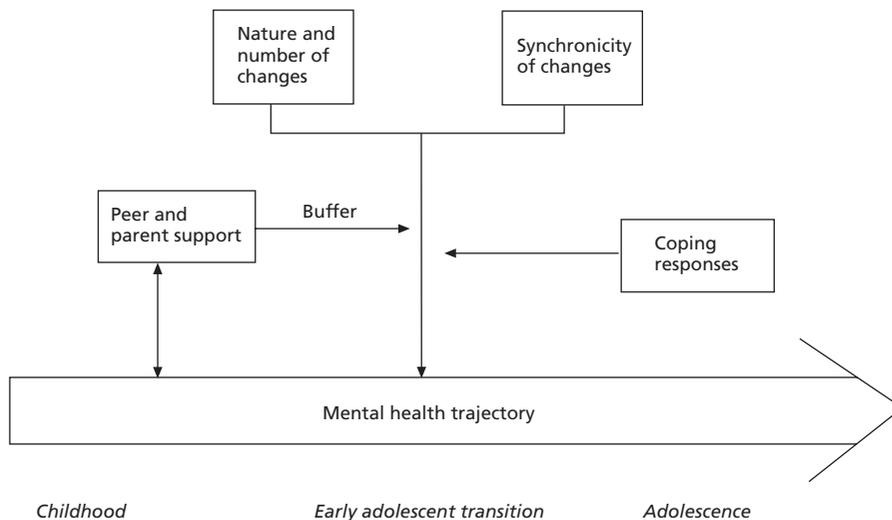

Fig. 31.1 Model of development transition in early adolescence.

ferent issues and challenges present at different ages and stages of development and are dealt with serially is not at all new and has data to support it, as in Coleman's (1974) focal theory of adolescent psychological development. There is converging agreement that the impact of experiences is a function of the above variables. Rice *et al.* suggest a diagram for their model (Fig. 31.1) (Coleman & Hendry 1999).

In determining whether a particular experience or event will be stressful, additional so-called *event parameters* are referred to. To such variables as number, synchronicity and timing, one can add unpredictability (Seiffge-Kranke 1995) so that there is no opportunity for anticipatory coping. As far as individual characteristics of the child are concerned, age, previous exposure (both sensitizing and steeling), gender, social support (family and peers) and culture will modify the perception of the stressor and thus the subjective significance of it (*event appraisal*) as well as the coping style used. With respect to event appraisal, lack of control (Lazarus & Folkman 1991) with respect to the individual's perception of the event or process seems particularly important.

Coping strategies have usually been conceptualized according to three main dichotomies:

- 1 emotion-focused strategies (Lazarus 1966);
- 2 engagement (approach) vs. disengagement (avoidance); and
- 3 problem-solving (primary control) vs. cognitive reframing (secondary control) (Compas 1995; Seiffge-Kranke 1995; Compas *et al.*, 2001).

Wishful thinking is also quite often included as an avoidant strategy. The type of stressor itself, considered objectively, is a weak determinant of which coping strategies are selected. Which strategies are actually used depends on a number of factors and some preliminary generalizations can be made on the basis of empirical studies.

Age and gender

Younger children are more likely to use family resources, with a

particular focus on attachment relationships and figures for emotion-focused coping, and instrumentally dependent relationships for problem-solving coping; adolescents increasingly employ friends or adults outside the family. Emotion-focused coping on one's own increases with age (Compas 1995). By the teenage years, most adolescents have acquired a good range of coping strategies, mostly functional (active problem-solving, such as seeking information or advice, discovering social support and accepting it, reflecting upon a choice between possible courses of action). This stands in contrast to dysfunctional coping (social withdrawal, avoidance of confrontation, wishful thinking). Across a range of cultures, those teenagers who employ functional coping strategies outnumber those who do not by 4:1 (Seiffge-Kranke 1995). Generally speaking, the repertoire of coping strategies increases with age and stabilizes at around 15 (Seiffge-Kranke 1995, 2000). Boys use more problem-solving than girls who use more in the way of social supports (Schonert-Reichl & Muller 1996). This means that girls are doubly disadvantaged by avoidant strategies which deprive them of a coping resource. A child is more likely to use problem-solving approaches if the stressor is appraised as being controllable.

Family background

The type of parenting employed in a family (authoritative, authoritarian, permissive, neglectful) exerts an influence, probably by inducing control beliefs to varying degrees. Children who have confidence in their ability to control events or processes are more likely to use problem-solving strategies and come from families in which there is authoritative parenting (McIntyre & Dusek 1995). Put slightly differently, children and adolescents from families that encourage independence and the open expression of feeling are more likely to use family and social resources actively rather than withdraw (Shulman 1993).

It may be reasonable to conclude that although a framework

for beginning to understand coping and adaptation is developing, it is premature to indicate what deviant coping would be. We still must have recourse to a crude notion of maladaptation in the sense of a cost to the individual's well-being or function.

Empirical information about adjustment disorder

There is remarkably little published about adjustment disorder and there is an impression that the term is less used than previously. Some findings may be gleaned from a sparse literature.

What form does adjustment disorder predominantly take?

Clearly, any clinical account can be affected by ascertainment bias. Kovacs *et al.* (1994, 1995) found considerable consistency of type in two studies of adjustment disorder in children presenting either to a psychiatric clinic or following the onset of diabetes. Diagnoses were made by structured processes and formal criteria and were independent of clinicians' diagnoses. Depressive subtype predominated in both settings, followed by mixed anxiety and depression. These two subtypes accounted for 24 of 30 of the psychiatric clinic patients and 30 of 33 of the new diabetics. Other subtypes with predominantly anxiety or conduct disturbance were unusual. The same was found in the very large-scale field trial undertaken for DSM-IV (Strain *et al.* 1998). These findings contrast with observations deriving from older studies, such as the influential work by Andreason & Wasek (1980) which has informed a number of textbook accounts.

With respect to suicidal phenomena, just over half (58%) of the depressive subtype in the psychiatric clinic and 53% of the diabetic group had suicidal ideation. The papers cited do not mention self-harm but no children seem to have killed themselves during 7–8 years of follow-up. A related study (Kovacs *et al.* 1993) found lower rates of suicidal behaviour in adjustment disorder compared with dysthymic and major depressive disorder and on the basis of their own studies stated that suicide attempts occur only 'rarely in the context of adjustment disorder' (Kovacs *et al.* 1994). Nevertheless, that there is some risk is demonstrated by Martunnen *et al.* (1994) who were able to find 11 cases of adjustment disorder among all the Finnish teenagers and young adults who killed themselves in 1987–78.

How prevalent is adjustment disorder?

Because of the shift in diagnostic criteria, only recent studies can be used to determine the answer. However, recent whole population studies mainly used categories that did not include adjustment disorder. An exception is the general population study of 4–16-year-olds in Puerto Rico using DSM-III criteria which gave a prevalence rate for definite adjustment disorder of 4.2% within a total prevalence rate for psychiatric morbidity of 17.8%, i.e. about one-quarter of all cases (Bird *et al.* 1989). Curiously, ad-

justment disorders in this population showed no relationship with the number of life events or family dysfunction, nor with age or sex as variables. A similar figure of 3.4% was found in a total birth cohort study of 8–9-year-olds in Finland (Almqvist *et al.* 1999).

Within clinic populations, just under twice this rate is suggested for the prevalence of adjustment disorder by relatively recent criteria. For instance, Doan & Petti (1989) found a rate of 7% among nearly 800 patients attending day-units in Western Pennsylvania. In Steinhausen & Erdin's (1991a) study 5.9% were diagnosed as having adjustment disorder. These figures stand in contrast to the higher figures found in inpatient population studies (see above) and it seems likely that other forces are guiding the diagnostic behaviour of psychiatrists in such settings.

Viewing the questions somewhat differently, Kovacs *et al.* (1995) found that systematically diagnosed adjustment disorder occurred in 36% of 92 children following the onset of diabetes. It was by far the most common psychiatric diagnosis to follow this well-defined stressor and was twice as likely to occur among those children whose parents also had marital problems, suggesting that the contribution of background chronic adversity is significant. Similarly, the DSM-IV field trial (based on referrals in the 1980s) found that the diagnosis was made in about one-third of cases (Strain *et al.* 1998).

How reliably is the diagnosis made?

Traditionally, adjustment disorder and similar categories have had poor interrater reliability (Newcorn & Strain 1992). The development of more structured criteria have apparently improved matters somewhat but perhaps not greatly. Rey *et al.* (1989) calculated a mean value for Cohen's kappa of 0.41 across studies using DSM-III, the lowest for any axis I diagnosis apart from attention deficit disorder without hyperactivity. According to ICD criteria, Steinhausen & Erdin (1991b) found a high interrater agreement of 82% for the diagnosis using ICD-10 criteria applied to a written vignette. In view of the small number of vignettes (5) used in the latter study, this may be an unrepresentative finding.

Validity of the diagnosis

From examination of the literature, two sources of empirical information as to the validity of the concept emerge. One is the predictive power of the diagnosis with respect to health compared with other diagnoses as revealed on follow-up. The other is whether follow-up studies suggest that symptomatology breeds true to type.

Older work was pessimistic as to validity. Andreason & Hoenk (1982), following up a group of 50 adolescent patients with a diagnosis of adjustment reaction made 5 years earlier by clinicians in a very reputable centre, commented that with respect to diagnostic practice, 'the disorder was not transient, the reaction not acute and the stress not overwhelming'. This figure was comparable to the high rates of serious pathology of various

kinds found on follow-up in studies on undiagnosable disorder in adolescence (Fard *et al.* 1979) and transient situational disturbance (Looney & Gunderson 1978).

One might dismiss such findings as merely reflecting confused diagnostic practice. Logically, the diagnostic criteria for adjustment disorder require that when psychopathology is persistent beyond 6 months, the condition be redefined diagnostically so that adjustment disorder cannot breed true by definition. Nevertheless, the conditions found at longer follow-up were often severe. Compared with the older studies, the use of somewhat more recent and tighter diagnostic criteria yields a picture less different from that which one might predict. Cantwell & Baker (1989) carried out a 4-year follow-up of children seen at a speech and language clinic with a psychiatric disorder rate of about 50%. The diagnosis of DSM-III adjustment disorder made in 19 children was the least stable (0%) of all diagnoses made, presumably an artefact of the criteria, but the overall recovery rate was remarkably low at 26%. There was no correspondence between the type of symptoms exhibited initially and those on follow-up. On the other hand, Lewinsohn *et al.* (1999) found that adolescents diagnosed with adjustment disorder with depressed mood had the same rate of major depressive disorder 5 years later in early adult life as those initially diagnosed as major depressive disorder; in other words the condition appeared to breed true in the instance of affective disorder as well as having as poor a prognosis as the major category disorder.

Kovacs *et al.* (1994, 1995) were able to follow up the cases they detected systematically for 5 years or more. The children with adjustment disorder first seen in a psychiatric clinic at an average age of 10 years were equally likely to develop a new psychiatric disorder over the next 5 years compared with a carefully matched control group. Matching had taken account of comorbid psychiatric disorder at initial diagnosis, and the lack of difference at follow-up was thought to be accounted for by the common (60%) existence of these comorbid conditions. In other words, the lack of difference was a function of sample and matching. A clearer result is found in the follow-up of children with diabetes who developed adjustment disorders; 27% had a new psychiatric disorder on follow-up, adjustment disorder increasing the risk of developing subsequent disorder by a factor of 3.4. Among those affected, depressive disorder was the most common type (36%), reflecting the predominance of this subtype at the outset; 24% had conduct disorder; and 20% an anxiety disorder. There is not enough detail in the papers to determine whether disorder bred true to type for each individual, but probably enough to indicate that adjustment disorder increases the risk for future psychiatric disorder.

The stressful experiences identified

Stressful experiences are probably no different in adjustment disorder to the types of acute stress that might be implicated in the precipitation of non-neurodevelopmental psychiatric disorder generally (Al-Ansari & Matar-Ali 1993). In the one recent

study that has made the comparison, the number of adverse life-events preceding adjustment disorder in a year did not exceed that found preceding major category disorder (Kovacs *et al.* 1994), something which raises a question about the whole concept of adjustment disorder. The DSM-IV field trial finding that the rate of stressors did not differ across diagnostic groups and, in particular, was not higher in the adjustment disorder cases, raises doubts about the validity of tying the diagnosis to the association with a stress experience (Strain *et al.* 1998).

Assessment

A conventional child psychiatric assessment is as necessary for the diagnosis of an adjustment disorder as for any other psychiatric condition. It would seem particularly important to interview the child to obtain quantification of the impact of supposed adversity for the following reasons.

- 1 Parents may be unaware of experiences, such as bullying, which characteristically is kept secret by its victims.
- 2 The parents may conceal an adversity that implicates them, sexual abuse being a case in point.
- 3 An apparently moderate stressor may be severe for the child in question because of idiosyncratic personal elements, such as previous sensitization.
- 4 Skilled interviewers who know what questions to ask may reveal symptoms that would otherwise remain undisclosed.

In related vein, it may be only the child who can reveal the timing of onset of private symptoms. This should not mean that only the child can provide information; life events interviews have shown how the best data are derived from combining parental and child accounts (see Sandberg & Rutter, Chapter 17). Certainly, parental mental state must be assessed, given the evidence that this may be the maintaining factor in responses to a number of stressors (see above).

Careful formulation of the mechanisms involved in the genesis and maintenance of disorder must include specification as to how the child has attempted to cope with the stressor or new life circumstances as well as to what extent his or her efforts have contributed to exacerbating their impact. There would seem to be some advantage in documenting how previous stresses and life transitions have been successfully managed because this may indicate a logical approach to treatment (see below).

There is a potential risk in jumping to an assumption that an apparently adverse event is aetiological. In Dunn & Kendrick's (1982) work on the impact of the birth of a sibling, rather more than half of the elder siblings showed some signs of being more 'grown-up' in areas such as independence in self-care or language, suggesting that the birth of a sibling is by no means necessarily entirely adverse and can, like divorce may for some adolescents (Wallerstein & Kelly 1980), act as a developmental stimulus. To make an inferential leap in judging a psychological disturbance to be a consequence of an event may be misleading unless the content of the child's disturbance supports such a link; there may be different reasons.

If DSM-IV guidelines are followed, a reassessment at 6 months is mandatory to examine whether redesignation to a major category diagnosis is required.

Prevention

Although there are no solid data on prevention of adjustment disorders as such, the evidence that preparation by discussion, explanation, visiting and provision of mitigating circumstances will minimize the distress of young children admitted to hospital with minimal contact with their parents (Wolfer & Visintainer 1975) suggests that other predictable changes in life circumstances can be constructively prepared for along similar lines. Otherwise, the recommendations for prevention are rather diffuse: reducing the number of stressors (such as divorce) through mental health education or social support systems; building self-esteem; and educating children about how to cope with predictable stressors, such as examinations. These are untested and, in current formulation, probably too diffuse to be testable.

Treatment

There are no substantial data on treatment choice or effectiveness for adjustment disorders as currently defined. At first glance, an approach combining environmental manipulation with individual or family counselling that hinged upon removing or minimizing the stressful situation while supporting the child and family in constructive adaptation would seem appropriate.

If it were possible to identify how children's coping strategies related to immunity from stress-related psychiatric disorder then this would provide a basis on which to use a more educational model that could build coping mechanisms. However, most of the work on invulnerability documents personality characteristics rather than coping skills. Nevertheless, there are early indications as to how matters might develop. In a 3-year longitudinal study of stressors and coping styles, Seiffge-Kranke (2000) identified only withdrawal (avoidant coping) as associated with the development of psychopathology. The same study also indicated that avoidant coping in the face of major and daily stressors did not only lead to psychopathology but also maintained it; psychopathology in adolescents leading to deficits in coping skills. It may also be the case that the more extensive use of social support by girls (Seiffge-Kranke 1995) means that social withdrawal associated with depressive symptomatology deprives them of a coping resource which is less important for boys. With this in mind, tutoring in more active coping and social engagement ought to prove beneficial, yet attempts to explore the deployment of coping skills and vulnerability to disorder have not yet yielded sufficient positive results on which to build treatments (see Jenkins *et al.* 1989 for a well-executed but ultimately disappointing instance).

As far as secondary level care is concerned, there is evidence

that cognitive therapies assist children with a mild depressive reaction (Harrington *et al.* 1998) and it seems plausible that this would apply to anxiety too. However, the chances of a child being detected as likely to have an adjustment disorder, accepted into a treatment programme, assessed and treated to completion within a maximum period of 6 months are not high enough to make many treatment outcome studies feasible in the future. It may be more relevant to concentrate on prevention research, particularly with a view to reducing the risk of future major category psychiatric disorder. On the other hand, most cases of adjustment disorder would be seen in primary care and counselling/social support approach would be viable. There is just a possibility that less orthodox approaches, such as relaxation/massage, might be applicable for those with anxious subtype, given some evidence for effectiveness (Field *et al.* 1992). Nevertheless, a generally optimistic prognosis could mask apparent effect and lead to wasted treatment resources.

Conclusions

Refining diagnostic criteria has led to a more satisfactory position with respect to the nosological validity of adjustment disorder compared with 10 years ago. It is popular, probably because of its non-pejorative status, and what is described according to diagnostic criteria seems broadly valid. However, logic leads to a reconceptualization of subthreshold minor disorder category with nearly the same time constraints as currently apply; a 9-month duration would seem more valid. Tying such minor disorder categories to a perceived adverse event to create a concept of a type of psychiatric disorder different from the way other major episodic category disorders are precipitated by adversity seems unnecessary, both from early empirical findings and given the existence of Z codes.

Introduction

Both ICD-10 (World Health Organization 1987, 1988, 1991) and DSM-IV (American Psychiatric Association 1994) diagnostic systems now acknowledge that major stressors can cause serious morbidity and that children may suffer from post-traumatic stress disorder (PTSD). The past 15 years has seen a great increase in studies of the effects of major stresses, as encountered in disasters, war and other life-threatening experiences. However, the question for child psychiatry remains whether severe acute stresses, as opposed to chronic ones linked to social adversity (see Friedman & Chase-Lansdale, Chapter 15), or more ordinary acute stresses (see Sandberg & Rutter, Chapter 17), carry a substantial increased risk of psychiatric sequelae. If so, what sort of stressors carry such increased risk? What are the most common psychological sequelae? Do these vary according to stressor, or according to developmental level? What is the role of the family in moderating the reactions? Are there other known risk and protective factors? Indeed, is PTSD truly a separate disorder or is it merely a variant of other well-recognized disorders, such as anxiety, phobias or depression? Finally, what is currently known about intervention?

The concept of post-traumatic stress disorder

The diagnosis of PTSD was first conceptualized in response to observations of Vietnam war veterans presenting with what came to be recognized as a particular pattern of symptoms in three clusters:

- 1 intrusive thoughts about a traumatic event;
- 2 emotional numbing and avoidance of reminders of that event; and
- 3 physiological hyperarousal (American Psychiatric Association 1980).

In retrospect, similar patterns were noted as reactions in earlier wars and, in prospect, the criteria were adapted, partly operationalized and applied to adult civilians. Next, the diagnosis was applied to children who had experienced an 'event outside the range of usual human experience . . . that would be markedly distressing to almost anyone' (DSM-III-R, American Psychiatric Association 1987).

Thus, it was argued that there were certain types of stressful experiences that were very severe and/or unusual and that

there was a distinctive form of stress reaction to these. PTSD was classified as an anxiety disorder, but many argued that it should be included as a dissociative disorder. It was increasingly described as 'a normal reaction to an abnormal situation' and so, logically, it was queried whether it should be regarded as a psychiatric disorder at all (O'Donohue & Eliot 1992). Even if it were regarded as a normal reaction, as will be shown below, it causes substantial impairment in sufficient cases to be regarded as a disorder.

Results from studies of adults have reasonably established that PTSD, while being predominantly an anxiety disorder, differs from other anxiety disorders in important ways. Foa *et al.* (1989) showed that the trauma suffered violated more of the patients' safety assumptions than did events giving rise to other forms of anxiety. There was a much greater generalization of fear responses in the PTSD groups and, unlike other anxious patients, they reported far more frequent re-experiencing of the traumatic event. Indeed, it is this internal subjective experience that seems most to mark out PTSD from other disorders (Jones & Barlow 1992). In adults, the argument is increasingly made that PTSD is an 'abnormal reaction to an abnormal event' that involves a complex interaction of biological, psychological and social causes (Yehuda & McFarlane 1995).

Recently, Ehlers & Clark (2000) have pointed out that, unlike most anxiety disorders, PTSD involves reactions to memories of past events rather than anticipation of any impending threat. They put forward an integrative cognitive model which helps to account for previously puzzling findings and which has been useful in developing effective treatment approaches for adult patients. As yet, the model has not been applied to children and adolescents.

There is still considerable debate in the adult literature as to whether there needs to be specification of 'Criterion A', the inadequately operationalized description of the unusual traumatic event. There are cases where patients meet the criteria for the presence of all three clusters of reactions, but have either no known exposure or only a trivial exposure to a stressor. This is important because, if true, then a diagnosis of PTSD does not automatically mean that the patient has suffered a trauma. Concern has been expressed that the diagnosis is being made too liberally, without due attention being paid to the impact on social functioning. Equally, concern has been expressed that there are other forms of stress reactions to chronic stress as experienced in repeated physical or sexual abuse (see Glaser, Chapter 21). Terr (1991), for example, drew a distinction between Type I

and Type II traumas, roughly the distinction between acute and chronic. While these are important debates that will alter the views taken on PTSD, here we will concentrate on acute conditions as manifested in children and adolescents.

With its roots in studies of adult psychopathology, the concept has been uneasily extended to apply to stress reactions in children and adolescents. The major difficulty from the outset has been that some of the symptoms are developmentally inappropriate for younger people. Indeed, the younger the child, the less appropriate the criteria.

Many writers agree that it is very difficult to elicit evidence of emotional numbing in children (Frederick 1985). Some children do show loss of interest in activities and hobbies that previously gave them pleasure. Preschool-age children show much more regressive behaviour as well as more antisocial, aggressive and destructive behaviour. There are many anecdotal accounts of preschool-age children showing repetitive drawing and play involving themes about the trauma they experienced.

Although parents and teachers initially report that young children do not easily talk about the trauma, recent experience has been that many young children easily give very graphic accounts of their experiences and are also able to report how distressing the re-experiencing in thoughts and images was (Sullivan *et al.* 1991; Misch *et al.* 1993). All clinicians and researchers need to have a good understanding of children's development to be able to assist them to express their inner distress.

Scheeringa *et al.* (1995) examined the phenomenology reported in published cases of trauma in infants and young children and evolved an alternative set of criteria for diagnosing PTSD in very young children. Re-experiencing is seen as being manifested in:

- post-traumatic play;
- re-enactment of the trauma;
- recurrent recollection of the traumatic event;
- nightmares; and
- flashbacks or distress at exposure to reminders of the event.

Only one positive item is needed.

Numbing is present if one of the following is manifested:

- constriction of play;
- socially more withdrawn;
- restricted range of affect; or
- loss of previously acquired developmental skill.

Increased arousal is noted if one of the following is present:

- night terrors;
- difficulty getting off to sleep;
- night waking;
- decreased concentration;
- hypervigilance; or
- exaggerated startle response.

A new subset of new fears and aggression was suggested and is said to be present if one of the following is recorded:

- new aggression;
- new separation anxiety;
- fear of toileting alone;

- fear of the dark; or
- any other unrelated new fear.

To date, these altered criteria have not been tested against the traditional ones. Almqvist & Brandell-Forsberg (1997) provided evidence on how a standard set of play materials can be used to obtain objective data on traumatic stress reactions from preschool-age children. Thus, one can anticipate a refining of criteria and methods of assessment of PTSD in preschool-age children in the next few years.

Manifestations of stress reactions in children and adolescents

Immediately following a very frightening experience, children are likely to be very distressed, tearful, frightened and in shock. They need protection and safety and to be reunited with their families wherever possible. Clinical experience, surveys and clinical descriptive studies quoted below show that the main manifestations of stress reactions are as follows.

Starting almost immediately, most children are troubled by *repetitive, intrusive thoughts* about the accident. Such thoughts can occur at any time, but particularly when the children are otherwise quiet, as when they are trying to drop off to sleep. At other times, the thoughts and vivid recollections are triggered off by reminders in their environment. Vivid dissociative *flashbacks* are uncommon. In a flashback, the child reports that he or she is re-experiencing the event, as if it were happening all over again. It is almost a dissociated experience. *Sleep disturbances* are very common, particularly in the first few weeks. *Fears* of the dark and bad dreams, *nightmares*, and waking through the night are widespread, and often manifest outside the developmental age range in which they normally occur.

Separation difficulties are frequent, even among teenagers. For the first few days, children may not want to let their parents out of their sight, even reverting to sleeping in the parental bed. Many children become much more *irritable and angry* than previously, both with parents and peers.

Although child survivors experience a *pressure to talk* about their experiences, paradoxically they also find it very *difficult to talk with their parents and peers*. Often they do not want to upset the adults, and so parents may not be aware of the full extent of their children's suffering. Peers may hold back from asking what happened in case they upset the child further; the survivor often feels this as a rejection.

Children report a number of *cognitive changes*. Many experience *difficulties in concentration*, especially in school work. Others report *memory problems*, both in mastering new material and in remembering old skills, such as reading music. They become very *alert to danger* in their environment, being adversely affected by reports of other disasters.

Survivors have learned that life is very fragile. This can lead to a loss of faith in the future or a *sense of foreshortened future*. Their priorities change. Some feel they should live each day to the full and not plan far ahead; others realize they have been

overconcerned with materialistic or petty matters and resolve to rethink their values. Their ‘assumptive world’ has been challenged (Janoff-Bulman 1985). Not surprisingly, many develop *fears* associated with specific aspects of their experiences. They avoid situations they associate with the disaster. Many experience ‘*survivor guilt*’—about surviving when others died; about thinking they should have done more to help others; about what they themselves did to survive.

Adolescent survivors report significantly high rates of *depression*, some becoming clinically depressed, having suicidal thoughts and taking overdoses in the year after a disaster. A significant number become very *anxious* after accidents, although the appearance of *panic attacks* is sometimes considerably delayed. When children have been *bereaved*, they may need bereavement counselling.

In summary, children and adolescents surviving a life-threatening disaster show a wide range of symptoms that tend to cluster around signs of re-experiencing the traumatic event, trying to avoid dealing with the emotions that this gives rise to, and a range of signs of increased physiological arousal. There may be considerable overlap of symptoms with depression, generalized anxiety or pathological grief reactions although whether this indicates the presence of mixed disorders or comorbidity of separate disorders remains to be clarified.

However, this has implications for assessment. It is not sufficient to inquire solely about symptoms of PTSD. Symptoms of anxiety, depression and grief need also to be formally investigated. Nor are self-completed questionnaires measuring these aspects sufficient to make a diagnosis. They have an important role, but sensitive clinical interviews with the child and separately with the parents remain the cornerstone of good assessment.

Incidence and prevalence of post-traumatic stress disorder in children

Following initial scepticism that children develop PTSD, many studies of survivors of specific disasters appeared (see reviews in Vogel & Vernberg 1993; Shannon *et al.* 1994; Pfefferbaum 1997; Yule *et al.* 1999). These indicated that where reasonably standard assessment had been undertaken, then the incidence of PTSD in survivors was often in the range of 30–60%. More recently, studies of child survivors of road traffic accidents, again using standardized methods, report that around 25–30% develop PTSD (Yule 2000a). Thus, a substantial minority develops PTSD. At the same time, a substantial minority and often a majority are resilient and do not develop PTSD. Thus, the experience of a traumatic event is necessary but not sufficient to cause PTSD.

In community studies in adults, the Epidemiological Catchment Area (ECA) Survey found a lifetime rate of PTSD of 1% (Helzer *et al.* 1987) while the National Comorbidity Survey reported a much higher rate of 7.8% (Kessler *et al.* 1995). Breslau *et al.* (1991) reported a rate of 9.2% in younger adults while Giacomonia *et al.* (1995) reported a rate of 6.3% in older adolescents.

One of the largest studies of adolescents following a disaster has been the study of survivors of the sinking of the cruise ship *Jupiter* in 1988. Out of nearly 400 children on board, 200 were traced and systematically assessed some 5–8 years later (Yule *et al.* 2000). Fifty-two per cent were found to have developed PTSD, mainly in the first few weeks after the sinking. In keeping with Meichenbaum’s (1994) view, there were very few cases of late-onset PTSD. About one-third recovered within a year of onset, but one-quarter still suffered from the disorder for over 5 years, with 34% still meeting criteria 5–8 years after the sinking. Thus, not only did the survivors of this disaster develop higher rates of PTSD than had previously been recorded, the problems remained over many years in a substantial minority of cases.

The follow-up study of *Jupiter* survivors established that the adolescents also developed a wide range of other positive psychiatric disorders (Bolton *et al.* 2000). They showed considerably raised rates of anxiety and affective disorders compared with controls. Rates of diagnosis were higher in females than males. The disorders were especially raised among those children who had also developed PTSD.

Dose–response relationship

One of the key concepts in PTSD is that anyone can develop the disorder, irrespective of prior vulnerabilities, provided the stressor is sufficiently great. There is therefore considerable interest in whether there is any evidence for a dose–response relationship between stressor and pathology. A number of studies bear on this point in relation to children.

In the California School Sniper study, Pynoos *et al.* (Pynoos & Eth 1986; Pynoos *et al.* 1987; Pynoos & Nader 1988) reported that approximately 1 month after the event, nearly 40% of the children had moderate to severe PTSD on their Post-Traumatic Stress Reaction Index. There was a very strong relationship between exposure and later effects in that those children who were trapped in the playground scored much higher than those who had left the vicinity of the school before the attack or were not in school that day.

At 14-month follow-up, Nader *et al.* (1990) found that 74% of the most severely exposed children in the playground still reported moderate to severe levels of PTSD, contrasted with 81% of the unexposed children reporting no PTSD. Earlier PTSD Reaction Index scores were strongly related to those obtained at follow-up. Only among the less-exposed children did greater knowledge of the victim increase the strength of the emotional reaction to the trauma (Nader *et al.* 1990). In other words, the level of exposure to the life-threatening trauma was more important than other factors, such as knowledge of the victim. In this study, the moderating effects of families reactions was not reported, but the strength of the associations noted challenges McFarlane’s (1987) claim that most effects are mediated by parental reaction.

There was a clear exposure–effect relationship among chil-

dren affected by the Armenian earthquake of 1988, with the most exposed children at the epicentre reporting highest scores (Goenjian *et al.* 1995). In a systematic study of nearly 3000 9–14-year-old children following the Bosnian war in Mostar, a very strong relationship between exposure to war trauma and self-reported psychopathology was found (Smith *et al.* 2001). In a 1 in 10 sample, mothers' mental health was also assessed but, although this did account for a small but significant proportion of the variance in the children's adjustment scores, direct exposure to the war trauma remained the single most important predictor (Smith *et al.* 2001).

Further evidence linking severity to outcome comes from studies which used similar measures following different levels of disaster. The Revised Children's Manifest Anxiety Scale was used in both the study of children who survived the sinking of the cruise ship *Jupiter* (Yule *et al.* 1990b; Yule 1992), and those who experienced Hurricane Hugo in South Carolina on 21 September 1989 (Lonigan *et al.* 1991). In the hurricane study, degree of exposure was significantly associated with increased scores on both anxiety and stress reaction. However, the average anxiety scores for the hurricane survivors were much lower than those obtained from the 334 survivors of the *Jupiter* sinking (Yule 1992), suggesting that the hurricane was less of a direct threat to the children.

The findings from these studies strongly suggest that, within a single disaster, there is a strong relationship between degree of exposure to the stressor and subsequent adjustment. However, subjective factors also have a role. Studies of adult survivors find that high levels of pathology are related to the belief that the survivors were going to die during the incident, as well as to the experience of seeing dead and mutilated bodies (Williams *et al.* 1993). Similar findings are emerging from the study of the most severely affected children assessed individually after the sinking of the *Jupiter* (Yule *et al.* 1992).

Physiological reactions

Reactions to major stress have both physiological and psychological components. Any major life-threatening experience may activate primitive flight/fight/freeze mechanisms which are regarded as less adaptive in young children (Perry *et al.* 1995). In some individuals following some threats, these reactions seem to get stuck. The trauma is then relived at all levels: behavioural, emotional, physiological and neuroendocrinological. The reactions involve many systems, including the release of norepinephrine from the locus caeruleus and endogenous opiates in the septohippocampal system (van der Kolk *et al.* 1985; Goodyer 1990). Some fear that large increases in neurotransmitter activity following trauma may place children at risk of developmental disorders (Perry 1994). The main point to emphasize here is that massive threat can lead to major changes in brain function that may remain over many years, as demonstrated by Ornitz & Pynoos (1989) in their study of persisting startle reaction in a child with PTSD. Goenjian *et al.* (1996) still found a relationship

between intrusion symptoms and baseline cortisol levels 5 years after the Armenian earthquake.

Treatment of post-traumatic stress disorder

While there have been a number of single case reports of treatment of children suffering PTSD, as yet there are few accounts of randomized controlled studies. For the most part, treatment approaches are predominantly cognitive-behavioural and appear to consist of adaptations of approaches used with adults (Yule 1991). Practice guidelines have recently been issued by the American Academy of Child and Adolescent Psychiatry (Cohen 1998), the International Society for Traumatic Stress Studies (ISTSS; Foa *et al.* 2000) and the American Psychological Association (Vernberg & Vogel 1993). They show good agreement in their appraisal of the evidence on which current practice is based.

Critical incident stress debriefing

Critical incident stress debriefing techniques have been adapted for use with groups of children following a variety of traumas (Dyregrov 1991). These involve group leaders structuring discussion with a group of children in such a way that both knowledge and feelings aroused during a traumatic incident are shared and start to be processed. Such a structured crisis intervention approach was used with some children following the *Jupiter* sinking, with good effects on lowering the levels of intrusion and of fears (Yule & Udwin 1991). Stallard & Law (1993) used two debriefing sessions to reduce distress in girls who survived a school bus crash.

Currently, the role of crisis intervention with adults is being called into question with some evidence being cited to the effect that early intervention may cause more rather than less PTSD (Canterbury & Yule 1999). Following the arguments of Rachman (1980) and of Saigh (1986), there is a clear danger that inappropriate exposure sessions that are too short and leave the child in an aroused state may sensitize them rather than help the anxiety habituate. Moreover, the wide range of individual differences to experience have already been emphasized. Even as apparently simple an intervention as giving out a leaflet to survivors has been found to be helpful to the majority but distressing to a significant minority (Yule *et al.* 1990a). Thus, one must entertain the notion that any crisis intervention might have untoward effects in at least some children. The onus is on therapists to monitor which children are helped and which are not by any of the crisis intervention techniques.

There are now a number of leaflets available for distribution to children and their parents alerting them to possible emotional sequelae of accidents and other life-threatening experiences. Among these are the age-specific leaflets prepared by the Child Accident Prevention Trust (Troyna 1998).

Group treatments

Group treatments are obviously to be preferred as a first line of intervention when large numbers are involved. Gillis (1993) suggests that groups of 6–8 are optimum, and advises that separate groups should be run for boys and girls. However, different types of incident surely require different responses from professionals (Galante & Foa 1986; Yule & Williams 1990) and it is too soon to pontificate on what should be a standard approach.

As with debriefing, the aims of such therapeutic groups will be to share experiences and feelings, to boost children's sense of mastery and control, and to share ways of solving common problems. Pynoos & Nader (1993) point out that it is not sufficient for groups to provide a forum for the expression of feelings: this may only renew feelings of anxiety unless a constructive, therapeutic approach is taken.

School-based classroom interventions are particularly recommended when there is a widespread disruption of services and community life as in earthquakes or war. Returning some semblance of normality and predictability into children's lives is widely favoured, and helping them within the context of familiar groups is seen as advantageous. Klingman (1987) and Eth (1992) suggested that mental health professionals run the psychoeducational meetings, with the class teachers in attendance. Smith *et al.* (1999a) described a flexible, yet structured, intervention designed to be delivered by teachers or primary health care workers with minimal training but adequate support from mental health workers. The manual is currently being field tested with survivors of the Turkish and Greek earthquakes of 1999.

March *et al.* (1998) reported a single case group design in which 17 children who had witnessed a fire were treated in two small groups, with the treatment being staggered. Overall, symptom counts dropped only as treatment was started. Impressively, 8 of the 17 (57%) no longer met criteria for PTSD after the 18 weekly sessions and 12 out of 14 (86%) were free of PTSD at 6-month follow-up. The treatment was both psychoeducational and active cognitive-behavioural.

While the group treatment approaches reported above are well described and appear promising, there are no controlled studies providing evidence for the efficacy of such groups. There is a consensus that group interventions will be effective for some, but not all, children. However, one function of therapeutic groups is to screen for high-risk children who may need individual therapy. More generally, children whose problems persist despite group help should be treated individually.

Individual treatment

Individual treatment centres mainly on cognitive-behavioural therapies that aim both to help the survivor make sense of what happened and to master their feelings of anxiety and helplessness (Perrin *et al.* 2000; Smith *et al.* 1996). Drug treatments have little place at present. Asking children to draw their experiences can be useful in helping them recall both the event and the emotions associated with it (Newman 1976; Blom 1986; Galante &

Foa 1986; Pynoos & Eth 1986) but merely drawing the trauma is not a sufficient therapy. A recent study from former Yugoslavia where great emphasis was placed on getting children to express their emotions through drawing found that 6 months after having had very structured sessions on drawing and other expressive techniques, there was no measurable change in children's adjustment on a whole range of self-report measures of stress reactions (Bunjevack & Kuterovac 1994).

Saigh (1986) was one of the first to provide clinical evidence that, as Rachman (1980) had predicted, there were dangers in using standard systematic desensitization approaches as the length of exposure sessions may be too short to permit adequate habituation of anxiety. It should also be remembered that where children are frightened by the vividness of their memories then relaxation may only serve to intensify the vividness. The theoretical aspects of exposure therapy in treating PTSD in children are discussed elsewhere (Saigh *et al.* 1996).

Given the nature of traumatic events, children are not infrequently bereaved as a consequence. Pynoos & Nader (1988) emphasize the need to help children to distinguish their trauma-related responses from those related to grief, and suggest that where several children are bereaved, small groups can be beneficial in the initial stages. Dyregrov's (1993) account of the distinguishing features of traumatic bereavement implies that the traumatic nature of the death and post-trauma reactions need to be addressed before grieving can begin. Black (1993) uses a wide variety of techniques including the use of drawings and play in her work with children who have been bereaved as a consequence of one parent killing another. Importantly, she also describes how family work—including that with new carers—is necessary in cases where a child has lost a parent.

Pynoos's (1994) developmental framework for understanding trauma reactions has a number of implications for therapeutic intervention. The model suggests that the interaction over time of many critical factors (including the complexity of the traumatic experience and the interactions of traumatic reminders, secondary stress, post-traumatic distress, and development) have a role in the progression from traumatic exposure to psychopathology. Each of these factors can be seen as a potential focus for intervention. Similarly, James (1989) describes the use of early intervention with subsequent 'pulsed intervention' over time using multifaceted treatment approaches.

Eye movement desensitization and reprocessing

There is considerable interest and scepticism in eye movement desensitization and reprocessing (EMDR) treatment (Shapiro 1991). In this technique, children are asked to conjure up an image of the traumatic event while simultaneously moving their eyes to follow the therapist's hand. The therapist makes few, if any, verbal interventions or interpretations. In some children, the images spontaneously alter and lose their ability to generate anxious feelings. To date there are no published accounts of controlled trials with children and adolescents. Tinker & Wilson (1999) described many successfully treated cases but no com-

parison data were provided. C. Chemtob, J. Nakashima, R. Hamada & J. Carlson (unpublished data, 1998) used 3–6 sessions of EMDR with adolescents traumatized following a hurricane and report good results, but again with no control data. As with all techniques that have no clear rationale, caution has to be exercised. However, if symptomatic relief can really be attained in a few brief sessions, then the approach needs to be carefully evaluated. As there does seem to be a different quality to the memories of a trauma that appear at the same time to be locked in, vivid, and unchangeable merely by talking about them, then any technique that will allow emotional processing to proceed must be examined.

Contingency planning

When trauma affects a large number of children at once, as in an accident at school, then a public health approach to dealing with the emergency is required (Pynoos *et al.* 1995). Schools need to plan ahead not only to deal with large-scale disasters, but also to respond to the needs of children after threatening incidents that affect only a few of them. Thus, there are now a number of texts written especially for schools to help them develop contingency plans to deal with the effects of a disaster (Johnson 1993; Klingman 1993; Yule & Gold 1993).

Most developed countries have well-established plans to deal with major civil emergencies. Increasingly, these include a psychosocial or mental health component and it is advisable for child and adolescent mental health services to be involved in the planning (Canterbury & Yule 1999). UN agencies are increasingly prepared to meet the mental health needs of children after war and major disasters (Report of the UN Secretary General on the Impact of Armed Conflict on Children 1966), and again mental health services need to collaborate with other agencies to meet such needs.

Overview of treatment

In formulating their recommendations for practice, the ISTSS task force (Foa *et al.* 2000) used very stringent criteria when judging the evidence for treatment efficacy. The strongest evidence was viewed as deriving from randomized well-controlled clinical trials (Level A) while the poorest evidence (Level F) encompassed anecdotal evidence from recently developed approaches that had not been tested empirically. They rated cognitive-behaviour therapy as being at Level A; EMDR as being at Level B–C; dynamic psychotherapy as being at Level D; and other forms of intervention such as debriefing, family psychotherapy, group psychotherapy and art therapy as all being at Level E.

Cognitive processing

Rachman (1980) conceptualized what was to be labelled as PTSD as a failure to process emotions that arose following

exposure to a traumatic event. Since then, there has been a great deal of work examining emotional and cognitive processing in adult PTSD patients (Dalglish 1999; Thrasher & Dalglish 1999). More recently, the paradigms developed to study these processes in adults have been adapted to study PTSD in children. Thus, in a series of related studies of children presenting with general anxiety disorder, depression and PTSD, Dalglish, Yule and colleagues have shown that on measures of attention and memory, the three groups of children not only differ but do so in the same way as adults; both groups of anxious children respond more quickly to threat words on the Stroop task, especially threat words directly related to the trauma in the case of children with PTSD (Dalglish *et al.* 1998; Moradi *et al.* 1999a–c; Neshat-Doost *et al.* 1998, 2000; Taghavi *et al.* 1999).

Conclusions

Since its formulation in 1980, the diagnosis of PTSD has become widely used in child mental health practice. Using standard criteria and measures, significant minorities of children and adolescents have been diagnosed with PTSD following a variety of major stressors from transport accidents, natural disasters such as hurricanes, and war. These reactions have now been shown to be both long-lasting and disabling in many cases. Moreover, the few studies of psychophysiology and biochemistry confirm that there are underlying changes that may be difficult to reverse.

While it is comforting to children who develop PTSD following a life-threatening experience to be told that their frightening symptoms are ‘normal’, not all children do react this way and so greater emphasis is needed to discover why some children are more vulnerable than others. It seems clear that there is a dose–response relationship between severity of exposure and severity of symptoms, both within and between different types of incident.

There is considerable overlap in disorders that present after a major traumatic event (Pfefferbaum 1997; Bolton *et al.* 2000); however, there seems more than heuristic value in regarding PTSD to be both separate from other anxiety disorders and separate from depression. For example, following their intervention after the Armenian earthquake, Goenjian *et al.* (1996) found that in the group who had treatment first, PTSD scores reduced while depression scores remained stable. By contrast, in the waiting list control group, the PTSD did not resolve but the depression increased. In other words, the two disorders react differently to intervention.

One can also argue that these disorders are indeed different in so far as the content of the intrusive thoughts is so specific to the particular event and so characteristic of the disorder in a way that is not found in depression or other anxiety disorders. This needs to be explored more systematically. Indeed, studying PTSD has proved a remarkably fertile ground for studying child psychopathology and so one hopes that there will be more investigations of the nature of traumatic stress reactions in younger

children as well as better intervention studies. In the mean time, PTSD is a diagnostic category that helps focus mental health professionals on the needs of the children—always providing that they ask the children themselves about their inner experiences and reactions.

Introduction

Suicide and attempted suicide are two closely related phenomena but they differ in important ways. Suicide is a relatively unusual event. In the USA, about 1 in 10 000 15–19-year-olds commit suicide each year. Attempted suicide, on the other hand, is extremely common. All suicidal features are more common in females but suicide ideation is extremely common in both sexes, being present in 14% of boys and 25% of girls (Centers for Disease Control 2000). Further, most ideators also make a plan. If we assume a male attempt rate of 2.1% and a male death rate of 14.6 per 100 000, the ratio of serious attempts to completed suicides in males is about 140 : 1, compared with approximately 1000 : 1 in females.

Completed suicide

Incidence

Suicide in prepubertal children is rare in all countries (Table 33.1). Among 10–14-year-olds, most suicides occur in those who are oldest. The incidence of suicide then increases steadily through the teenage years, reaching a peak in the early or mid-twenties (see Fig. 33.1). In all developed countries (except the USA, where homicide is the second leading cause), suicides are the second leading cause of death, exceeded only by accidents. In the USA—a country with a relatively low suicide rate—the number of suicides outnumbers the number of deaths from all other natural causes combined (National Center for Health Statistics, Centers for Disease Control and Prevention 2000).

Rate changes over time

In recent years, the rate of suicide among teenagers has shown marked and sustained changes (Fig. 33.2): US male teenage suicides increased more than threefold in the 20-year period from the mid-1960s until the mid-1980s (National Center for Health Statistics, Centers for Disease Control and Prevention 2000), and similar increases were reported in many other countries (UNICEF 1996; Lynskey *et al.* 2000; McClure 2000; World Health Organization 1997–1999). However, between 1990 and 1998, in the USA as well as in other countries, the rate declined by around 20% in *both* males and females.

A number of reasons have been proposed to explain the ear-

lier increase and the more recent decrease in teenage suicide deaths. Reasons that were once proposed for the *increase* include broad social changes, such as high divorce rates and the increasing proportion of mothers in the workplace; and cultural influences, such as rock music lyrics, the broad acceptance of assisted suicide, and the increasing availability of firearms. However, empirical research suggests that a lack of family cohesion is not a powerful risk factor (Gould *et al.* 1998a), nor is there evidence for any noxious consequences of songs and lyrics that dwell on morbid subjects. A more convincing explanation is that the period of increasing rates was a period of increasing drug and alcohol use, a known risk factor for suicide (Robins *et al.* 1959; Murphy & Robins 1967; Murphy & Wetzel 1990; Shaffer *et al.* 1996a; Renaud *et al.* 1999). Furthermore, the relationship between suicide and substance and alcohol abuse is stronger in males (Shaffer *et al.* 1996a) and occurs mainly in older teenagers, the gender and age group most affected by the rate increase.

The more recent *fall* in the suicide rate does not seem to be caused by a reduction in alcohol exposure because, at least in the USA and the UK, drug and alcohol usage rates have remained steady during the period of declining suicide incidence (Centers for Disease Control 2000; UK Office for National Statistics 2000). A widely accepted explanation is that the reduction is a result of the much more frequent prescribing and acceptance of the newer antidepressants for teenagers (Isacsson *et al.* 1997; Safer 1997a; Ohberg *et al.* 1998; Olfson *et al.* 1998; C. Blanco & M. Olfson, personal communication 2000).

Gender

In adolescence, suicidal ideation and suicide attempts are more common in females (Safer 1997b; Centers for Disease Control 2000), whereas completed suicides are more common in males. In a small number of developing countries in South Asia and Latin America, the male and female suicide rates are similar or are even higher among girls (World Health Organization 1997–1999; Yip *et al.* 2000). The reasons for these gender differences are not known, but in all probability reside in gender differences in psychopathology and in method preference.

Psychopathology

Teenagers who commit suicide can be grouped into:

1 a large, predominantly male, group with a history of

Table 33.1 Youth suicide rates per 100 000, latest year available, in selected countries (World Health Organization 1997–1999).

Country	Year	Ages 5–14		Ages 15–25	
		Male	Female	Male	Female
Australia	1995	0.3	—	23.1	6.1
Belgium	1994	1.6	0.2	22.7	3.7
Canada	1997	1.9	0.6	22.4	4.5
France	1996	0.5	0.1	12.8	4.2
Germany	1997	0.6	0.2	12.9	3.2
Ireland	1996	1.3	—	25.4	4.5
Italy	1995	0.5	0.0	7.3	1.6
Japan	1997	0.5	0.03	11.3	5.5
Netherlands	1997	1.1	—	11.3	4.4
New Zealand	1996	1.0	1.5	37.8	13.9
Russian Federation	1997	3.0	0.7	53.2	9.0
UK	1997	0.1	0.1	11.1	2.3
England & Wales	1997	0.1	0.1	9.9	1.9
Northern Ireland	1997	0.7	0.8	18.6	4.4
Scotland	1997	—	—	19.5	5.3
USA	1998	1.2	0.4	18.5	3.3

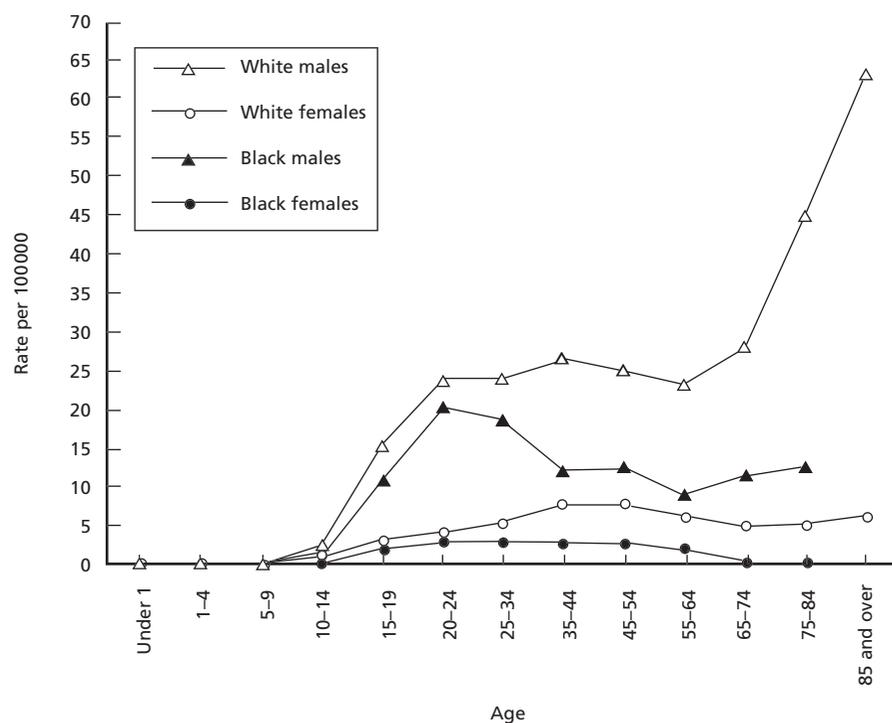

Fig. 33.1 Suicide rates at different ages (US, 1998) (NCHS, 2000).

aggressive behaviour and impulsive and intense responses to stress and comorbid substance and alcohol abuse; and

2 a much smaller group of males and females with anxious or depressive symptoms without associated antisocial behaviour (Shaffer *et al.* 1996a; Brent *et al.* 1999).

It is likely that the predominance of males in the first group accounts, in large measure, for the male excess in completed suicides.

Choice of method

Most female suicide attempts and many female suicides involve an overdose, but in most countries this is not an effective method. In some countries, the supply of rapidly lethal ingested substances, such as barbiturates, is restricted and, in most developed countries, treatment resources for intentional ingestions are well developed. In countries with high female suicide rates, the

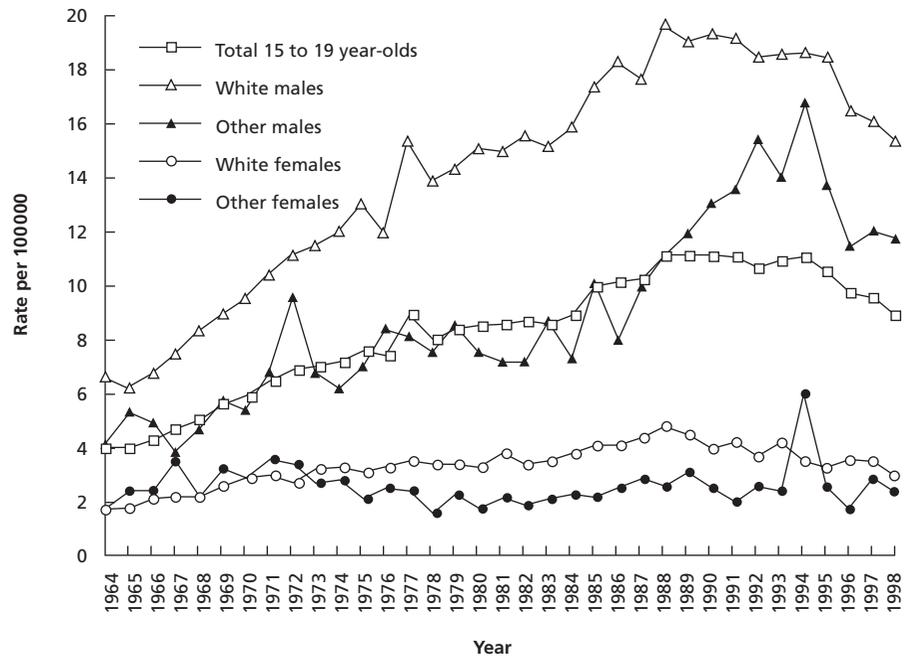

Fig. 33.2 Adolescent suicide rates (15–19-year-olds) (US, 1964–1998) (NCHS, 2000).

type of self-poisoning used cannot be treated—e.g. paraquat and organophosphate ingestion in Southeast Asia and the South Pacific (Haynes 1987; Jeyaratnam 1990; Eddleston *et al.* 1998)—and good medical services are not readily available.

Age

Completed suicide is exceedingly rare before age 12 and is, on average, less common in teenagers than in adults. The incidence increases each year until the mid-twenties when in most, but not all, countries, it increases more gradually until late middle age. This incidence pattern makes it unlikely that teenage suicide results from specifically adolescent psychological ‘tasks’ or stresses. If that were the case, the incidence of suicide would have a peak incidence in the mid-teenage years with a subsequent decline. The rarity of suicide before puberty has been attributed to more difficulty in accessing lethal methods and poorly developed planning skills. A youngster who intends to hang himself needs to find an appropriate and private site or a degree of technical sophistication. This is not an entirely plausible explanation, because a degree of privacy is available to most 12–15-year-olds who, nevertheless, have a very low suicide rate. Further, many suicide threats in young children involve a threat to jump from a height or into traffic—potentially effective methods that are readily accessible to most children and can be executed without much planning. It seems more likely that the incidence gradient across the teenage years is also influenced by the appearance of new risk factors in later adolescence. The two leading risk factors for suicide in adolescence— affective illness and alcohol abuse (Brent *et al.* 1989, 1993a; Gould *et al.* 1990; Shaffer *et al.* 1996a)—are uncommon before the mid-teens

(Kashani & Simonds 1979), but are increasingly prevalent after that.

Ethnicity

Cultural differences in prevalence are conveniently studied in a multiethnic country, such as the USA or the UK, where recording and reporting procedures are similar for different groups. In the USA, suicide is more common in whites than in non-whites in all age groups (see Fig. 33.1). In the UK, the suicide rate is much higher among the Scots and the Welsh than among the English (World Health Organization 1997–1999).

The reasons for these cultural differences are not known. In the USA, American Indian and Native Alaskan youth have more than twice the national rate of suicide (Indian Health Service 1996). Historically, African-Americans, both adolescents and adults, have had lower suicide rates than Caucasians. However, in the mid-1980s the African-American suicide rate in teenagers began to climb precipitously, levelling off in the mid-1990s. The current difference between African-American and Caucasian adolescent suicide rates, although still significant, is not as great. The African-American : Caucasian 15–19-year-old USA suicide rate ratio went from 1 : 2 in 1979, to 2 : 5 in 1986, to 2 : 3 in 1998. In the USA, black–white differences have been variously attributed to religiosity (Neeleman *et al.* 1998) and/or more effective social support systems (Gibbs & Martin 1964; Bush 1976; May 1987; Neeleman & Wessely 1999) or to reporting biases (Monk & Warshauer 1978). However, it is possible that variations in the suicide rates in different groups and countries are only indirectly related to culture, and that the mechanisms for the differences lie in imitation and contagion (see below) that operate

within and not across cultural boundaries. If this were so, it could account for the quite stable regional differences that can exist for many generations within a country.

Although there appear to be cultural or regional differences in vulnerability to suicide, there is little evidence that the characteristics of suicide differ in different groups. The rates and types of psychiatric disorders, family histories of suicidality and recent stresses are similar in countries as different as the USA (Shaffer *et al.* 1996a), Finland (Marttunen *et al.* 1991, 1993), India (Vijayakumar & Rajkumar 1999), Taiwan, in the Han Chinese and two distinct aboriginal groups (Cheng 1995).

Characteristics of suicide

Season

Contrary to popular belief, suicide is not more common during the holiday season (Lester & Beck 1975; Hillard *et al.* 1981; Bollen 1983; Phillips & Wills 1987). However, there may be a 'delayed effect', with lower suicide rates during the holiday and then higher rates immediately afterwards (Phillips & Liu 1980; Jessen & Jensen 1999). In both the northern and southern hemispheres, suicide is most common during the spring months (Lester 1979; Chew & McCleary 1995; Flisher *et al.* 1997), with a second peak in autumn (Kevan 1980; Meares *et al.* 1981; Hakko *et al.* 1998). There are similar seasonal peaks in hypomanic behaviour among individuals with bipolar illness (Eastwood & Peter 1988; Goodwin & Jamison 1990; Silverstone *et al.* 1995; Szabo & Blanche 1995). Suicide in bipolar illness is most common at the time of mood shifts, and there might be an association between the two phenomena.

Method

In the USA, the large majority of teenage boys and a smaller majority of teenage girls commit suicide with firearms, most often legally registered but inadequately secured rifles or shotguns. Only 20% of suicides committed with firearms in the USA are committed with handguns. In Great Britain, hanging is the most common method for boys, while girls are more likely to die from an overdose or fall from a height. The increase in hanging in young males in the UK and New Zealand has offset the decrease in overdose and asphyxiation deaths. Some studies have reported a relationship between diagnosis and method. Brent *et al.* (1991) found that firearms were more likely to be used by boys with substance or alcohol abuse problems, but this finding has not been consistently reported. There is some evidence that the method is largely determined by availability (Moens *et al.* 1988; Hawton *et al.* 1998a; Fisher *et al.* 2001).

Occasionally, a boy will be found having seemingly hanged himself in a state of semiundress or cross-dress, with evidence of recent orgasm and the presence at the scene of death of fetishistic objects. It is then assumed that his death was an accidental result of erotic activity (Stearns 1953; Coe 1974; Sheehan & Garfinkel 1988). Shaffer *et al.* (1996a) found that fewer than

3% of hanging deaths occurred in these circumstances. Very few published accounts of alleged auto-erotic deaths provide evidence of habitual semistrangulation, and the gender, seasonal and ethnic distribution of the victims closely resemble that of suicides. In the few psychological analyses that have been published, depression and substance abuse were common, as in suicide (Sheehan & Garfinkel 1988). Taken together, these facts suggest that, rather than many auto-erotic accidental deaths being misclassified as suicide, the reverse is equally likely.

Precipitants

Although some adolescents, predominantly girls, suffering from a major depressive disorder appear to have thought about suicide for some time and will often have made some preparation for their death, most adolescent suicides appear to be impulsive (Negron *et al.* 1997). Often they were preceded by a stress event, such as a disciplinary crisis, a ruptured relationship with a boyfriend or a girlfriend or a fight among friends (Brent *et al.* 1993b; Gould *et al.* 1996). In many instances, these stress events can be seen as a by-product of an underlying mental disorder. The events that precede a suicide often reflect the victim's underlying psychopathology. The most common precipitant is a 'disciplinary crisis', school suspension or appearance in juvenile court (Brent *et al.* 1993b; Gould *et al.* 1996). A typical situation will be that a teenager is discovered truanting or stealing and is told by the school or police that some action will be taken in the near future, e.g. parents or the court will be informed. The teenager commits suicide shortly afterward, before the anticipated response. The frequency of the situation reflects the high rate of aggressive conduct disorder in the suicidal population. By contrast, suicide victims with predominantly anxious symptomatology might commit suicide shortly before a feared event, such as an examination, starting at a new school or moving to a new neighbourhood (Shaffer 1974; Shaffer *et al.* 1996a). Suicides in the context of an acute depression might have no obvious external precipitant. A small number of suicides occur on the anniversary of a friend's death. In one study (Shaffer 1974), just over one-quarter of the children died within two weeks of their own birthdays. About half of all suicides had discussed or threatened suicide within 24 hours of their deaths.

Aetiology

Biological abnormalities

In 1976, Asberg *et al.* (1976) noted a relationship between low levels of cerebrospinal fluid 5-hydroxyindoleacetic acid (5-HIAA), the major metabolite of serotonin, and a prior suicide attempt in a group of adult patients suffering from melancholic depression. This has now become one of the most replicated findings in biological psychiatry (see Oquendo & Mann 2000 for a review). This relationship is stronger among suicides who died by firearm and hanging than in those who died from an

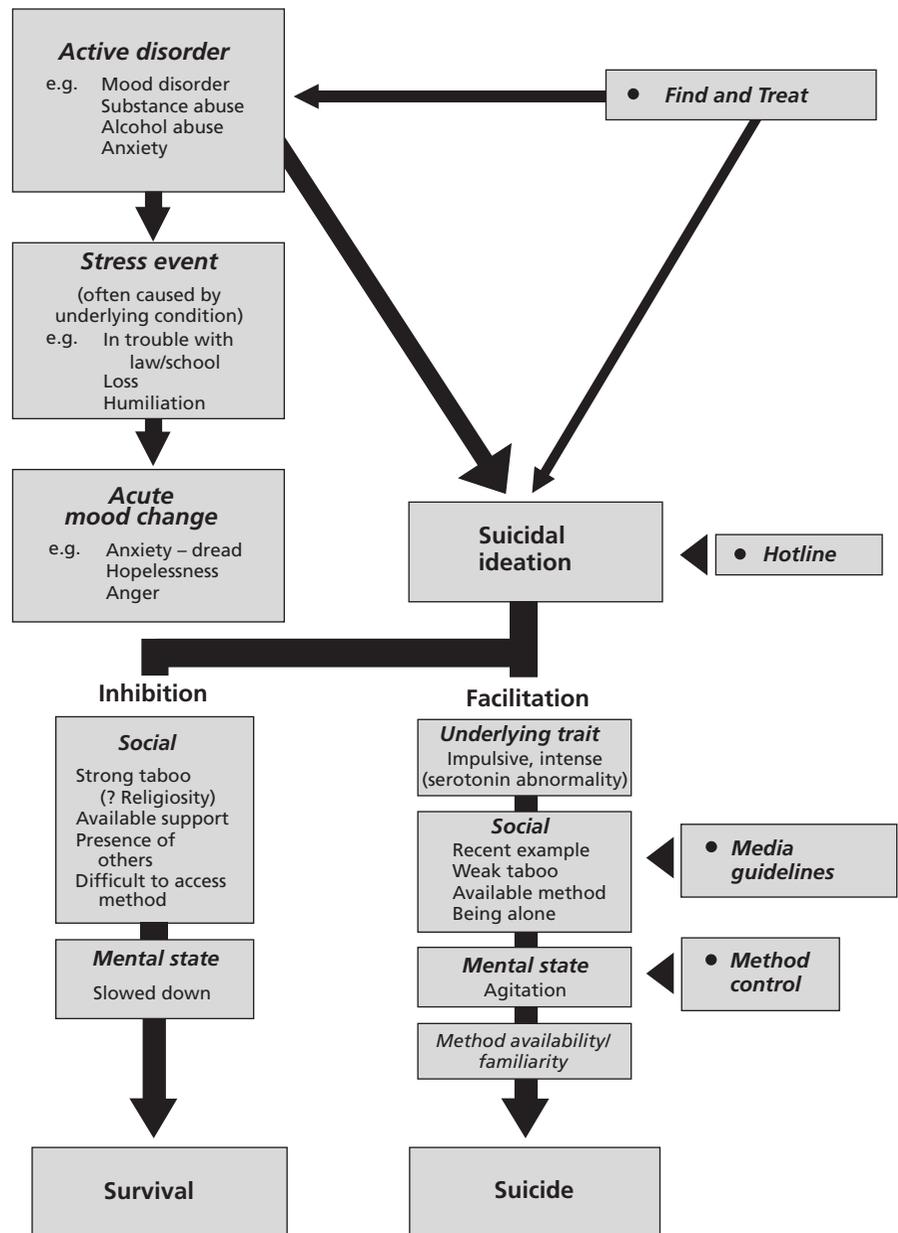

Fig. 33.3 How do suicides occur and how can they be prevented?

overdose. It is found in suicides regardless of diagnosis. However, there is as yet no information about the proportion of suicides in which serotonin abnormalities are found. Although such studies are now in progress, there are no descriptions of how suicides with evidence of serotonin dysregulation differ from those without. However, similar abnormalities have been reported in impulsive and aggressive individuals, and it is generally assumed that these behaviours distinguish the suicides with this type of biological dysregulation.

The working model (Mann 1999; Mann *et al.* 1999) is that serotonergic dysregulation is a biologically determined trait and that a mentally ill individual who possesses this trait is more likely to respond to a stressful experience in an impulsive and aggressive fashion. This response mode could lead directly to

suicide or could simply increase the stressful consequences of their behaviour, ultimately leading to their suicide (Fig. 33.3). There is some evidence that suicide attempters with low levels of cerebrospinal fluid 5-HIAA are significantly more likely to make a future attempt and/or to commit suicide (Nordstrom *et al.* 1994).

Autoradiographic studies suggest that the abnormality is presynaptic and results in compensatory upregulation of postsynaptic type-2 serotonin (5-HT₂) receptors in the ventral and ventrolateral prefrontal cortex—the area of the central nervous system that is in large measure responsible for behavioural inhibition. These findings have led to an active investigation of two candidate genes: the promoter region of the serotonin transporter gene; and the gene for tryptophan hydroxylase (*TPH*), the

rate-limiting enzyme for the synthesis of serotonin. Despite the large number of studies that have reported these abnormalities, a number of unanswered questions remain. The specific behavioural correlates of low serotonin states have yet to be documented in large samples; there are conflicting reports about whether 5-HIAA levels are stable or fluctuate with mental state; and it is not known in what proportion of suicide victims such abnormalities occur. If, as has been held, declining or stable low levels of 5-HIAA predict a poor prognosis, then secondary or tertiary prevention could be served by routine cerebrospinal fluid monitoring of patients who have made a suicide attempt, with special care being given to those with abnormally low levels.

Family history

Controlled psychological autopsy studies (Brent *et al.* 1996a; Shaffer *et al.* 1996a) have found that completed suicides are between two and four times more likely than matched controls to have a first-degree relative who committed suicide. A similar relationship has been reported in a community-based study of suicide attempters (Bridge *et al.* 1997a; Johnson *et al.* 1998). These findings could be the consequence of such environmental influences as imitation or identification, or be a consequence of being brought up by or with a psychiatrically ill parent or sibling. However, family history of suicidal behaviour remains a risk factor, even after accounting for parent and youth psychopathology (Brent *et al.* 1996a; Gould *et al.* 1996), and findings from both adoption and twin studies suggest that the relationship involves a genetic component.

Schulsinger *et al.* (1979), using the Danish adoption registry, found significantly higher rates of suicide in the families of adoptees who committed suicide than in a matched control group. Twin studies have found significantly greater concordance for suicide (Roy *et al.* 1991), suicide attempts (Roy *et al.* 1995, 2000) and suicide ideation (Statham *et al.* 1998) among monozygotic than dizygotic twin pairs. These findings, and the implication of dysregulation of the serotonergic system in suicidality, have led to a search for single-gene polymorphisms of two candidate genes involved in the synthesis of serotonin (see above): the promoter region of the serotonin transporter gene and the *TPH* gene — the rate-limiting enzyme for the synthesis of serotonin. Findings on these candidate genes has been inconsistent (Nielsen *et al.* 1994, 1998; Ohara *et al.* 1998; Bennet *et al.* 2000; Geijer *et al.* 2000). It is not clear whether this is because the suicide phenotype comprises many different aetiological factors, because the genetic effect is small and requires the analysis of large numbers of patients, or because the clinical importance of a single genetic variant might not be apparent unless studied with other related genes (Marshall *et al.* 1999).

Imitation and contagion

It appears that suicidal behaviour, including completed suicide, can be triggered by exposure to knowledge about other actual or fictional suicides (Velting & Gould 1997). Strong evidence for

this includes case accounts of suicides that occurred shortly after a teenager saw a film or read a book or news story about a suicide (Shaffer 1974). In a quasi-experimental ABABA design, Schmidtke & Hafner (1986) showed that the showing of a fictional account of a 19-year-old male student's railway suicide was followed by a sharp but time-limited increase in similar method suicides among youth of similar age and sex. This phenomenon was repeated when the series was rebroadcast a year later.

Ecological studies have also shown a time relationship between media reports of a suicide and a subsequent increase in suicide and suicide attempt rates (Holding 1974, 1975; Gould & Shaffer 1986; Gould *et al.* 1988). None of these studies established whether an individual suicide was exposed to the purported stimulus. The excess of suicides in such circumstances lasts between 7 and 14 days, is proportional to the number of times that the news story is repeated (Phillips 1974, 1979, 1980, 1984; Bollen & Phillips 1981, 1982; Wasserman 1984) and mainly affects young people (Phillips & Carstensen 1986). Studies of the impact of a single stimulus, such as a TV programme, are not always consistent (Berman 1988; Gould *et al.* 1988). The inconsistencies might be a result of variations in the age and size of the exposed viewership and the context in which the material is seen (e.g. whether or not the programmes were accompanied by material that could direct a disturbed viewer to obtain help, etc.).

Evidence for contagion also comes from the well-documented occurrence of cluster or epidemic suicides that are estimated to account for up to 4% of all adolescent suicides in the USA and to be increasing in incidence (Gould 1990). In a suicide cluster, an unexpected number of deaths occur in a short period of time in a circumscribed community. There is no evidence that clusters occur as a response to significant changes in the community itself, and little is known about the characteristics of the suicides. In a description of one cluster (Davidson *et al.* 1989), the victims, like sporadic suicides, were predominantly male and several had a history of past suicidal attempts. Suicide clusters in time can also be triggered by publicity accorded to an unusual suicide method such as self-immolation (Ashton & Donnan 1981), or the use of a specific location such as the Golden Gate Bridge in San Francisco (Kirch & Lester 1986). The Centers for Disease Control in the USA have prepared guidelines for minimizing the problem accorded to an individual suicide, but there is as yet no evidence that applying the guidelines will reduce imitative suicides.

Associated psychiatric disorder

Almost all children and teenagers who commit suicide were suffering from a psychiatric disorder at the time of death (Marttunen *et al.* 1991, 1995; Shaffer *et al.* 1996a; Brent *et al.* 1999). In this respect, as in many others, suicide in adolescents resembles suicide in adults (Robins *et al.* 1959; Barraclough *et al.* 1974; Rich *et al.* 1988). At the time of the suicide, psychiatric disorder is usually well established and, in approxi-

mately half (Shaffer *et al.* 1996a), it has been present for 2 years or more. The most common forms in completed suicides are the following.

1 *Some form of mood disorder* in about two-thirds of all suicides. In girls this usually takes the form of an uncomplicated major depression, while in boys it is often comorbid with conduct disorder and/or substance abuse. Many of these boys are markedly irritable, impulsive and volatile, and are prone to outbursts of aggression.

2 *Substance and/or alcohol abuse*, which is present in up to two-thirds of older boys (Shaffer *et al.* 1996a; Brent *et al.* 1999) and is usually complicated by comorbid mood and or conduct problems.

3 About one-quarter to one-third have an *anxiety disorder* (Shaffer *et al.* 1996a; Brent *et al.* 1999). Performance and anticipatory anxiety are particularly prominent and might be viewed by parents as a sign of 'perfectionism'. This group of suicides will usually have gone undiagnosed and been considered to be excellent students and well liked by their peers.

4 *Conduct or oppositional disorder* is present in between one-third and one-half of suicides (Shaffer *et al.* 1996a; Brent *et al.* 1999). It is more common in males and in older suicides and is often comorbid with one of the other disorders listed above. The mechanism underlying the relationship is not known. It could reflect a common biological predisposition mediated by dysregulation of the serotonergic system; it could reflect the depression that often develops in teenagers who are in 'trouble', failing at school, unwelcome at home, and who may be distanced by their peers.

Although the rate of suicide is greatly increased in schizophrenia, because of the rarity of the condition it accounts for very few suicides in the child and adolescent age group. However, mental health professionals who care for individuals with schizophrenia should be aware of their greater risk for suicide.

About 40% of suicides have made a previous known suicide attempt (Shaffer *et al.* 1996a; Brent *et al.* 1999). Previous attempts are more common in girls and among suicides suffering from a mood disorder at the time of their death. In the New York study (Shaffer *et al.* 1996a), approximately half of all suicides had had previous contact with a mental health professional. The very few suicides who were found to be free of significant psychiatric symptomatology included a disproportionate number of prepubescent suicides.

Psychiatric disorder as risk factor

Suicides share many characteristics with other children and teenagers who have psychiatric problems and who do not commit suicide. Determining unique risk factors for suicide requires controlled comparisons, and the sizes of both the index and the control samples are small in nearly all cases. Nevertheless, certain robust findings stand out. Similar risk factors operate for both boys and girls (Shaffer *et al.* 1996a; Brent *et al.* 1999), but they differ markedly in their relative importance (Shaffer *et al.* 1996a). The most significant risk factor for girls is the presence

of major depression, which in some studies increases the risk of suicide 20-fold (Shaffer *et al.* 1996a). The most significant risk factor for boys is a previous suicide attempt, which increases risk more than 30-fold (Shaffer *et al.* 1996a; Brent *et al.* 1999). Although alcohol abuse and disruptive behaviour disorders are the most prevalent diagnoses, their base rate in the general population is high, and value for prediction is therefore low.

Family circumstances

Both large controlled psychological autopsy studies found that adolescents who committed suicide were less likely than controls to live with both of their biological parents. Whereas Brent *et al.* (1994) ($n=67$) found that suicide victims were more likely to have been exposed to parent-child discord and residential instability, Gould *et al.* (1996) ($n=120$) found that parent-child discord, discord between parents and divorce had only small or marginal effects. Poor parent-child communication was significantly more apparent in adolescents who committed suicide than in their matched controls, even after taking into account parent and teenage psychopathology. Socioeconomic status did not differentiate white or Hispanic adolescent suicides and controls, but African-American adolescent suicide victims had a significantly higher socioeconomic status than their matched controls (Gould *et al.* 1996).

Perinatal morbidity

Salk *et al.* (1985) examined the birth records of a large proportion of consecutive teenage suicides in Rhode Island and found significantly higher perinatal risk scores in the suicides compared with surviving controls. Jacobson *et al.* (1987) reported broadly similar findings in a Swedish birth cohort: 10% of suicides compared with 2.3% of controls experienced asphyxia at birth. The mothers of the suicides also received less antenatal care and were more likely to smoke and drink alcohol during pregnancy. These relationships could be a direct consequence of some induced neuropathy; they could reflect a 'common course', with some disturbed mothers predisposing their children to both perinatal morbidity and to later psychiatric illness; or they could be linked to one another, with the consequences of neurological damage impacting on parental competence and enhancing the likelihood of psychiatric illness.

Attempted suicide

Definition and subtypes

A suicide attempt is one of the more common psychiatric symptoms of youth. Children and teenagers who are psychotic, depressed, anxious, impulsive or, rarely, some who have no psychiatric or personality disorders at all, may think about or attempt suicide. The prognostic significance of a suicide attempt ranges from benign, with few if any negative sequelae,

to malignant with later suicide. Given this heterogeneity, it is not surprising that a number of efforts have been made to define subgroups among suicide attempts.

The World Health Organization adopted the following definition of attempted suicide for its large multinational study. Attempted suicide is, 'An act with non-fatal outcome, in which an individual deliberately initiates a non-habitual behaviour that, without intervention from others, will cause self-harm, or deliberately ingests a substance in excess of the prescribed or generally recognized therapeutic dosage, and which is aimed at realizing changes which the subject desired via the actual or expected physical consequences' (Platt *et al.* 1992). What is remarkable about this lengthy definition is the careful omission of any mention of a wish to *die* and the use of the broader concept of 'self-harm'. Clinicians and parents alike are often reluctant to accept that all attempts and like behaviours are accompanied by lethal intent. This reluctance led Kreitman (1969) to coin the term *parasuicide*, which is now used loosely (Linehan *et al.* 1991) to describe overdoses or self-cutting behaviour of low medical lethality. Although parasuicidal behaviours may be repeated, they are considered to carry a low absolute risk of ultimate suicide. Another common term used by both lay individuals and professionals is a *suicide gesture*. This term assumes that the behaviour was undertaken without lethal intent and that it was intended as a 'communication'. Depending on the benevolence of the user, it can be seen as a 'cry for help', or as an act designed 'to attract attention'. Less inferential terms such as *deliberate self-poisoning* or *deliberate self-injury* (Hawton 1986) are preferable, but the avoidance of the word suicide skirts the problem of how these behaviours relate to suicide.

Because of the frequency of ideation and attempts, and the rarity of completed suicide, it is statistically reasonable to regard all attempts as benign, but the clinician needs to move beyond this actuarial position in order to assess the degree of individual risk. This is not easy. A teenager's 'intent' is very difficult to gauge after the event. Teenagers are, within certain bounds, quite naïve about the actual dangers of their behaviour. Between 30 and 50% of teenagers seen in an emergency room after an 'attempt' say that they wanted to die, but few took active precautions against being discovered (Piacentini *et al.* 1991), and their view is often at variance with that of the clinician. Hawton *et al.* (1982a) reported that examining psychiatrists confirmed lethal intent in only one-third of adolescents who said they wanted to die. How is this to be judged? Low intent cannot be inferred from the size of an overdose, because adolescents are frequently misinformed about the potential lethality of ingestions, in some instances overestimating (Piacentini *et al.* 1991) and in others underestimating (Myers 1992; Harris & Myers 1997) lethality. Piacentini *et al.* (1991) compared attempter and paediatrician estimates of the lethality of overdoses and found that, whereas 26% of attempts were rated as having a potential to cause death by the adolescents, only 2% were considered potentially lethal by the physicians. Prior planning is a time-honoured but probably poor index of serious intent, as both suicide attempts and suicides commonly occur very shortly after a

stressful event, giving little opportunity for careful planning (Shaffer *et al.* 1996a). Furthermore, the biennial Youth Risk Behaviour Survey (YRBS; Centers for Disease Control 2000), with ideation rates of between 15 and 20%, shows that 75% of teenagers who have thought about suicide have made a plan about how to commit suicide, although most will *not* go on to attempt or commit suicide.

For public health purposes, suicide attempts may be subclassified by whether or not the subject received medical treatment (Centers for Disease Control 2000). Although this is a reliable operationalized approach, it may not denote severity of intent. Medical treatment may be a function of availability and could be sought more often after an ingestion (in which the lingering presence of the ingestant requires treatment) than, say, after a failed hanging, which may indicate severe intent but leave no residual physical injury beyond a bruise. These imprecisions might not matter if the terms did not carry important implications. Parasuicide is broadly assumed to be benign, even though just under a half of completed suicides have been preceded by non-lethal ingestion or other attempts (Brent *et al.* 1993a; Shaffer *et al.* 1996a). Some patients who have made a non-lethal ingestion make a more substantial or lethal ingestion hours or days later. The unfortunate term suicide 'gesture' lends support to a causal dynamic (attention-seeking) that may not be accurate and strengthens the stigmatizing view held by many professionals and parents. Behaviour intended to obtain attention may be seen as a waste of professionals' and parents' valuable time. It may also reduce the likelihood of a subsequent referral for a psychiatric opinion.

Continuum of self-injurious behaviour

A completely different approach to the classification of suicidal behaviour is to treat it as a subcategory of a variety of behaviours that cause harm to the patient as a part of a spectrum of 'self-destructive behaviour' (Menninger 1938), such as interpersonal aggression, substance and alcohol use, compulsive gambling, unprotected sex, etc. The co-occurrence of these different behaviours is not in question (Flisher *et al.* 2000). It is possible, but by no means demonstrated, that they have in common some underlying trait such as impulsiveness (Mann *et al.* 1999), or some common prior experience such as early deprivation or abuse. It is also likely that co-occurrence reflects some sequential mechanisms, such as a suicidal response to the stresses experienced by youth with conduct disorder or secondary mood changes induced by intermittent substance and alcohol abuse (Schuckit 1995).

In summary, there is clearly a need to differentiate among the large heterogeneous group of patients who attempt suicide. The assumption that attempts are benign, although true in most instances, is dangerous because a prior suicide attempt is the single most important predictor of completed suicide (Brent *et al.* 1993a; Shaffer *et al.* 1996a). It is probably most reasonable to view a suicide attempt as a symptom or behaviour with varying

aetiologies. Motivation and severity are difficult to assess, and in most instances the patient's mental state will be a better predictor of later outcome than the features and circumstances of the method (Beck 1972).

Epidemiology

Incidence

Since 1990, the USA's Centers for Disease Control has conducted biannual self-report surveys (the Youth Risk Behaviour Survey) to assess the 12-month prevalence of suicide ideation and behaviour in high-school students (Centers for Disease Control 2000). The surveys are large (sample sizes ranging between 12 000 and 16 000), and are representative of 14–17-year-old school attendees. The technique is appropriate because endorsement of questions on adolescent suicide attempts in the community is consistently higher in surveys that use a self-report method than in those given by interview (Safer 1997b). The biennial replication give these data added weight. The surveys consistently show an overall suicide attempt rate of between 8 and 9% with a rate of between 2 and 3% for attempts requiring medical attention.

Age

The YRBS shows a much higher incidence in 15–16-year-olds than in older teenagers, the age effect being strongest in girls. However, school-based studies can be misleading because a disproportionate number of suicide-prone students drop out of the last 2 years of high school.

Gender

In the YRBS, the suicide attempt rate is nearly twice as high in females (approximately 11%) as in males (approximately 6%). In many clinical populations, such as adolescents attending an emergency room, the proportion of females is significantly greater, with ratios ranging from 3:1 to 7:1 (Chung *et al.* 1987; Sellar *et al.* 1990; Piacentini *et al.* 1991). The reason for these differences could be that females use more serious methods; are more disturbed and thus more likely to seek medical treatment; that the methods used by females, e.g. a higher proportion of overdoses, are more likely to require medical attention; or assignment bias, e.g. a greater willingness among girls to seek help. Clinical experience suggests that the last two are the most likely explanations. Medical intervention is indicated for even small ingestions, the method favoured by females, whereas failure to die after one of the methods favoured by males (e.g. hanging) may not require medical intervention.

Ethnicity

In the YRBS, attempt and ideation rates are generally higher among Hispanic (approximately 13%) than among white (7%)

students, with African-Americans' rates occupying an intermediate position. Reasons for the higher rate of suicidal ideation and attempt behaviour in Hispanic youth are not known. However, the risk factors for attempted suicides in African-Americans and white youths seem similar (Juon & Ensminger 1997).

Secular change

Secular changes in the suicide attempt rate in the general population have been assessed in the YRBS, which has shown a steady decline in the 1990s. These data may give a better idea of true changes than studies of clinical samples, e.g. the WHO multinational study of clinical referrals that showed an increase in Europe (Schmidtke *et al.* 1996; Hawton *et al.* 2000a). This may have resulted from changes in referral and payment procedures and may not reflect any real community change. Recent trends have not changed the fact that suicide attempters are the most common cause of hospital admission for young women (Hawton & Fagg 1992) and, as such, place a significant burden on clinical resources (Lukianowitz 1968; Leese 1969; Mattson *et al.* 1969; Pfeffer *et al.* 1980, 1984; Hawton *et al.* 1997).

Methods

In non-clinical samples of teenagers who self-report having made a suicide attempt, there are marked differences in the methods used by boys and girls. In girls, the most common attempt method is ingestion (55%), followed by cutting (31%). Among American males, the most common methods are cutting (25%), closely followed by ingestion (20%), firearms (15%) and hanging (11%) (Lewinsohn *et al.* 1996). In clinical samples, the majority of adolescents will have taken an overdose, most commonly (in North America and in Western Europe) of a non-narcotic analgesic or a psychotropic drug (Velez & Cohen 1988; Spirito *et al.* 1989; Michel *et al.* 2000).

Suicidal ideation

Suicidal ideation is very common among high-school students. In the YRBS surveys, approximately one in four females (25%) and one in six males (14%) endorse the question 'Have you seriously considered suicide in the last 12 months?' (Centers for Disease Control 2000). As with suicide attempts, ideation is more common in girls and in Hispanics.

Clinical aspects

Precipitants

Suicide attempts in young people nearly always follow some stressful event, most often a problem in a relationship, which are generally common in adolescence. Stress events that seem to have a more specific relationship to suicidal behaviour are disciplinary crises, such as a recent or anticipated arrest or court appearance, or academic failure and punishment (Lewinsohn

et al. 1996; Beautrais *et al.* 1997). Clinical experience suggests that many of the stressors arise from the teenager's underlying psychiatric disorder or personality problem. Suicide attempters are not simply passive or chance recipients of adverse experiences. As many as one-third of adolescent attempters are unable to identify a clear precipitant (Hawton *et al.* 1982b; Kienhorst *et al.* 1995) and this should be evaluated carefully for evidence of an underlying depression.

Psychiatric disorder

Almost all adolescents who attempt suicide have a current or recent history of psychiatric illness (Andrews & Lewinsohn 1992; Beautrais *et al.* 1998; Gould *et al.* 1998b). About three-quarters will have a mood disorder, and this will often coexist with a conduct, anxiety or substance abuse disorder or, much less commonly, an eating disorder. A number of suicide attempters have what can best be described as an adjustment disorder (see Hill, Chapter 31): although they might have subthreshold symptoms, their mental state will have deteriorated abruptly in response to a stress and will recover to its former mildly abnormal level shortly after the attempt. This is in keeping with the findings from numerous studies of unreferred groups that show that suicide attempts are nearly always associated with other psychopathology (Velez & Cohen 1988; Garrison *et al.* 1991; Fergusson & Lynskey 1995; Lewinsohn *et al.* 1996; Gould *et al.* 1998b).

Personality disorders

A proneness to outbursts of aggression, anger and impulsivity is an important risk characteristic. Aggression and anger increase the likelihood of a medically severe method and later repetition (Gispert *et al.* 1985, 1987; Stein *et al.* 1998; Hawton *et al.* 1999), and high levels of impulsivity were found both in first-time attempters and repeat attempters (Stein *et al.* 1998; Kingsbury *et al.* 1999).

Cognition

Most suicide attempts in teenagers are impulsive. In one series of consecutive emergency room admissions, only 10–15% reported thinking about their attempt for more than a day (Rotheram-Borus *et al.* 1990; Piacentini *et al.* 1991; Negron *et al.* 1997). Those who made suicide attempts, compared with those who had suicidal ideation only, reported more hopelessness before the attempt and continued to have suicidal ideation after the attempt (Negron *et al.* 1997). Feelings of hopelessness are commonly reported by suicide attempters, and there is some evidence that when they occur with depression they might worsen the prognosis (Kienhorst *et al.* 1992; Morano *et al.* 1993; Steer *et al.* 1993).

Other cognitive factors that might promote suicidal behaviour include being 'problem-focused': dwelling on problems and employing wishful thinking when dealing with fantasies about

interpersonal problems (Levenson 1974; Asarnow *et al.* 1987; Orbach *et al.* 1987; Rotheram-Borus *et al.* 1990). There is little evidence that a pessimistic attributional style, the most common cognitive distortion found in depression, is characteristic of suicide attempters (Asarnow *et al.* 1987; Rotheram-Borus *et al.* 1990). In one study, teenage attempters were more likely to make positive attributions than psychiatric controls (Spirito *et al.* 1991).

Family factors

Suicide attempters are more likely than controls to live in single-parent families (Groholt *et al.* 2000; Wichstrom 2000), and their parents have high rates of psychiatric illness and high levels of marital conflict and conflict with children (Taylor & Stansfield 1984; Trautman & Shaffer 1984; Asarnow 1992). Hostile, punitive, indifferent and insensitive parenting is common (Jacobs 1971; Yusin *et al.* 1972; McIntire & Angle 1973). The teenagers frequently view the relationship with their parents as more dysfunctional than the parents acknowledge (McIntire & Angle 1973; McKenry *et al.* 1982). In many instances, conflicts arise from unresolved differences about what is or is not age-appropriate behaviour for a teenager. Adolescent suicide attempters are more likely than normal, but not depressed, controls to have been sexually and/or physically abused at some time in their lives (Brand *et al.* 1996; Swanston *et al.* 1999).

Sexual orientation

Several large community studies have shown that gay, lesbian and bisexual youth are between two and seven times more likely to think about and attempt suicide than heterosexual adolescents (Faulkner & Cranston 1998; Garofalo *et al.* 1998; Remafedi *et al.* 1998; Fergusson *et al.* 1999; Lock & Steiner 1999). In these studies, gay, lesbian and bisexual youth also had higher rates of drug and alcohol use and higher rates of other psychiatric symptoms, such as major depression, generalized anxiety disorder and conduct disorder (Fergusson *et al.* 1999), and they were also more likely to have been victimized at school. Any of these features could contribute to their suicidal behaviour. However, in a study of completed suicides (Shaffer *et al.* 1996a) that included a small number of gay suicides, the precipitating events were similar to the precipitants in heterosexual suicides (interpersonal and disciplinary crises) and were not specific to the victims' homosexuality.

Death

Depending on the length of follow-up, between 0.1 and 11% of adolescent suicide attempters will eventually commit suicide (Otto 1972; Motto 1984; Goldacre & Hawton 1985; Shaffer *et al.* 1988; Spirito *et al.* 1989). Later suicide is more likely in male attempters, attempters who had been hospitalized, and teenagers who were older at the time of their initial attempt.

Otto (1972) reported that 70% of attempters who ultimately completed suicide died by methods similar to their initial attempt, the remainder using a more lethal method. Suicide attempters who would later commit suicide were much more likely than controls to be unmarried or divorced and to be listed in national registries as having criminal behaviour, alcohol problems or disability pensions.

Repeat attempts

Approximately 12–30% of adolescent suicide attempters report having made a previous attempt (White 1974; Rohn *et al.* 1977; Hawton *et al.* 1982b), and approximately 10% will go on to make another attempt within 2 years. Repeat attempts are most likely to take place during the first 3 months following the initial attempt and are more common in males; in teenagers who have a history of a prior attempt, substance abuse, previous psychotic inpatient hospitalization; those found to be less ‘physically attractive’ by raters (Lewinsohn *et al.* 1994); and in those with depressive symptomatology in which ‘hopelessness’ is a feature (Stanley & Barter 1970; McIntire *et al.* 1977; Goldacre & Hawton 1985; Gispert *et al.* 1987; Choquet & Menke 1989; Sellar *et al.* 1990; Pfeffer *et al.* 1991; Hawton *et al.* 1993, 1999; Nordstrom *et al.* 1995).

Evaluation and treatment

Setting

Because of the possibility of future suicidal crises, treatment should, if possible, be in a system that provides inpatient, outpatient and emergency care (Rotheram-Borus *et al.* 1996). Many attempters are first seen in a casualty/emergency room, where staff are not always well disposed to suicide attempters. Frequently held views are that the family is to blame for the teenager’s behaviour or that the teenager is simply looking for attention. These attitudes militate against keeping later appointments (Rotheram-Borus *et al.* 1996, 1999) and could be modified by staff training.

Initial evaluation

After medical stabilization, the task of the psychiatrist is to decide whether the patient needs hospital admission. This will require information obtained from a parent, guardian or best friend. No adolescent who has attempted suicide should be discharged before a third party has been interviewed.

There are very few studies on the effects of hospitalization (Waterhouse & Platt 1990; King *et al.* 1995). Nevertheless, common sense and comparison with suicide completers (Marttunen *et al.* 1991; Shaffer *et al.* 1996a; Brent *et al.* 1999) suggest that admission should be considered for attempters who:

- 1 are male;
- 2 used a method other than ingestion or superficial cutting;

- 3 have persistent ideation or significant depressive or psychotic symptoms;

- 4 are reported to have had complications from alcohol or substance abuse;

- 5 have a history of recurrent attempts; and

- 6 have no adult guardian or companion to ensure the safety of the environment (remove all medications, guns, knives, etc.).

Because children under 12 years so rarely commit suicide, either suicidal ideation or suicidal behaviour should not, in itself, indicate hospitalization in that age group.

It is important not to miss the opportunity to obtain a detailed account of the events and feelings that preceded the attempt and its consequences at the first visit. This information can be invaluable for planning more definitive treatment and is best obtained while memory of the event is fresh. It will also be helpful to the clinician who will care for the youngster to have some understanding of the amount of support that will be available for the child or adolescent when they are discharged home. Treatment recommendations are more likely to be followed if they match family expectations, are affordable, and if the parent is well and available enough to support attendance.

Initial management

The parent, guardian or companion who accompanies the patient to the emergency room should be told to lock away potentially poisonous medications or firearms. When these instructions are given clearly, compliance is good (Kruesi *et al.* 1999; Brent *et al.* 2000) but, despite their obvious merits, the procedure is often overlooked (McManus *et al.* 1997). The accompanying parent should also be told to limit the adolescent’s access to alcohol or other potentially disinhibiting substances. In the USA, it is common to require an attempter to make a *contract* with the clinician to the effect that he or she will not make a further attempt before the next clinic visit or, if they have a strong urge to do so, will first contact the clinician. There is no evidence about the impact of contracting (Reid 1998) and it should never substitute for other types of intervention, especially if the patient has a disturbed mental state. The clinician must understand that risk can persist, even if the patient agrees to a contract (Egan *et al.* 1997). Another common procedure is to facilitate arrangements for the teenager to contact the clinic or a clinician if he or she feels distressed or suicidal. This does not seem to affect re-attempt rates (Cotgrove *et al.* 1995) but it can impart a sense of support to the family.

Fewer than half of suicide attempters who present in crisis will develop a therapeutic relationship after their initial evaluation and treatment in the emergency room (Litt *et al.* 1983; Taylor & Stansfield 1984; Kienhorst *et al.* 1987; Trautman & Rotheram-Borus 1988; Spirito *et al.* 1989; Swedo 1989; Piacentini *et al.* 1991). Trautman & Shaffer (1989) and Piacentini *et al.* (1991) found that non-attendance was more common in attempters who were persistently suicidal and in

those who had a large number of psychiatric symptoms. By contrast, maternal substance abuse, depression and poor physical health were associated with *inconsistent* compliance results. Maternal psychopathology was associated with less treatment attendance in some studies (King *et al.* 1997; Rotheram-Borus *et al.* 1999) and with greater attendance in others (Trautman & Shaffer 1989; Piacentini *et al.* 1991).

There is evidence that compliance can be improved if the clinic or clinician:

- 1 educates the family on the condition and psychological treatment of the patient and engages their co-operation (Rotheram-Borus *et al.* 1996);
- 2 addresses factors other than the patient's suicide attempt, e.g. parental conflict and other stressors;
- 3 develops procedures to allow emergency rooms to offer appointments directly to a family before discharge, ideally to see a specific clinician at a specific time and location; and
- 4 develops procedures to follow up on missed appointments.

Specific treatments

There have been few studies into the optimal treatment of suicidal behaviour in adolescents, and those tend to be small, with inadequate statistical power. For the following reasons, this is a difficult area to research.

- 1 *Diagnostic heterogeneity.* It seems likely that treatment findings may differ between attempters with different diagnoses or levels of severity (Verkes *et al.* 1998). Small unplanned subgroup analyses can be difficult to interpret.
- 2 *Outcome measures.* There is uncertainty about outcome measures. Most studies have used the rate of attempt repetition (Hawton *et al.* 2000b); however, only a small proportion of suicide attempters (between 8 and 20%) make repeat attempts (Hawton *et al.* 1982a; Spirito *et al.* 1994), and those who do differ from those who do not with respect to gender, diagnosis and cognitive status. Attempt repetition is also a poor index of seriousness. Approximately one-third of suicides are known to have made a previous attempt (Shaffer *et al.* 1996a; Brent *et al.* 1999), and of those only a minority have made repeat attempts. Finally, repeat attempts are relatively uncommon, so that a large sample is needed to show a statistically significant effect. Alternative outcome measures, such as reduced ideation, reduced impairment, fewer associated psychiatric symptoms and reduced levels of subjective distress, are all relevant but are rarely used.
- 3 *Exclusion from research.* It is possible that useful inferences about treatment efficacy could be drawn from treatment studies of conditions in which suicide attempts are common, such as depression or substance abuse. However, it is common that treatment studies among children and adolescents specifically exclude patients with a past history of a suicide attempt in order to minimize risk and/or liability.
- 4 *Unstandardized psychotherapy.* Manualized psychotherapies are only now becoming available, and, until they are, analyses of multiple studies will be difficult.

5 *Control conditions.* Many studies do not clearly delineate exactly what constitutes 'standard care' or 'treatment as usual' in their control groups.

A comprehensive meta-analysis of randomized control trials of suicide attempters of all ages (Hawton *et al.* 1998b, 2000b) examined the efficacy of several treatments on attempt repetition. These included problem-solving therapy, intensive intervention plus outreach, family interventions and antidepressants. Only two treatments showed a statistically significant reduction in attempt repetition: *dialectical-behaviour therapy* (DBT; Linehan *et al.* 1991, 1994) (see below), and the long-acting neuroleptic flupentixol (Montgomery & Montgomery 1982). Each of these has been tested in a single randomized trial of modest size. A trial of selective serotonin reuptake inhibitor (SSRI) antidepressants (Verkes *et al.* 1998) on multiple suicide attempters showed no overall effect, although suicidal ideation was reduced in a subgroup of attempters who had made fewer than five previous attempts.

In studies comparing problem-solving therapies with standard care (Gibbons *et al.* 1978; Hawton *et al.* 1987; Salkovskis *et al.* 1990; McLeavey *et al.* 1994; Evans *et al.* 1999), there were only non-significant trends toward reduction of repeat suicide attempts. Facilitating contact with a clinical service (allowing 24-hour on-demand phone contact with a therapist or admission to a hospital at the patient's request) in addition to standard care, vs. standard care alone (Hawton *et al.* 2000b), did not reduce repetition rates significantly but did increase treatment attendance (Hawton *et al.* 1981; Kerfoot & McHugh 1992; Van Heeringen *et al.* 1995; Rotheram-Borus *et al.* 1996; van der Sande *et al.* 1997; Spooen *et al.* 1998). Only a minority of first-time adolescent suicide attempters repeat their attempt in the 1- or 2-year follow-up period, and only a minority of these repeaters make multiple attempts.

A final methodological/analytical problem is the vast variety of types and delivery of treatment. There was no beneficial effect, as measured by reduced attempt repetition, in intensive intervention (often with a home-based component) vs. standard aftercare; in some therapies, between different therapists; in general admission vs. discharge; in long-term vs. short-term therapy; or in antidepressant (traditional) vs. placebo.

Harrington *et al.* (1998a) found no advantage overall between tested home-based family therapy and treatment as usual in a sample of suicidal ideators, but noted significant improvement in non-depressed attempters, and only a non-significant trend towards fewer symptoms was found in a study of the value of an 'emergency card' that expedited access to hospitalization vs. treatment as usual (Cotgrove *et al.* 1995). The absence of evidence for a 'best' therapy leaves several treatment goals that have to be addressed as well as possible by the clinician. These include:

- 1 treatment of any associated psychiatric disorder;
- 2 teaching the patient and the family to recognize and avoid or diffuse situations or events that lead to conflict, upset and suicidal behaviour (Rotheram-Borus *et al.* 1994); and

3 reducing the sense of guilt and improving the morale and sense of agency that are commonly damaged in the families of teenagers who have attempted suicide (Stuart 1980; Trautman & Shaffer 1984; Miller *et al.* 1992a).

Dialectical-behaviour therapy

Dialectical-behaviour therapy is a manualized treatment developed specifically for suicide attempters by Linehan *et al.* (1991, 1993). It assumes that the core problem in suicide attempters is an abnormality of emotional regulation such that, in a stressful environment, the patient will attempt suicide as a response to negative feelings. The suicidal behaviour is reinforced by the help it *elicits* from others and it may make the patient feel better independently of outside reinforcement (Negron *et al.* 1997).

As tested and described, DBT is a lengthy treatment (approximately 1 year) given in individual and group contexts. It employs a range of techniques to:

- 1 improve self-acceptance;
- 2 increase assertiveness in order to reduce opportunities for interpersonal conflicts;
- 3 train the patient to avoid situations that trigger negative moods; and
- 4 increase tolerance of psychological distress.

In adults, the treatment has been found to improve mental state, reduce the need for rehospitalization, and reduce the incidence of repeated attempts. It demands a significant commitment of time from the patient, numerous skills from the therapist and a generous insurance or benefits system. DBT-A is an adaptation developed for adolescents (Miller *et al.* 1997) that involves parents and is less lengthy (24 weeks). It has not yet been tested in a controlled study.

Cognitive-behaviour therapy

Cognitive-behavioural therapy, the treatment most often used for depressed adolescents (see Harrington *et al.* 1998b for a review), has generally been found to be more effective than family or supportive therapy in depressed non-suicidal adolescents over the short-term (Brent *et al.* 1997). The benefits do not seem lasting (Birmaher *et al.* 2000), and its value in the suicidal teenager has not been established.

Psychopharmacological treatment after the crisis

SSRI antidepressants

SSRI antidepressants reduce suicidal ideation in both depressed (Letizia *et al.* 1996) and non-depressed adults with cluster-B personality disorders (Verkes *et al.* 1998). SSRIs are, in general, safe and effective for adolescent depression (Emslie *et al.* 1997; Ryan & Varma 1998) and are much less dangerous in overdose than tricyclic antidepressants (Ryan & Varma 1998). Pending evidence to the contrary, it is reasonable to regard

SSRIs as a first-choice medication for suicidal children and adolescents.

Lithium

Lithium treatment significantly reduces the recurrence of suicide attempts in adults with bipolar or other major affective disorders (Tondo *et al.* 1997), and when lithium is discontinued the rate of suicide attempts and the risk of suicide increase considerably. The antisuicidal effects of lithium have not been assessed in children or adolescents. Using lithium with adolescents requires careful supervision because overdoses can be fatal, and common side-effects, such as acne and cognitive dulling, are particularly troubling for teenagers.

Neuroleptics

In a controlled trial of depot flupentixol, Montgomery & Montgomery (1982) noted a significant reduction in suicide attempt behaviour in adults who had made numerous previous attempts. This study has not been replicated, and similar studies have not been carried out with adolescents.

Drug-induced suicidality

In the past decade, there has been controversy over whether SSRI antidepressants may induce suicidal ideation and/or behaviour in both adults (Teicher *et al.* 1990) and children (King *et al.* 1991). This was suggested by one meta-analysis (Mann & Kapur 1991), and a small number of adult cases have been reported in which suicidal thoughts started after treatment was begun with an SSRI, stopped after its withdrawal, but reappeared once the drug was recommenced (Rothschild & Locke 1991). Many of the case studies report that the ideation was associated with akathisia and that it had an obsessive or ruminative quality (Hamilton & Opler 1992). These suicidogenic effects of the SSRIs are probably uncommon, and meta-analyses and re-analyses of large sets of SSRI treatment trial data of depressed, bulimic or anxious patients (Beasley *et al.* 1991; Montgomery *et al.* 1995; Letizia *et al.* 1996) suggest that the overall effect is for the medication to reduce rates of suicidal behaviour. Nevertheless, clinicians should be particularly observant during the early stages of SSRI treatment, should systematically inquire about suicidal ideation before and after treatment is started, and should, if SSRI treatment induces akathisia, be especially alert to the possibility of suicidality.

Clinicians should be cautious about prescribing medications that can reduce self-control, such as the benzodiazepines, and phenobarbital in patients who have made a suicide attempt. Phenobarbital also has a high lethal potential if taken in overdose (Carlsten *et al.* 1996). Montgomery (1997) noted that benzodiazepines might disinhibit some individuals, who then exhibit aggression and make suicide attempts. There are indications of similar effects from the antidepressants maprotiline

and amitriptyline, the amfetamines, and phenobarbital (Carlsten *et al.* 1996).

Suicide prevention

A model for prevention

For many years, the desire to commit suicide was seen by many as a logical one, arrived at after a period of consideration and, above all, open to everyone: everyone was at risk, and its prevention was comparable to finding a needle in a haystack. However, as research into the individual characteristics of suicide completers has progressed, it has become apparent that a small number of risk factors that are potentially amenable to treatment and change are present in most suicide victims. If suicide only occurs in a definable and limited population, suicide prevention should be an attainable goal.

The risk factors include specific psychiatric disorders, such as depression, alcohol abuse and a proneness to impulsive behaviour, which may in turn be caused by distinctive biological differences; adversities that are common to many types of psychopathology; and some external factors, such as exposure to media that feature suicidal behaviour. There is, in other words, a complicated chain of influences that lead to the moment when a teenager decides to commit suicide. It is likely that a small number of *necessary* and almost certainly no *sufficient* factors contribute to this fortunately unusual, but always tragic, event.

This information can be incorporated into an explanatory model (Fig. 33.3) that can be used to plan strategic prevention strategies. A factor that operates close to the execution of suicide should be a final common pathway and might be the most appropriate intervention. In practice, however, the only interventions that are appropriate for prevention are those that are modifiable. The factor that is clearly the most modifiable by clinicians is the identification and treatment of the mental disorders that are present in almost all suicide victims.

Furthermore, an active *mental disorder* is present in about 90% of adolescent suicides at the time of death and, together with *suicidal ideation* (see below), can conveniently be regarded as the closest thing we have to a *necessary* risk condition. Even though relatively few psychiatrically disturbed youths will commit suicide, aggressive case-finding and the development and provision of effective treatment for affected youth could be expected to reduce the suicide rate.

Adverse *stress events*, most often a disciplinary crisis, interpersonal loss or a perceived humiliation, often occur in close proximity to a suicide. However, such events are common during adolescence, can rarely be anticipated, and are usually beyond the influence of the clinician. They are therefore likely to be poor targets for prevention but, in many instances, these events might be a consequence of an adolescent's underlying mental disorder which, in a vicious cycle, might also deprive the teenager of parent, peer or teacher support and in other ways

impede the young person's ability to cope with or seek a solution to the stress. Case-finding and treatment of psychiatric disorder would provide an effective preventive activity at this level.

These stresses are often responded to in a harmful way by the potential suicide. They may induce feelings of hopelessness or anger and a wish for revenge or intolerable affects that stimulate a need to escape or be 'better off dead'. Suicide hot lines were originally designed to operate at this point in the process (Shneidman & Farberow 1957; Litman *et al.* 1965), but their low rate of use by acutely suicidal individuals limits their value. DLT and other forms of cognitive therapy that encourage stress avoidance and that alert the adolescent to dangerous internal mental states and provide skills for dealing with them could operate at this point.

Although an underlying disorder, recent stress and inadequate support, coupled with hopelessness or preoccupation with suicide, can set the stage for suicide, we must assume that many young people experience this confluence of risk factors but only a few commit suicide. It is probably at this point that specific enhancers and inhibitors operate.

Enhancement might be mediated by a biological trait such as impulsivity or emotional volatility, drug- or alcohol-induced intoxication, or other altered mental states; by high social value being placed on suicide (as by the victim's familiarity with peers or public figures whose suicide, related by the media, carries a sense of importance or romance); by the availability of a lethal method; or by the absence of any *inhibiting* factors, such as societal or religious taboos, the presence of social support, and difficulty in accessing a method. Preventive interventions operating at this final stage would therefore include media guidelines to promote responsible reporting of suicide and to minimize contagion, promotion of a strong taboo against suicide in society, and the removal of lethal medications and weapons from the homes of suicidal youth. However, nearly all of these involve non-medical, societal or political interventions that may be beyond the scope of the clinician.

In summary, the best routine suicide prevention would seem to be the effective identification (case-finding, see below) and treatment of associated psychiatric disorders. Untreated, these operate to promote suicide in many ways, and our ability to intervene effectively with them is probably greater than our ability to bring about the societal or political changes that are needed to alter the final chance precipitants of an individual's suicide.

Case-finding

Finding teenagers who are at high risk for suicide, either because they are currently suicidal or because they have an undiagnosed depression or other predisposing condition, and who are not currently being managed by a clinician, is an important aspect of prevention. Case-finding can be undertaken by *direct* evaluation of individual, or *indirectly* by educating third parties, such as parents, teachers, and guidance personnel, to watch for and refer individuals with suggestive behaviour patterns or 'warning signs'.

Indirect case-finding

The indirect, educational approach is inexpensive and may appear cost effective. It is widely applied in suicide-awareness programmes. However, this approach is beset with problems: many suicidal adolescents show no visible symptoms or behaviours that denote risk; some of the warning signs (such as social withdrawal, irritability, and declining academic performance) are common in non-suicidal teenagers and are not strongly predictive of suicidality; and more-specific warning signs, such as giving away possessions, leaving suicidal notes for others to read, or discussing specific plans with a friend, are relatively uncommon among suicide completers (Shaffer *et al.* 1996a). Indirect case-finding is not without risk, especially if it is directed to other students who are being asked to look for signs in their peer group. It is difficult for many young people to either persuade their friends to obtain help or, if that fails, break a confidence and disclose their observations to a responsible adult. This may be why teenagers who have received systematic training in case-finding are no more likely to recommend treatment to their distressed friends than those who do not (Vieland *et al.* 1991). Finally, suicide awareness programmes directed to peers inevitably involve presenting material about suicide to youngsters who, unknown to the educator, could include past attempters or currently suicidal teens, and there is evidence that they might think more about suicide or be emotionally upset as a result of exposure to such programmes (Shaffer *et al.* 1991).

Direct case-finding

Direct case-finding determines risk from the teenagers themselves. Teenagers are clearly capable of identifying their own feelings and behaviour, and there are many self-report measures that are based on this ability (Achenbach & Edelbrock 1987; Centers for Disease Control 2000). Teenagers' self-evaluations are highly correlated with those of clinicians (Renouf & Kovacs 1994) and appear to identify a different group of troubled teenagers than those identified by teachers or parents (Kovacs 1985; Achenbach & Edelbrock 1987; Bird *et al.* 1990).

Direct screening can be carried out in primary clinicians' offices or in high schools. A typical screening programme will use some type of screening instrument to identify students with important risk factors for suicide, such as current suicidal ideation, depressed mood or a history of suicide attempts (Smith & Crawford 1986; Harkavy Friedman *et al.* 1987; Shaffer *et al.* 1996b; Goldston 2000). Some focus narrowly on suicidality and do not include many other important risk factors, such as depression or substance abuse, but others cast the net more broadly. Depending on the sensitivity and specificity of the screening instrument, students who screen positive will then be given a second-stage evaluation and, depending on the outcome of that, will be referred to a clinician (Reynolds 1991; Shaffer *et al.* 1996b). An effective screening programme will include a mechanism for facilitating referral for appropriate treatment.

A sensitive screen will identify almost all teenagers at risk for

suicide (Shaffer & Craft 1999), but in the process will also identify many 'false-positives': students who are not at risk (see Fombonne, Chapter 4; Verhulst & Van der Ende, Chapter 5). In a screening of over 2000 New York teenagers (Shaffer & Craft 1999), the initial screen generated only three false-negatives (88% sensitivity), but 257 false-positives (76% specificity). If resources are abundant, the high false-positive rate might not be a problem because many of the screen-positive teenagers at low risk for suicide will be suffering from some psychiatric disorder that might be helped. However, in most instances, low specificity imposes a prohibitive financial and manpower burden and may threaten the whole programme. This problem can be addressed by giving a more specific second-stage screen to those who are positive on the initial screen. Like almost any procedure that enhances specificity, this might lower sensitivity and might miss some suicidal students but, in the final analysis, a less sensitive, two- or three-stage procedure is preferable. We routinely use a second-stage procedure that involves giving screen-positive students a more detailed assessment on a self-administered computerized diagnostic interview, such as the Voice Diagnostic Interview Schedule for Children (DISC; Shaffer *et al.* 2000), which minimizes the cost of the procedure.

A clinician, assisted by the results of a two-stage screen, can usually make a triage decision about whether the student needs to be referred for treatment or further evaluation in a relatively short time at a third and final stage of the screening process. Ideally, the clinician is assisted by a case manager who will contact the student's parents and establishes links with a clinic to facilitate treatment compliance.

Screening can be carried out in any setting attended regularly by large groups of older adolescents. An advantage of screening in a primary clinician's office is that there will be a mechanism for referring the case to a specialist when this is indicated. Because paediatricians and other primary care physicians rarely ask about suicidal ideation or behaviour (Frankenfield *et al.* 2000; Halpern-Felsher *et al.* 2000), screening for depression and suicidality is unlikely to be redundant with the practitioner's usual procedure.

School-based screening programmes can reach adolescents whose symptoms might not—for any number of reasons—be recognized by others as being clinically significant. They can reach the large number of teenagers who do not routinely attend a clinician's office or who, if they do, are not screened. Regardless of the method used, the value of case-finding may be restricted by the high base rate of some high-risk indicators, such as current suicidal ideation, a past suicide attempt, alcohol abuse and anxiety states; sparse treatment resources; and the prevailing limitations of knowledge on optimal treatment.

Crisis services

The original argument for crisis intervention (Shneidman & Farberow 1957; Litman *et al.* 1965) was that suicide intent is often associated with a critical stress event that is usually

contemplated with psychological ambivalence and that arises in the context of mental disturbance. If the model of suicide presented in Fig. 33.3 is accurate, then crisis services are potentially efficient because they operate at the final common pathway to death.

Crisis services are usually provided by so-called telephone hot lines. Some are manned by teenagers (Boehm *et al.* 1991), but most by specially trained adult listeners who give information about how to access appropriate services. Some, especially those that are part of a multiservice agency, carry out more active case management, making appointments with the appropriate clinical service and following up if the appointment is not kept (Sudak *et al.* 1977). Relatively few offer direct therapy on the telephone, and most will break confidentiality if they judge that it will avert a suicide, calling parental or police help. An exception is the Samaritan organization, whose *befriending* process emphasizes acceptance, warmth and *confidentiality* (Hirsch 1981).

The efficacy of crisis intervention has usually been tested by determining whether the establishment of a service results in lower suicide morbidity in a given area. The research is inevitably ecological: there is no information on whether suicides that occurred had contacted the crisis service to no avail, or the reverse, whether highly suicidal individuals were redirected from their intended plan by the crisis service. Regardless, the balance of evidence is that crisis services have no or, at best, very limited effects on the suicide rate (Barraclough & Jennings 1977; Bridge *et al.* 1977; Jennings *et al.* 1978; Miller *et al.* 1984). Possible explanations for this (see Shaffer *et al.* 1990a for a review) are the predominance of female callers (King 1977; Boehm & Campbell 1995), who are at relatively low risk for suicide; the indifferent quality of much of the advice given (Bleach & Claiborn 1974; Apsler & Hodas 1975; Slaiku *et al.* 1975; Knowles 1979; Hirsch 1981); and the fact that a significant proportion of suicides occur when the victim is preoccupied or disorganized, under the influence of alcohol, or in an otherwise agitated state where they might not be able to summon the resources to make or benefit from an appropriate call. Only a small proportion of teenagers know how to access a hot line (Litman *et al.* 1965; Greer & Anderson 1979).

It is probably a mistake to dismiss hot lines as well-intentioned but ineffective. Hot lines are widely available in the USA (Seeley 1996; American Association of Suicidology 1999) and provide help for a needy and otherwise underserved population. King (1977) showed that only 8% of callers were currently receiving other mental health services. In a survey of high-school students who had attended a suicide education programme (Shaffer *et al.* 1988), one of the few significant effects was an increase in a declared willingness to use a hot line when experiencing emotional difficulties, there being *no increase* in willingness to use any other type of service. There is a need to develop a standardized but clinically informed screening procedure, coupled with active case-management procedures, and broaden interest in hot lines, particularly among troubled boys, with appropriately directed advertising.

Educational programmes

Educational programmes generally aim at one or more of the following goals (Shaffer *et al.* 1988; Garland *et al.* 1989).

1 *To heighten awareness of the problem* by showing taped vignettes of teenagers who have attempted suicide or by quoting disturbing statistics, e.g. that suicide is the second leading cause of death in teenagers.

2 *To promote indirect case-finding* (see above).

3 *To promote disclosure of suicidal intentions or ruminations.* This is done by presenting a model of suicide that is intended to be non-stigmatizing. Thus, the programme might state that suicide is *not* a feature of mental illness but is a response to common adolescent stress, such as pressure to succeed, family upsets, residential mobility, changing value systems, use of drugs and alcohol, etc. This might be reinforced by showing taped vignettes of attractive youngsters who have made a previous attempt for these reasons.

4 *To provide staff and students with information about mental health resources*, specifically how they operate and how they can be accessed.

Didactic school-based suicide prevention programmes can be criticized for following a low-risk strategy. The overwhelming number of adolescents who are exposed to the programmes carry no risk for suicide. Further, there is no evidence that such programmes modify attitudes about suicide or help-seeking in either normal or high-risk students (Spirito *et al.* 1988; Shaffer *et al.* 1990b, 1991; Vieland *et al.* 1991). The failure of a purely didactic approach is broadly in line with educational strategies to prevent alcohol and drug abuse (Strasburger 1989) and early sexual activity (Kirby 1985). There is some suggestion that such programmes do shift students to a model of suicide that is held to be non-stigmatizing by the designers: one that renders suicide ‘understandable’ in the context of stress, rather than a psychopathological model (Shaffer *et al.* 1991). These programmes have not solved the dilemma of how to make suicide less shameful without, at the same time, reducing the prohibitions that might contribute to making suicide a mercifully rare event.

Educating/training primary care physicians and paediatricians

As noted above, only 20–40% of US primary care physicians and paediatricians report regularly asking about suicidal behaviours and suicide risk factors (Frankenfield *et al.* 2000; Halpern-Felsher *et al.* 2000). Those who did report screening regularly were those more likely to feel they had enough training and knowledge about suicidal risk factors, sufficient time, and the belief that they could be effective in reducing adolescent suicide (Frankenfield *et al.* 2000).

In Gotland, Sweden, a two-day course training primary care physicians to assess mood disorders and suicidality was associated with a subsequent lowering of the female suicide rate

(Rihmer *et al.* 1995; Rutz *et al.* 1995). Female suicide attempts decreased, and antidepressant prescriptions and hospitalizations for mood disorder increased. While this as yet unreplicated study of adult suicide is preliminary, and while the optimal treatment of adolescent depression is not as well understood as that of adult depression, educating all clinicians who encounter adolescents, not just mental health clinicians, in how to recognize and, if necessary, refer the suicidal child or adolescent is a worthwhile end in itself, regardless of its impact on suicide. In medical settings where, unfortunately, physicians are not given the time to take an extensive history or perform an evaluation, the case-finding screening instruments mentioned above could be administered.

Media guidelines

There is ecological evidence that media reports of suicide might induce contagion (Gould & Shaffer 1986; Velting & Gould 1997; Fekete & Macsai 1990; Ishii 1991), and so guidelines for journalists and liaison public health officials have been drafted, suggesting that reporting of suicide not be predominant and excessive, not romanticize the suicide, idealize the suicide victim, minimize the victim's multitudinous difficulties and mental illness, or provide extensive details of the method that could allow modelling (Gould *et al.* 1999; American Foundation for Suicide Prevention 2001). However, as yet, only the most preliminary ecological studies have tried to assess whether these guidelines reduce or contain the adolescent suicide rate (Etzersdorfer *et al.* 1992; Sonneck *et al.* 1994; Jobes *et al.* 1996) or which of these strategies are most helpful.

Limiting access to methods

Because youth suicide is often an impulsive act, it is reasonable to expect that limiting access to commonly used methods could prevent its occurrence in some instances. The so-called 'British experience' is a frequently cited example of how this can happen. The British suicide rate declined *pari passu* with the replacement of poisonous domestic coal gas with carbon monoxide-free natural gas (Hassall & Trethowan 1972; Kreitman 1976). Over the period of transition, British suicide rates fell by 26%, with most of the decline being attributed to a decrease in deaths from domestic-gas asphyxiation, with no compensatory increase in suicidal deaths by other methods. British rates, in contrast to those in most other countries, remained at the new lower level (Farberow 1985) for many years. Most suicides in the USA are committed with legally owned and registered firearms. It would be reasonable to expect that the early British experience could be replicated by effective firearm control in that country, but, by extension, one would only expect a similar transient effect. Whereas the recent reduction in UK suicides has been attributed to the requirement of safer catalytic converters in automobiles, analyses show that one must look to other causal factors to account for most of the decrease (McClure 2000).

'Post-vention'

Post-vention refers to a public health intervention implemented after a suicide with survivors in the victim's school or community. Post-vention can, in principle, be useful in several ways. It can provide a basis for understanding the death, and thus lighten some of the guilt and isolation frequently experienced by family survivors (Calhoun *et al.* 1982; Rogers *et al.* 1982; Henley 1984) and minimize the scapegoating that may be directed at parents, teachers, the school or particular peers. However, post-vention programmes are often implemented to reduce the probability of imitation by other teenagers, addressing abnormal symptoms of grief and depression or post-traumatic stress disorder. Emotional sequelae are common in friends of adolescents who have committed suicide, especially among those who witnessed the suicide or were told of the suicidal intent and failed to avert it (Brent *et al.* 1996b).

Because the factors that facilitate imitation are only now starting to be understood, there is no clear rationale for the most appropriate type of post-vention for this purpose. Gould (2001) has proposed that imitative suicide is most likely in those at high risk: those who are suicidal at the time of the example. If this is the case, an appropriate intervention would be to identify those teenagers by launching a screening programme in the affected high school and institute appropriate treatment.

There has only been one completed controlled study on post-vention (Hazell & Lewin 1993) that found no significant improvement in symptoms of students attending post-vention group sessions compared to controls. Those chosen for the post-vention were close friends of the teenager who committed suicide, so perhaps the controls were not matched sufficiently. Reports of reduction in guilt and sadness in a two-month volunteer-led survivors support group (Rogers *et al.* 1982) could have occurred spontaneously.

Conclusions

It is possible to view suicide, attempted suicide and suicidal ideation as part of a broad spectrum of suicidal behaviour whose prevalence is influenced by developmental factors. Suicidal ideation occurs throughout childhood, adolescence and early adulthood—and is very common in 15–17-year-olds. Suicide attempts are made relatively infrequently by prepubertal children and they increase in prevalence through adolescence, reaching a peak at around 16 years, after which they almost certainly decline (Kessler *et al.* 1999). Suicide, like suicide attempts, is rare before puberty and becomes increasingly common through late adolescence. However, unlike suicide attempts, which decline thereafter, the incidence of suicide increases until it reaches a level in early adulthood that is maintained until the end of the fifth decade.

The reason for these varying incidence patterns is not known. However, they are compatible with developmental differences in how suicidal ideation is translated into behaviour. If attempts

really are attempts—if they are always associated, at some level and for some duration, no matter how brief, with a wish to die—then they could be seen as failed suicides. Failure rates are high in the young for any number of developmentally related reasons: brevity of the thought; lack of competence; lack of a sense of agency; diminished opportunity; and/or the absence of truly powerful stimuli, such as are provided by the effects of drugs and alcohol, the impact of clinical depression, and possibly some as yet unknown biological promoter that only becomes active at that age. As the youth becomes older and more competent and starts to experience these more potent stimuli to suicide, attempts are less likely to fail. However, it is possible that older teenagers also become more aware of the noxious consequences of suicide for themselves and for others they love, and develop a greater awareness, and comfort with, alternative coping strategies for common stresses. If this is the case, development could be expected to have an inhibiting effect that reduces the total amount of suicidal behaviour, redistributing it from attempts to completions and from the moderately impulsive to the seriously disturbed.

Such a model is compatible with the observation that ideation is a necessary but far from sufficient precondition of attempted and completed suicide, that the great majority of attempters will never commit suicide, and that more than half of teenage suicides have never made a known previous attempt. This model is inferred from morbidity and from retrospective data and would need to be confirmed by appropriate research. Hopefully, this would have practical benefits, perhaps in the area of suicide nosology, just as the development of heuristic models of the chain of events that lead to suicide (see Fig. 33.3) has provided a rational basis for suicide prevention.

This is not our only area of ignorance. We know little about how environmental factors operate to cause the great variability in incidence that is seen between communities and countries across time. Could these differences all be a function of imitation? Between 1960 and the late 1980s, there was a threefold increase in male adolescent suicides in the USA and similar phenomena in many developed countries (Shaffer & Hicks 1993). However, during the 1990s, there was a slow but consistent decline. Existing studies cannot confirm the suspicion that the initial increase was caused by the greater exposure of young people to drugs and alcohol, and that the recent decline was a result of the ever greater rate of prescribing the newer antidepressants to adolescents.

Given the burden of suicidality, there is an urgent need for more information on optimal treatment. The quality of psychopharmacological research on suicidality is generally poor, most studies being small and unreplicated. This is especially unfortunate because of the efficacy of psychotropic medication in other conditions, its low cost and its transportability. Well-designed studies on candidate medications need to be conducted as a matter of urgency. Psychotherapy is more demanding and costlier, but it deserves study. A form of behavioural therapy (dialectical-behaviour therapy) has been shown to be

effective in adult attempters; this needs to be studied in young people, together with ways to reduce its cost and complexity.

As suicide is nearly always associated with a pre-existing psychiatric disorder, it makes the most sense to orientate prevention to identifying and effectively treating teenagers with disorders that place them at risk for suicide. The benefits of the more popular approach to prevention, through education, lacks empirical support. Furthermore, the phenomenon of suicide ‘contagion’ has implications about how safe it is to discuss suicide with teenagers in a group situation. No doubt, research will continue to complete this and other gaps in our knowledge in this important area of psychopathology.

Introduction

In contrast to early forms of eating disorder originating in childhood, such as rumination, failure to thrive, pica, faddiness and obesity (see Stein & Barnes, Chapter 45), the age period for the onset of anorexia nervosa and bulimia nervosa is most typically adolescence. Prepubertal onset is rare for anorexia nervosa and the first onset peak is around 15 and 19 years. The onset for bulimia nervosa is, in most cases, at the end of adolescence, peaking initially at around 19 years. Thus, anorexia nervosa is typically connected with the transition from childhood to adolescence and, in most cases, bulimia nervosa reflects the transition from adolescence to young adulthood. However, the literature for both disorders is dominated by research on adult patients with only a few reviews entirely devoted to children and adolescents with eating disorders (Lask & Bryant-Waugh 1993; Steinhausen 1995; Steiner & Lock 1998). Because of the predominance of anorexia over bulimia nervosa in children and adolescents, the two disorders will be described in unequal proportions in this chapter.

Anorexia nervosa

Clinical features

Anorexia nervosa is characterized by highly specific behavioural and psychopathological symptoms and significant somatic signs. The majority of cases are female, and the onset of the disorder is usually during adolescence, but there are also cases in which males are afflicted and cases of premenarcheal onset.

Behaviour and psychopathology

The core psychopathological feature of anorexia nervosa is the dread of fatness. There are many synonyms for this symptom, e.g. weight phobia, fear of becoming fat or drive for thinness. In the behavioural sense, it implies that the patient is deeply convinced that his or her body is too large. This pursuit of thinness may, in the classical case, persist even at times when the patient is extremely emaciated. Typically, the following pattern emerges. In the beginning, the patient starts to diet and may appear like any teenager concerned about being overweight. Sometimes, the patient is indeed slightly overweight and has been taunted by family members, schoolmates and peers. The feeling of being

overweight may be related to the whole body or to particular parts, such as the thighs or buttocks.

The typical diet starts with a reduction of sweets and high-caloric, carbohydrate-rich foods, and the patient soon becomes an expert with regard to the caloric content of all sorts of food and beverages. Weeks or even months may pass before this behaviour is noticed by others. By this time, the patient may have lost control over dieting and the resulting weight loss. Usually, at this stage, the adolescent anorexic has not yet recognized the abnormal nature of her or his behaviour and denies the illness. Indeed, she or he feels better being thin and does not seek any help, despite the perceived concern of family members who feel helpless in the face of the patient's powerful behaviour.

In many of the patients, this distorted drive for thinness is associated with a disturbance in body image. Despite being emaciated, the patient does not consider herself thin or even ugly. There may also be an inability accurately to identify internal sensations, such as hunger, satiety or affective states. In addition, patients are rather vague or defensive about their feelings and are susceptible to undue influence by significant others. This in turn reinforces the bodily mistrust and the fear of loss of control. Dieting continues and may be accompanied by further efforts to reduce weight and to control bodily functions. Such efforts can include rigorous exercise, abuse of laxatives or diuretics, and vomiting, which are not only intended to promote weight loss but also serve to rigidly regulate bodily functions. From the purging and vomiting behaviour there is only a small step to binge-eating, in which the patient consumes enormous amounts of food within a very short period of time. This bulimic component is followed by either a restrictive period of fasting for several days or else vomiting to prevent weight gain. Bulimic features within the spectrum of anorexia nervosa are, however, rather infrequent during adolescence.

Aside from these very specific behavioural features of anorexia nervosa, there are further psychopathological symptoms that are shared with other psychiatric disorders. These include poor self-esteem, rigid dichotomous 'either/or' thinking, a highly restricted realm of interests and cognition that excludes almost everything but the topics of food and weight, the loss of social contacts, irritability, mood swings and insomnia. Anorexic patients rarely engage in sexual activity and, when they do, they usually experience it as being unpleasant and joyless. Many patients show signs of a depressive syndrome, including major affective disorder. (Strober 1991; Herzog *et al.* 1992). All these

non-specific symptoms can be, at least partially, the result of the effects of starvation.

Many patients manifest obsessional behaviour, including compulsive behaviour and obsessional thinking about foods. This pertains not only to the peculiar eating habits, for example, eating rituals—but also to other areas, such as exercising and food and non-food-related hoarding. Comorbid obsessive-compulsive disorders are quite frequent (Råstam 1992; Thiel *et al.* 1995). Premorbid personality traits can be identified in the history.

Physical characteristics

Anorexic patients are apparently emaciated and show effects of downregulation of the autonomic nervous system, indicated by bradycardia, hypotension and hypothermia. In addition, complications arise as a consequence of the effects of the eating disorder on virtually every organ system and deserve careful consideration (Beumont *et al.* 1993, 1995; Carney & Andersen 1996).

The medical illnesses needing to be considered for differential diagnosis include: tuberculosis, acquired immune deficiency disease, primary endocrine disturbances such as anterior pituitary insufficiency, Addison's disease, hyperthyroidism, diabetes mellitus, inflammatory bowel disease, hypothalamic tumours and a variety of malignancies. All of these are conditions that manifest significant and prominent weight loss but lack the psychological characteristics of anorexia nervosa (the deliberate attempt to reduce weight by exercise, purging, vomiting or dieting). There are also a variety of drugs that may produce weight loss. Binge-eating also occurs in a number of rare medical illnesses and certain chronic illnesses, such as premorbid obesity and diabetes, which in turn can act as risk factors for the development of eating disorders. Finally, there are also instances in which symptoms in patients with an eating disorder are misdiagnosed as being a medical illness.

Specific features of premenarcheal cases and of anorexia nervosa in males

The manifestation of anorexia nervosa before the age of 14 or before the menarche is rare. However, the clinical features of the prepubertal cases are essentially similar (Gowers *et al.* 1991; Lask & Bryant-Waugh 1993; Robin *et al.* 1998). Other types of closely related food refusal, selective eating and appetite loss have to be distinguished from anorexia nervosa (Lask & Bryant-Waugh 1993). Weight loss in these very young patients arrests the process of puberty and interferes with growth in stature and breast development (Russell 1992). Early diagnosis and competent treatment are therefore important for the child's development.

Anorexia nervosa in males is rare but may also be underdiagnosed. The clinical pattern is strikingly similar in the two sexes. Various studies report conflicting findings with respect to whether males show an earlier onset of the disease, atypical

gender role behaviour, more grave symptomatology and poorer prognosis (Andersen 1995; Carlat *et al.* 1997).

Clinical assessment

A thorough examination of patients with an eating disorder requires the assessment of the history, development of the symptoms, psychopathology, family functioning and physical status (Beumont *et al.* 1995; Steinhausen 1997a). More specifically, the behavioural assessment of the anorexic and bulimic spectrum of symptoms should be focused upon. In addition, structural interviews and rating scales, as well as self-report questionnaires, can augment the assessment process.

The behavioural assessment should start with issues concerning food intake and eating behaviours, including thoughts and attitudes towards eating and weight. This should be followed by a systematic analysis of further significant clinical symptoms and an analysis of events and emotional states preceding food refusal or binge/purge episodes. Furthermore, the patient should be asked to report any attempts to alter eating behaviour. The assessment can be enhanced through the inclusion of one of the structured interviews designed for this purpose. These include the Eating Disorder Examination (Fairburn & Cooper 1993) and its adaptation to children (Bryant-Waugh *et al.* 1996), the Clinical Eating Disorder Rating Instrument (Palmer *et al.* 1987) and the Structured Interview for Anorexic and Bulimic Disorders (Fichter *et al.* 1998).

Self-report questionnaires are sometimes used for epidemiological and screening purposes, such as the Eating Attitude Test (Garner & Garfinkel 1979; Garner *et al.* 1982), and the Eating Disorders Inventory (Garner *et al.* 1983) which is an instrument that covers clinically relevant dimensions of the eating disorders. Their validity for case identification has been called into question (Steinhausen 1984; Neumärker *et al.* 1992; Steinhausen *et al.* 1992).

The assessment of body image disturbance should concentrate on the measurement of attitudinal body dissatisfaction by either questionnaire or self-ideal discrepancy measures rather than the measurement of perceptual size estimation inaccuracy. The latter is not only more expensive in terms of the employed techniques (e.g. video distortion) but was also shown to produce much less substantial effect sizes than attitudinal measures in a meta-analysis of 66 studies of body image among patients with eating disorders relative to control groups (Cash & Deagle 1997).

Finally, the variety of potential medical complications requires a careful physical assessment, including body weight and height in order to calculate the body mass index (BMI). Percentile charts appropriate for age and sex should be used because the diagnostic criteria of BMI < 17.5, as set up by the ICD-10, is inappropriate for prepubertal and most of the adolescent patients. In these age groups, large parts of the normal population fall under this criterion so that the BMI cut-offs need to be adjusted for growth. National reference data in combination with either the third or fifth percentile should be used in

order to define clearly an abnormal BMI. If these data are not available, paediatric tables may be used, setting a weight commensurate to the same percentile as the patient's height as a standard of normality (Beumont *et al.* 1995).

Routine laboratory investigations should include serum electrolytes, liver enzymes, complete blood count (CBC), blood urea nitrogen (BUN), glucose, full protein and albumin, renal function, pelvic ultrasound and an electrocardiogram. Further investigations are seldom necessary. Significant abuse of laxatives might require endoscopic or roentgenographic examination to assess the extent of bowel damage. Other investigations for some selected patients may include further haematological studies, bone densitometry for chronic cases, oesophageal sphincter pressure studies for reflux, urine and blood osmolality, lactose deficiency tests for dairy intolerance, and total body nitrogen.

Classification

DSM-IV and ICD-10 share some similarities with regard to defining criteria of anorexia nervosa. These pertain to the criteria of weight loss, body image distortion, amenorrhoea, and the so-called weight phobia. However, the two systems differ to some extent with regard to the definition of these criteria. Whereas the ICD-10 makes use of Quetelet's Body Mass Index for the definition of weight and therefore considers height as well, DSM-IV uses an absolute weight threshold of 85% of expected weight loss. Both classification systems consider the special situation of prepubertal patients who fail to make the expected growth.

There are some advantages of the ICD-10 scheme as compared with those of the DSM-IV. It not only covers the criterion 'self-induced loss of weight' but also provides a clinically useful operational definition of this criterion and links the body image distortion to the main theme of psychopathology, namely, fear of becoming fat, whereas these two aspects are listed separately among the DSM-IV criteria.

Furthermore, the widespread endocrine disorder in anorexia nervosa is clearly indicated in the ICD-10 set of criteria, whereas the DSM-IV refers only to amenorrhoea. The latter criterion is more difficult to assess in young patients because of the absence of menstruation in early puberty and the sometimes irregular course soon after menarche. Finally, both ICD-10 and DSM-IV consider two different types: a restrictive type, which refers to patients who exclusively starve; and a binge-eating/purging type, which refers to patients who binge-eat and practise self-induced vomiting or misuse laxatives, diuretics or enemas.

Beyond the different eating behaviour, there are several arguments in favour of this typology: bulimic anorexic patients more frequently display premorbid overweight medical complications, various sorts of impulsive behaviours and borderline, narcissistic and antisocial personality disorders (Garfinkel *et al.* 1995). Furthermore, various outcome studies indicate a less favourable prognosis for this subtype (Steinhausen 1999). Little is currently known about whether these subtypes reflect different entities or only different indices of severity that may

alternate over time in individual patients. Because of the spectrum character of the eating disorders, there are atypical cases of anorexia nervosa that do not fulfil the entire sets of criteria listed in the two major systems of classification. Atypical cases, such as where there is an absence of amenorrhoea or significant weight loss or where the key symptoms are present only to a mild degree, are explicitly considered both in the ICD-10 and the DSM-IV.

Epidemiology

Most of our current knowledge about the frequencies of eating disorders stems from incidence and prevalence studies that are based on either psychiatric case registers or medical records of hospitals in circumscribed areas. Obviously, such studies lead to an underestimation of the true incidence and prevalence because not all community cases are referred to doctors or hospitals.

An analysis of 16 incidence studies published between 1970 and 1992 shows a peak for age at onset between 15 and 19 years, a decrease in frequency at 20–24 years, and no bimodal distribution (Fombonne 1995). In five of these studies there was an increase in incidence over time, but these studies were ill-controlled for reliability and validity of diagnoses, changes in health services, demographic changes and tests of statistical significance. Also, the more recently published incidence studies provide conflicting results concerning increases in incidence rates. Some are negative (Hoek *et al.* 1995; Turnbull *et al.* 1996); others are positive (Eagles *et al.* 1995), even after correction for several register biases (Munk-Jorgensen *et al.* 1995). Another recent integrative review of 12 cumulative incidence studies covering 40 years found no increased risk over time of anorexia nervosa among teenagers, whereas a near threefold increase was observed among women in their 20s and 30s (Pawluck & Gorey 1998).

Community surveys that yield prevalence rates may circumvent some of the methodological problems of incidence studies. The 29 prevalence studies published between 1976 and 1993 provide median prevalence rates for females aged 15–2, of 1.3 in 1000 (range 0.35–2.39 in 1000) for the entire period, 1.3 in 1000 in studies published before 1985 and 1.8 in 1000 in studies published since 1985. Thus, there is no indication that prevalence rates increased over time (Fombonne 1995). A more recent study in Switzerland obtained a prevalence rate of 0.7% for the 14–17 years age range (Steinhausen *et al.* 1997).

All epidemiological data support the clinical experience that anorexia nervosa is 8–40 times more common in females than in males (Fombonne 1995; Turnbull *et al.* 1996; Pawluck & Gorey 1998). In contrast to clinical series, little evidence of anorexia nervosa being associated with higher social class has emerged from epidemiological studies. Cultural factors are clearly operative. Whereas anorexia nervosa is rarely observed among blacks in the USA, Great Britain and Africa (Andersen & Hay 1985; Pumariega *et al.* 1984; Thomas & Szmukler 1985; Silber 1986; Dolan 1991) and is almost absent in the Chinese population — with only a few cases being reported from Hong Kong (Lee &

Chiu 1989)—it is quite common in Japan (Suematsu *et al.* 1985). There is some evidence that outside Western culture, the disease may be restricted to prosperous backgrounds and the upper social strata. Reports of increasing rates of eating disorders that have been found in some cross-cultural studies may be caused by either the adoption of Western cultural values (Nasser 1988) or to conceptual errors and problems of translation of diagnostic instruments (Patton & King 1991).

Aetiology

Considering the diversity and complexity of both anorexia and bulimia nervosa, a single-factor aetiology is unlikely. Current theories emphasize multiple determinants and risk factors interacting within a developmental framework. This model is based on the following predispositions and determinants: individual, familial, sociocultural, biological factors and precipitating events (see Steiger & Stotland 1995; Steiner *et al.* 1995; for reviews of the supporting empirical evidence).

Individual factors

From a developmental point of view, anorexia emerges at a time when body fat increases and the changes in physical appearance, bodily feelings and reproductive status require reorganization and transformation of the body image (Attie *et al.* 1990).

Huon & Strong (1998) have proposed that different factors influence the initiation and the maintenance of dieting in adolescents. The initiation of dieting is most strongly affected by perceived social encouragement to diet from family members, peers and the media; with individual differences in autonomous functioning and social skill-related competencies equipping adolescent girls differently with the ability to resist those social influences. The maintenance of adolescent dieting includes a central role of motivation: dieting persists when the goals are specific and difficult; when there is a high level of commitment toward these goals; and when the reasons for dieting indicate that the adolescent is controlled. According to the theory, efficacy and personality features (such as the tendency to be autonomous) are operating only indirectly and are mediated by the proposed motivational processes.

An epidemiological study on abnormal eating attitudes in London schoolgirls (Patton *et al.* 1990) showed that dieting in the great majority of girls was a benign practice, without progression to clinical status. A previous psychiatric history and some association between general psychiatric morbidity and eating disorders in this sample gave rise to the suggestion that there is an extra set of factors that strengthens excessive dieting. Similarly, a more recent Australian epidemiological study (Patton *et al.* 1997) found psychiatric morbidity to be associated with extreme dieting only. The causal link may be bidirectional with psychopathology leading to dieting but dieting also affecting neurotransmitter systems that are involved in the regulation of mood.

Uncertainties remain about the degree to which overt

anorexia nervosa (which is uncommon—see above) is on the same continuum as the much milder eating disturbances that are so frequent in adolescent girls. There is bound to be a measure of continuity because some of the same cognitive concerns (over body image and the like) are associated with both, and because some cases of anorexia nervosa must (at least for a while) exist at a subclinical level of severity. On the other hand, some discontinuity is suggested by the evidence that even severe dieting in ballet dancers and athletes is rarely accompanied by self-induced vomiting, and by the infrequency with which such dieting leads to overt anorexia nervosa (Patton *et al.* 1990). Twin studies could be informative in determining whether anorexia nervosa in one twin is associated with milder eating disturbances in the cotwin, but the sample sizes studied (see below) have been far too small for such an analysis. Follow-up studies of milder eating difficulties, similarly, could throw light on the issue but few of the investigations have presented their findings in ways that could address the question. Dieting is an early manifestation of anorexia nervosa but probably it leads to the overt disorder only in particularly susceptible individuals, perhaps in conjunction with a broader psychological disturbance.

Other possible risk factors include disturbances of self-perception of body size and of internal affective and visceral states—poor body-image (Shisslak *et al.* 1998) and poor interoceptive awareness (Leon *et al.* 1995). Furthermore, it has been speculated that the earlier heightened nutritional state in weight pathologies may lead to an earlier prepubertal maturity. This and the accompanying sexual development would require an earlier confrontation with the developmental demands of adolescence, for which the individual may be unprepared. In fact, there is some evidence that early maturity is associated with eating disorder symptoms (Atkins & Silber 1993). In addition, premorbid obesity may expose adolescents to humiliation and force them to use dieting and other weight-reducing measures. However, findings from one epidemiological study have called the aetiological relevance of premorbid obesity into question because it appeared to be more closely identified with dieting than with eating disorders (Patton *et al.* 1990).

Careful clinical history-taking often reveals a premorbid personality pattern of compliance, perfectionism and dependence. These children present few if any educational problems prior to the onset of the eating disorder. Early eating and digestive problems in childhood may also be present (Manchi & Cohen 1990). There is little evidence that psychosexual factors are involved in the causation of eating disorders. Whereas a high proportion of adverse sexual experiences in childhood has been reported in various series of anorexic women, the pathogenic relevance of these experiences to the subsequent illness is uncertain (Palmer 1995; Vanderlinden & Vandereycken 1995).

Familial factors

Empirical tests of family system models reflected in anorexic patients and their families have not supported the theoretical notion of a typical anorexia nervosa family (Kog &

Vandereycken 1988; Råstam & Gillberg 1991). There is some empirically based evidence for a significant amount of dysfunction in families of patients, not acting specifically in the development of eating disorders but rather as an indirect vulnerability to developing an eating disorder (Steiger & Stotland 1995).

Beyond the importance of communication and interaction patterns there are further family risk factors that may play a part in the multifactorial determination of eating disorders: higher incidence of weight problems and eating disorders in the family; and high incidence of physical illness, affective disorders, obsessive-compulsive disorders and alcoholism in relatives (Kog & Vandereycken 1988; Lilenfeld *et al.* 1998; Stein *et al.* 1999).

Sociocultural factors

It is possible that the pressure in Western societies to achieve, the importance of physical attractiveness and the emphasis on slimness and dieting in women may all contribute to increased risk for the development of eating disorders. The tendency in Western societies to judge self-worth in terms of shape and weight is superimposed on the need for self-control as the central feature of the disorder (Fairburn *et al.* 1999b). For adolescent girls, the importance of TV and magazine models and peer pressures pertaining to weight concerns have been documented (Barr Taylor *et al.* 1998; Shisslak *et al.* 1998).

Ballet dancers, some kinds of athletes and modelling students form particular risk groups for eating problems (Smolak *et al.* 2000) but it is less clear whether there are increased rates of anorexia nervosa. It is also an open question whether participation in these activities or sports causes eating problems or whether certain individuals with such problems are drawn to these activities. However, besides specific physical demands in terms of body shape and size and specific diets, additional risk factors result from performance pressure, including anxiety and demanding competition; from authoritarian relationships to coaches and trainers; from passive obedience to these authorities; and from visibility and public control of bodily activities. In some individuals, personality characteristics such as perfectionism may contribute both to physical performance and eating disorders.

Biological factors

There is sufficient evidence that once malnutrition and starvation have started, significant alterations occur in a broad spectrum of neurobiological parameters (Pirke & Platte 1995). These include every endocrine system, the cholinergic, norepinephric and serotonergic systems, the regulation of immune functions, and endogenous opioid activity. Once weight loss and starvation occur, the usual mechanisms for the release and inhibition of various regulators of eating behaviour change, and a new set of regulating mechanisms is established. Whereas the increased body of knowledge on these pathophysiological mechanisms has not necessarily contributed to a better understanding of the origins of anorexia nervosa, it is clear that

many of the pathophysiological alterations serve to sustain the disorder.

Twin and family studies both suggest that genetic factors have a role in the liability for anorexia nervosa. Holland *et al.* (1988) found that 56% of monozygotic twin pairs were concordant for anorexia nervosa as compared with 5% concordance among dizygotic twins. Heritability was found to be high, especially in 'restricting' anorexia nervosa with adolescent onset, whereas it was almost non-existent among patients with bulimia nervosa (Treasure & Holland 1990). However, as Strober (1991) pointed out, direct recruitment and voluntary referral in this study may have led to potentially biased conditions of ascertainment. In any case, genetic influences may be on dispositional traits rather than the eating disorder itself.

Conflicting findings include those of the large-scale study based on the Virginia twin registry (Walters & Kendler 1995). Although cotwins of twins with anorexia nervosa were at significantly higher risk for lifetime anorexia nervosa (and bulimia nervosa, major depression and low BMI), the dizygotic proband-wise concordance rates were larger than the monozygotic rates. This pattern is contradictory to that expected for a genetic influence. Although the data suggest the presence of a familial component, it was not possible in this sample confidently to partition this component into genetic and common environmental factors and to estimate accurately a measure of heritability for anorexia nervosa. Given the very small number of concordant twins (six pairs, even with the broadest diagnostic criteria) and the possibility that the fundamental assumption of equal environments for the twins was violated, no conclusions are possible.

Precipitating events

Dieting is an antecedent of new eating disorders, and psychiatric morbidity predicts the onset of eating disorders independent of dieting status, as shown in a recent adolescent cohort study (Patton *et al.* 1999). As in many other psychiatric disorders, further significant events in the individual's life have been reported to have preceded the manifestation of anorexia nervosa. External precipitants have been identified in 50–100% in various studies, but the type of precipitant appears non-specific. Common initiating factors include separation and loss, disruptions of family homeostasis, new environmental demands, direct threat of loss of self-esteem and, in a small number of patients, physical illness (Atkins & Silber 1993; Robin *et al.* 1998). As a consequence of these threats to the patient's sense of worth and control over the world, preoccupation with the body is increased and weight-reducing measures are initiated.

Development and maintenance of the disorders

As with other psychiatric disorders it is the balance between the individual vulnerability to particular risk factors and the operation of protective factors that determines the development and maintenance of an eating disorder. Research so far has suffered

from a lack of appropriate clinical control groups, and has not convincingly shown whether or not the various risk factors are specific to eating disorders. Most of the evidence stems from clinical samples instead of population studies so that a selective bias may have influenced the findings. Dieting is the first aspect to be noted in anorexia and bulimia nervosa but it is not yet the disorder. Longitudinal studies still have to show which factors have to be present in order to explain the transition from dieting to frank disorder. Both the isolation of disorder-specific risk factors in association with dieting and their timing are important research issues. The maintenance of anorexia nervosa is, at least in part, better understood. Whereas the disorder is sometimes transient, anorexia nervosa often becomes chronic. Several factors are known to sustain it. Starvation intensifies the patient's preoccupation with food and negatively affects self-concepts and mental state. It also produces a reduction of interests and social isolation. In addition, vomiting is another powerful sustaining factor. Delayed gastric emptying and chronic constipation lend the sensation of fullness after meals and serves to prolong dieting. Furthermore, distorted body perceptions may be linked with a feeling of being out of control after small increases in weight.

Certain cognitive factors continue the chain of detrimental factors, such as positive self-reinforcement resulting from weight loss or phobic avoidance of weight gain, and/or personality features such as obsessiveness, the generally restricted ability to cope with stress, and the level of impulse control. Unresolved predisposing factors from the patient's family or her own biography may also add to chronicity, unless they are addressed in psychotherapy. Secondary gain in terms of receiving considerable attention from the environment is another powerful perpetuating factor, as is the prevailing cultural emphasis on slimness.

Finally, there are also iatrogenic factors that are responsible for the perpetuation of the illness. These include rapid weight gain programmes that neglect both provisions for instituting external controls for the patient and attention to other psychosocial issues, and failure to recognize the necessity of weight gain to counteract the effects of starvation.

Treatment

Patients who suffer from anorexia nervosa require intensive professional and interdisciplinary intervention because of inherent complications and the danger of chronicity (Touyz *et al.* 1995; Garner & Garfinkel 1997; Steinhausen 1997a; Robin *et al.* 1998). Although there is a variety of treatment approaches, comparative studies evaluating the effects of treatment are scarce (Steinhausen 1999). Currently, the main psychotherapeutic approaches used with adolescent anorexic patients are individual psychotherapy, behaviour therapy and family therapy. In addition to the various psychotherapies, nutritional counselling and supervised exercise (Beumont *et al.* 1997) and psychoeducational measures both for the patient and the family (Garner 1997) are important components of treatment.

General principles

The treatment of anorexic patients must be based on a comprehensive and detailed assessment of both the mental and the physical status. The treating physician must then decide whether an inpatient or outpatient setting is more appropriate. This decision rests partly on rather non-specific factors, such as the availability of treatment modalities or the 'treatment philosophy' of a given centre or therapist. At many treatment centres in recent years, management has shifted increasingly from inpatient to outpatient treatment with emphasis placed on family therapy and on empowering parents as controllers of the patient's food intake. This shift may be caused by greater awareness of eating disorders both among physicians and the public, resulting in many patients presenting before they have become severely emaciated.

Unfortunately, beyond the evidence that early intervention may be a positive prognostic factor, there is a lack of solid empirical data to form a rationale for the selection of the type and setting of treatment intervention. Certain clinical criteria, e.g. severe emaciation (less than 70% of the average weight), medical complications, suicidal ideation and comorbid psychiatric conditions, are undoubtedly indices for hospital treatment. Familial factors too might tip the scales in favour of inpatient treatment; for example, in cases where conflict within a family or demoralization of the family precludes or hinders outpatient treatment. Inpatient treatment does have certain specific advantages that should be acknowledged. These include a higher degree of control and consistency, a removal of eating-related conflicts from the family, the fostering of what might otherwise be a fragile treatment alliance, greater awareness on the part of the physician of complications and/or responses to intervention, and the possibility of using—for both the patient and the family—a psychoeducational approach in which the patient's eating behaviour is modified to foster healthy nutritional attitudes and habits and to assure the maintenance of an acceptable weight.

Whereas medical and nutritional stabilization are clearly the major goals of inpatient treatment, a fuller psychiatric recovery may require subsequent outpatient psychotherapy. So far, partial hospitalization in day-treatment programmes has received little attention for young patients with eating disorders. From the beginning, outpatient treatment might be considered in cases in which purging and vomiting are not part of the clinical picture, the family is very supportive and the patient is highly motivated and co-operative. However, because anorexic patients characteristically deny that they are ill, high motivation for treatment is unusual among these patients.

The recent increase in clinical cases has affected admission rates not only in psychiatric institutions but also in paediatric and medical wards. Whereas it is evident that severely emaciated patients need intensive medical treatment, the psychological needs of the majority of these patients are better met in psychiatric wards, where it is easier to create a psychotherapeutic milieu and initiate a treatment alliance. Again, the emergence of special units and centres in many countries in the recent past

is mainly because of the increase in admissions. These units are attractive in terms of accumulated clinical experience; however, there is no definite evidence that they should form the basis for service. Patients with eating disorders can also be adequately treated on adolescent psychiatric wards that treat a variety of different problems and patients.

Independent of treatment selection, weight restoration and return to physical health is the first major goal of treatment. The minimum target weight should be specified at the beginning of the treatment rather than later during the course of therapy. Although there is a lack of conformity in the literature on the degree of final weight restoration, many clinicians would agree that the goal should be set to within 10% of the recommended weight appropriate for age and height. Considering the patient's fear of losing control, a *gradual* but steady gain, averaging about 0.2 kg/day, is aimed for rather than a rapid weight gain. The patient therefore eats smaller portions but more frequent meals per day.

The regular intake of an adequate number of calories per day should start at 1500 and gradually increase to between 2000 and 3000 calories derived from four to six meals per day. With the help of a dietitian, the definite number of calories should be determined according to individual needs and whether the programme is for weight gain or for weight maintenance. Other schemes for calculating adequate calorie intake emphasize the weight at admission plus a 50% increase for activity and 50% increase every fifth day. Besides weight restoration, close monitoring of fluid and electrolyte balance, including the correction of imbalances, is an important part of the ongoing medical management. The provision of information feedback on weight gain and dietary re-education are further essential components. There are conflicting views concerning the inclusion of tube feeding, intravenous feeding or parenteral hyperalimentation for weight gain. Whereas these measures are often recommended in medical settings, many psychotherapists are concerned about the psychological side-effects: the disturbance of the fragile staff co-operation and the psychotherapeutic alliance with the patient. However, it is clear that these interventions can be life-saving in the extremely ill patient and that the various medical complications of the disorder require close collaboration with other medical disciplines.

Many clinicians consider a supportive and secure relationship with the treatment team to be the cornerstone of successful inpatient treatment. This especially applies to the nurse who is present during mealtimes and can encourage the patient to eat and to ventilate feelings related to eating. Regular weight monitoring with feedback to the patient is another essential treatment component. There is sufficient clinical evidence that improvement of the patient's weight also contributes to an improvement in his or her morbid mental state. Therefore, weight-reducing behaviours, such as hyperactivity, purging and vomiting, need to be controlled and the patient should be confronted with them in psychotherapy.

The therapeutic milieu of the ward contributes significantly to treatment, by reducing the patient's morbid fear of fatness,

establishing a sense of self-esteem and confidence, and treating concomitant psychiatric disorders such as depression. Supportive and encouraging relationships with the staff can reduce the necessity of using coercive measures, such as tube feeding or parenteral nutrition, in a small number of life-endangering situations.

The patient's individual emotional problems form another major goal of treatment and need to be met through psychotherapeutic methods, regardless of the treatment setting. Both individual and family psychotherapy may be indicated. Despite the variety of theoretical foundations that underlie the different psychotherapeutic approaches, there is a growing trend to combine therapeutic methods in the sense of multimodal approaches.

Because of the crucial role that parents play in the development and treatment of prepubertal and adolescent eating disorders, parent counselling is an intrinsic component of any intervention. In the early stages of treatment, the parents need to be relieved of self-blame and guilt feelings, and it is necessary to provide precise information on the various aspects of the eating disorder. In the middle stages of treatment, the procedure may vary according to the specific treatment modality, and in later stages the personal and partner problems of the parents should be addressed. Parent counselling is an important aspect of intervention but has not been thoroughly researched.

Clinicians differ in their views on the respective advantages and disadvantages of inpatient and outpatient approaches to treatment. The seriousness of the medical or psychological state may require hospital admission to deal with the risks involved, and sometimes this may necessitate some form of compulsion. Not surprisingly, the long-term outcome for those compulsorily admitted is worse than for those who enter hospital voluntarily (Ramsay *et al.* 1999), but this may reflect nothing more than the seriousness of their disorder. Follow-up studies have shown that there is a clear association between initial clinical severity and later outcome. Nevertheless, Gowers *et al.* (2000) found that, even after this was taken into account statistically, those admitted to hospital did worse than those treated in the community. There are inevitable doubts over whether or not their analyses took into account an adequate range of relevant variables. As Gowers *et al.* comment, there is a need for a randomized controlled trial comparing inpatient and outpatient interventions in the group for whom either could be justified (with a clinical severity sufficiently great to raise the question of admission but not so great as to require admission because of the immediate danger to life or health).

Individual psychotherapy

As with other psychiatric disorders, certain prerequisites must be fulfilled to institute individual psychotherapy with the anorexic patient, including sufficient motivation and cognitive ability. These prerequisites may be absent in cases when the patient is emaciated and manifests impaired psychological functioning; when severe depression is present; when the course of the anorexia nervosa is chronic; when severe intellectual

limitations are present; when the family sabotages therapeutic efforts; or when the patient is a very young pre-adolescent.

If psychotherapy is tailored to the individual level of cognitive development and the emotional needs of the young patient, and if the adolescent can utilize empathetic support, education, problem-solving, cognitive restructuring and insight, then clinical experience suggests they may profit from this measure. Furthermore, the continuation of psychotherapy after discharge from hospital treatment may contribute to the prevention of relapses.

Behaviour therapy, including cognitive methods

The main behavioural approaches for the treatment of eating disorders are operant conditioning procedures and cognitive methods. In some instances, social skill training programmes may also be used. Whereas operant conditioning procedures may be introduced regardless of age, cognitive methods may be more suitable for the older adolescent and the adult.

Operant conditioning measures in general are more frequently employed in the hospital setting where the control of target behaviours, for example, eating behaviour and/or weight gain, is more easily accomplished. The advantages of choosing one of these target behaviours over the other have been critically reviewed by Bemis (1987). Both negative and positive reinforcement contingencies are operative. The hospital itself can be an implicit negative reinforcer in terms of being experienced as an aversive environment that can be left only through sufficient weight gain. Other negative reinforcers may include bed rest, seclusion and tube feeding. However, many of these rather coercive measures are no longer components of a standard inpatient programme. Rather, most operant programmes claim to be based mainly on positive reinforcers such as access to recreational activities, visiting privileges or freedom of movement within or outside the hospital. Critics have objected that these privileges are also negative reinforcers because they imply relief from the prior situation of being deprived from these opportunities. In addition, it has been argued that isolation and deprivation of reinforcers are not required for effective treatment.

A cognitive-behavioural approach was originally developed for adult bulimic patients but has also been advocated for the treatment of anorexic patients (Garner *et al.* 1997). However, the efficacy of similar strategies in anorexia nervosa and, more specifically, in adolescent patients has still to be established. Methods emphasize teaching patients to examine the validity of their beliefs on a here-and-now basis. According to Garner *et al.* (1997), the treatment is divided into three major phases and includes a comprehensive list of content areas.

1 Phase I mainly deals with building trust and setting treatment parameters.

2 In Phase II, the beliefs related to food and weight are changed using specific cognitive methods supplemented by an interpersonal focus in therapy and the involvement of the family. Cognitive methods include the identification of dysfunctional thoughts, schemes, and thinking patterns, the development of

cognitive restructuring skills, and the modification of the self-concept.

3 Phase III aims to prevent relapse and prepare for termination of treatment.

Family therapy

Family therapy was advocated as the treatment of choice in anorexic patients for a number of years until more critical comments arose. Accordingly, some authors caution against the exclusive use of family therapy in a condition that is clearly multidetermined and object that the family therapy movement is based on personal beliefs rather than on solid research (Vandereycken *et al.* 1989; Vandereycken 1995). Objections pertain, for instance, to the possibility of finding no family dysfunction at all, the assumption that a family crisis is necessarily a sign of family pathology, and the uncritical use of family therapy without consideration for indications and contraindications.

Currently, there is some converging clinical agreement about the usefulness of family-orientated treatment approaches in fairly young children and adolescents who still live in intact families. However, in terms of relative contraindications for conjoint family therapy, the inexperienced family therapist should be warned with regard to chronic patients, those with delayed psychosocial development, single-parent families, broken homes, families in which one or both parents display severe psychopathology or in which a parent has physically or sexually abused the partner or a child, families with highly negative or destructive interactions, and families in which previous family therapeutic attempts failed (Vandereycken 1995).

Other limitations stem from a small number of empirical studies. Hall (1987) noted selection factors for family therapy in the treatment of anorexia nervosa. Most of her patients who underwent family therapy were younger, had a recent onset of illness and lived in an intact nuclear family with co-operative parents. In one of the few thoroughly controlled trials, family therapy was found to be superior to individual therapy in patients whose illness was not chronic and had begun before the age of 19 years, whereas individual supportive therapy tended to be more effective in older patients (Russell *et al.* 1987). Subsequent studies by the same group of researchers (Le Grange *et al.* 1992; Eisler *et al.* 2000) found family counselling (in which the parents and the adolescent were seen separately) to be effective as conjoined family therapy. Seeing and intervening with the entire family together was not necessary for good treatment outcomes. At a 5-year follow-up, long-term benefits of the intervention were still detectable, although the authors attributed much of the improvement to the natural outcome of the disorder (Eisler *et al.* 1997).

Another group of researchers compared Behavioural Family Systems Therapy (BFST) to Ego Oriented Individual Therapy (EOIT), which is a psychodynamic individual treatment with collateral sessions for the parents (Robin *et al.* 1999). BFST produced greater weight gain than EOIT and a higher rate of resumption of menstruation. The effects on eating attitudes,

depressed affect and interoceptive awareness were equal for the two therapies. All improvements had been maintained at 1-year follow-up, with the weight gain differences disappearing between the two treatments. Furthermore, both treatments resulted in improved family relations (Robin *et al.* 1995).

A third controlled study with adolescents and young adults combined outpatient individual therapy and family therapy and compared this to inpatient treatment, outpatient group therapy, or no-treatment control (Crisp *et al.* 1991; Gowers *et al.* 1994). At the 1-year follow-up, both outpatient treatments were as effective as inpatient treatment in restoring weight, and both were superior to the control condition. The treatment effects were maintained at the 2-year follow-up. However, the design of the study did not permit the effects of individual therapy components with cognitive, behavioural and dynamic approaches to be separated from the family therapy component.

As with other child and adolescent disorders, clinical practice—especially in a residential treatment programme—should profit most from a multifaceted approach that combines diet, behavioural contracts, individual and group psychotherapy, and occupational and art therapy with family-orientated philosophy. This family-orientated approach implies that various interventions from educational guidance to counselling are used and that family therapy should be introduced when there is a clear indication to do so. In this view, the family is used as a resource that has to be mobilized to help the child or adolescent with an eating disorder. Further research is clearly needed to substantiate this pragmatic view.

Psychopharmacological treatment

Several medications have been used in the treatment of anorexia nervosa both clinically and in controlled studies. These include neuroleptics, appetite stimulants and antidepressants. Phenothiazines are still used by some clinicians, though perhaps more in the treatment of adults than adolescents. Research evidence of their usefulness, weighed against the hazards of neuroleptics and appetite stimulants, indicates that neuroleptics are generally of no clinical value in the treatment of anorexia nervosa (Heebink & Halmi 1995).

Antidepressants would seem to be indicated in anorexic patients with accompanying depression. Although controlled trials clearly show that some of the antidepressants studied (amitriptyline, clomipramine, monoamine oxidase inhibitors, lithium and fluoxetine) may have some effect on weight gain or improve dysphoria and depression, the clinical value of these findings is rather limited, especially in adolescent anorexic patients (Heebink & Halmi 1995). In contrast, the effectiveness of the more recently developed selective serotonin reuptake inhibitors (SSRIs) has been proven for adult bulimic women (see below).

Outcome and prognosis

For more than four and a half decades, a considerable body of

knowledge on the outcome and prognosis of anorexia nervosa has accumulated. The following conclusions can be drawn from a total of 108 follow-up studies published in the English- and German-speaking literature from 1953 to 1996 (Steinhausen 1999) and a subset of 31 follow-up studies dealing only with adolescent and prepubertal patients (Steinhausen 1997b).

In approximately 60% of patients, weight is restored, normalization of menstruation occurs in about the same proportion, and eating behaviour returns to normal in just less than half of the patients. In the 31 studies of younger patients, the outcome was slightly better: normalization of weight occurred in 68%, in 65% for menstruation, and in 52% for eating behaviour. However, there was a wide fluctuation across studies.

Expressed in traditional terms, about half the patients with anorexia nervosa recover, nearly one-third improve but one-fifth become chronic. Mortality rates amount to 5.5% (range 0–21) for the entire series and to 2.2% (range 0–11) for the younger series of patients. After starvation, suicide is the second most common cause of death, accounting for 20% in a recent large population study of eating disorders in Denmark (Emborg 1999).

Affective disorders are noted in one-fifth of anorexic patients, anxiety disorders in one-quarter, obsessive-compulsive disorders in 1 in 8, personality disorders in 1 in 7, substance use disorders in about 1 in 7, and schizophrenia in 1 in 20. Psychosocial adaptation in terms of employment, interpersonal relationships, marriage and sexuality is the most diverse and elusive outcome parameter to study. Although close to two-thirds or even more of former patients accomplish employment and normal educational careers, only a minority enter marriage or a stable partnership.

In addition to these central trends, there is conflicting evidence on prognostic factors. According to a number of studies (frequencies in parentheses), favourable prognostic factors include: early age at onset (13), hysterical personality (8), conflict-free parent-child relationship (8), a short interval between onset of symptoms and treatment intervention (12), a short duration of inpatient treatment with no re-admissions (7), and high social status and level of education (6). However, it must be noted that the findings of a smaller number of other studies call into question the predictive value of these factors. Hyperactivity and dieting as weight-reduction strategies are prime examples of factors that many studies have found to be of no consequence with regard to outcome. The picture is even clearer for the factors that are prognostically unfavourable: vomiting (9), bulimia (10), chronicity or compulsiveness (8), and premorbid developmental or clinical abnormalities (4) have all been almost unequivocally related to poor outcome. Only very few studies have systematically tested a comprehensive list of prognostic factors in larger samples with at least an intermediate follow-up period of 5 years or more. The two studies by Strober *et al.* (1997) and by Steinhausen *et al.* (2000) found surprisingly few predictors that are associated with different facets of illness course and outcome.

There is no consistent long-term course of anorexia nervosa

(Pike 1998). In a small number of studies, there is some indication that anorexia nervosa develops into bulimia nervosa (Steinhausen 1999). In addition, recent research has shown that the offspring of mothers with eating disorders are at risk both with regard to growth and development (see Stein & Barnes, Chapter 45).

Bulimia nervosa

Clinical features

Russell (1979) introduced the term 'bulimia nervosa' to describe an ominous variant of anorexia nervosa. Within a relatively short period of time this new nosological entity received enormous attention among clinicians, researchers and the lay public.

Behaviour and psychopathology

The typical eating pattern of the bulimic patient is characterized by the rapid consumption of a large amount of food. Estimates of the caloric intake of these eating binges range from three to twenty thousand calories. These binges are often experienced as an altered state of consciousness in which the patient feels out of control. The frequency of bingeing varies considerably—from several times a day to less than once a week or fortnight. Binges can last from minutes to several hours and can be precipitated by feelings of anxiety, tension, boredom and loneliness. At least in the beginning, the binge itself brings temporary relief from negative mood states. However, the longer the binges continue, the more the patient experiences feelings of guilt, shame and anger.

Among the accompanying or counteracting behaviours, self-induced vomiting is not a necessary symptom for diagnosis. Whereas not all bulimics are vomiters, most vomiters are probably bulimics. Binge-eating usually precedes the vomiting. With increasing duration and severity of the disorder, patients do not require any mechanical device to induce vomiting but, rather, learn to vomit by reflex by contracting their abdominal and thoracic muscles. Purgative abuse of laxatives or other drugs are less often used than vomiting. However, most purgers also display vomiting.

Bulimic patients are not only preoccupied with constant thoughts about weight, body size and food but also the most frequently associated mental state is depression. Other personality characteristics include anxiety, emotional lability, strong needs for approval and external control, impulsiveness and compulsiveness. There is a high rate of comorbidity with other psychiatric disorders, including affective disorders, anxiety disorders, substance use disorders, and personality disorders (Mitchell *et al.* 1991; Holderness *et al.* 1994; Brewerton *et al.* 1995).

Physical characteristics

Most bulimic patients are of normal weight for their height.

Menstrual irregularities occur frequently, although amenorrhoea is not as common among bulimics as it is among anorexics. The list of medical complications associated with bulimia is a long one (Carney & Andersen 1996). Many of these complications are serious and are often overlooked; however, they may lead to the diagnosis in those patients who do not come into consultation because of bulimia. Thus, a careful physical examination of each patient suffering from bulimia nervosa is mandatory.

Specific features in males

Bulimia is rarely observed in males. Symptomatology and demographic characteristics are similar in both sexes. However, disturbances of psychosexual development, gender identity and homosexuality have been observed more frequently than in healthy males. In addition, sexual activity is more frequently inhibited in heterosexually orientated bulimic men than in those without bulimia (Fichter & Hoffmann 1990; Andersen 1995).

Clinical assessment

Because the weight of most bulimic patients is within the normal range, there is—in contrast to anorexia nervosa—no direct clinical sign of the disease. Some patients are detected by chance through careful routine physical assessment or during consultations that were made for other purposes. Thus, a high percentage of cases remain undetected unless the patients themselves report their symptoms. Diagnostic interviews and questionnaires can then be used to assist diagnosis and assessment. Examples of these measures are given in the respective section on anorexia nervosa. Further questionnaires that are designed more specifically for bulimic patients were reviewed by Fairburn *et al.* (1990).

Classification

The ICD-10 defines four major criteria.

- 1 A persistent preoccupation with eating, irresistible craving for food and episodes of overeating in which large amounts of food are consumed in short periods of time.
- 2 Attempts to counteract the fattening efforts of food with one or more of the following:
 - a self-induced vomiting,
 - b purgative abuse,
 - c alternating periods of starvation, and
 - d the use of drugs such as appetite suppressants, thyroid preparations or diuretics.

When bulimia occurs in diabetic patients, they may choose to neglect their insulin treatment.

- 3 A morbid dread of fatness so that the patient sets her- or himself a sharply defined weight threshold that is well below her or his premorbid weight and far below what would be clinically designated as optimal or healthy.
- 4 Often there is a history of an earlier episode of anorexia nervosa, the interval ranging from a few months to several years.

This episode may have been fully expressed, or may have assumed a minor cryptic form with a moderate loss of weight and/or a transient phase of amenorrhoea.

DSM-IV criteria are largely comparable with regard to the first two criteria. These criteria specify a minimum average of binge-eating and compensatory behaviours occurring twice a week for 3 months. In addition, DSM-IV states that self-evaluation is unduly influenced by body shape and weight and that these disturbances do not exclusively occur in the presence of anorexia nervosa. DSM-IV also introduces a purging type, designating patients who regularly engage in self-induced vomiting or the misuse of laxatives, diuretics or enemas, and a non-purging type. As stated above for anorexia nervosa, this distinction has some clinical relevance, whereas the validity of these two subtypes still awaits systematic studies.

Finally, both ICD-10 and DSM-IV introduce the category of atypical bulimia nervosa. It is reserved for cases in which one or more of the key features are absent. Most commonly, this applies to patients with normal or even excessive weight. Among these typical cases the DSM-IV also considers the category of binge-eating disorder with recurrent episodes of binge-eating in the absence of inappropriate compensatory behaviour characteristic of bulimia nervosa. Despite a number of questionnaire studies on the frequency of binge-eating, predominantly in adults, the nosological validity of the disorder and its potential relations to the other eating disorders in terms of continuities is yet unknown.

Epidemiology

In a review of the first studies published in the 1980s, Fairburn & Beglin (1990) concluded that consensus has increased regarding the prevalence rate among adolescents and young adult women, which is about 1%. Three recent large-scale epidemiological studies using either DSM-III-R or DSM-IV criteria support this conservative estimate. Lifetime prevalence rates were 1.1% for female subjects and 0.1% for male subjects in Ontario, Canada (Garfinkel *et al.* 1995), and 0.5% for females in the Virginia Twin Registry (Sullivan *et al.* 1998a). The 12-month prevalence rate was 0.5% in female adolescents in a Swiss canton (Steinhausen *et al.* 1997).

The incidence rates for case detection by GPs in the UK was 12.2 per 100 000. It was almost three times higher than that of anorexia nervosa, and the recording of bulimia nervosa increased threefold from 1988 to 1993 (Turnbull *et al.* 1996). Similarly, a sharp rise in incidence was observed in the Rochester Epidemiology Project in the USA from 1980 to 1983, with relatively constant rates thereafter (Soundy *et al.* 1995). However, the critical remarks of Fombonne (1996) have to be considered. Epidemiological studies conducted between 1980 and 1995 were partly unreliable and did not control for confounding comorbid disorders. Changes in diagnostic and referral practices were likely to account for the increase in patients seen in specialized treatment centres. Thus, there is no clear empirical evidence for secular changes in the incidence of bulimia nervosa.

Based on the findings of epidemiological studies, the following conclusions are justified. Independent of age, bulimia nervosa is more common than anorexia nervosa in non-clinical populations so that one would expect to find both more adult and more adolescent patients with bulimia nervosa than with anorexia nervosa. The majority of bulimic patients are adults with a peak onset of the disorder around the age of 19 years. Analogous to anorexia nervosa, females by far outnumber males. In contrast to epidemiological data, bulimic patients are underrepresented in clinical samples of adolescent patients with eating disorders.

Aetiology

The aetiology of bulimia nervosa shares many aspects of the model of anorexia nervosa outlined above. For the most part, the same determinants and risk factors are operative in both disorders: individual, familial, sociocultural, biological factors and precipitating events. Because these factors were extensively described above, with the exception of a few recent findings, they will not be discussed again.

A recent study found that early onset cases (at the age of 15 or below), in contrast to typical onset cases, showed premorbid overweight and parental lack of care twice as often. Deliberate self-harm was also more common in the younger patients (Schmidt *et al.* 1995). A large community-based case-control study on risk factors found that perfectionism and negative self-evaluation, as well as certain parental problems including alcohol use disorder, were even more common among patients with bulimia nervosa than among control subjects with other psychiatric disorders. Factors increasing likelihood of dieting were risks for bulimia, but not for anorexia. It was concluded that bulimia nervosa is the result of exposure to general risk factors for psychiatric disorders and specific factors for dieting (Fairburn *et al.* 1997). The same project also revealed that certain life events involving disruption of family or social relationships or a threat to physical safety may play a part in precipitating the onset of the disorder and that childhood sexual and physical abuse are also risk factors, but for psychiatric disorders in general and not bulimia specifically (Welch & Fairburn 1996; Welch *et al.* 1997).

Some support for the assumption that biological factors of vulnerability are important in the aetiology of bulimia nervosa comes from twin studies. Higher concordance rates for bulimia nervosa were found in monozygotic twins as compared with dizygotic twins (Fichter & Nögel 1990; Hsu *et al.* 1990). Statistic modelling indicated that additive genes accounted for a large proportion of the variance of a lifetime diagnosis of bulimia nervosa (Kendler *et al.* 1991), and the symptoms of binge-eating and vomiting (Sullivan *et al.* 1998b). However, the genetic influences are combined with strong individual-specific environmental factors (Bulik *et al.* 2000). One of the recent genetic studies found that environmental factors contribute more to the development of dietary restraint, eating concern and weight concern than genetic factors do (Wade *et al.* 1998). Additive genes also play an important part in the co-occurrence of bulimia nervosa

and major depression, but each disorder has its own set of unique environmental risk factors (Walters *et al.* 1992).

The interpretations of the genetic findings vary among experts. Critical reviews point to the inconsistencies of findings, with estimates of the heritability of liability to bulimia nervosa ranging from 0 to 83%, and emphasize that a broad view on the aetiology of eating disorders should be maintained (Fairburn *et al.* 1999a).

Treatment

A variety of treatment strategies are available to bulimic patients. These include psychological methods (individual and group psychotherapy, cognitive and behavioural treatment) and biological approaches, such as medication and nutritional management. Self-help and support groups have also received considerable attention. Recently, the efficacy of using a self-care manual for guided self-change has also been documented (Schmidt & Treasure 1993; Treasure *et al.* 1996; Thiels *et al.* 1998).

In the past, hospitalization had been recommended by a number of experienced clinicians and experts in the field (Garfinkel & Garner 1982; Russell 1979) as a method for breaking through the vicious cycle of starvation, binge-eating and vomiting. More recently, however, others have emphasized that the vast majority of patients with bulimia nervosa can be treated on an outpatient basis (Freeman 1991; Fairburn 1995) or in a day clinic and that initially, inpatient treatment in bulimia nervosa is rarely required. The latter should be reserved for cases in which there are serious medical problems, serious concurrent psychiatric disturbances that would warrant hospitalization in their own right, and unremitting severe symptoms that have not responded to adequate trials of outpatient treatment. Individual or group approaches with bulimic patients in both inpatient and outpatient settings depend on the willingness of the patient to co-operate and on the disorder being uncomplicated (free of laxative abuse, alcohol or drugs, psychosis, suicidal or anti-social behaviour).

Practical treatment advice includes diary-keeping and self-monitoring of eating behaviour and meals, self-induced vomiting, and any abuse. In addition, dietary and eating advice must be given and educational material for implementing weight control is helpful (Freeman 1991; Garner 1997). Among the various treatment approaches, two stand out and deserve additional comments: cognitive-behavioural treatment, and psychopharmacological treatment. As in the whole field of bulimia nervosa, most experience comes from the treatment of adult patients, and there is little empirical information on controlled studies of any therapeutic intervention with adolescent patients.

Cognitive-behavioural treatment

This treatment approach and its proven efficacy and effectiveness has received the widest attention, at least among all controlled trials of psychotherapy for bulimia nervosa (Fairburn

1995; Lewandowski *et al.* 1997; Wilson *et al.* 1997; Steinhausen 1999). With the intent to disrupt the habitual binge-eating, vomiting and laxative abuse, programmes centre on the monitoring of eating, weight stimulus control, the provision of information, and education and advice regarding the normalization of eating behaviour in early stages of the treatment. Later, during the course of the therapeutic process, dysfunctional thoughts, beliefs and values that perpetuate the eating problem are identified and modified and, finally, a maintenance programme is instituted. Further characteristics of this approach are described above in the section on the treatment of anorexic patients.

Psychopharmacological treatment

A large number of psychopharmacological agents has been tested in bulimia nervosa, including anticonvulsants, antidepressants, lithium and fenfluramine. The antidepressants are the most promising agents because of their short-term effect in terms of reduced frequency of binge-eating. Nevertheless, the mechanisms underlying the effectiveness of these agents are not understood. Long-term efficacy is jeopardized by high relapse rates upon withdrawal of medication and the frequent changes of drugs required over time.

Among the various effective antidepressants, no single drug is particularly effective (Mitchell *et al.* 1993; Heebink & Halmi 1995; Walsh 1995). Fluoxetine has two advantages: its established efficacy and a relatively low rate of side-effects (Goldstein *et al.* 1995). The combination of antidepressant medication and cognitive-behavioural therapy is not superior to the latter alone. The clinical decision for the application is restricted for the following reasons.

- 1 The effects of treatment are still insufficient because the majority of treated patients remain symptomatic at the end of treatment.
- 2 Very little is known about matching patients to treatments.
- 3 The specific efficacy of many antidepressants in adolescents is not known.

A final caveat comes from the knowledge that, at least in affective disorders, the efficacy of antidepressants is generally lower in adolescent than in adult patients (see Harrington, Chapter 29).

Outcome and prognosis

Outcome analysis studies indicate that half fully recover from the disorder whereas one-quarter improve and another quarter run a chronic course (Steinhausen 1999). Other psychiatric disorders at outcome include affective disorders in 25%, anxiety disorders in 13%, substance use disorders in 15%, and personality disorders in almost 5%. Crude mortality rates amount to only 0.7% (range 0–6%), which is considerably lower than in anorexia nervosa, but may also partly reflect the fact that follow-up periods in bulimic patients have been shorter. In comparison with anorexia nervosa, less is known about prognostic factors. Findings are contradictory on whether either early age

of onset or duration of illness are favourable or unfavourable prognostic factors. Severity has no clear prognostic value. Neither comorbidity with anorexia nervosa or substance use disorders, nor obesity as premorbid conditions influence prognosis. So far, no firm conclusions can be drawn as to the prognostic relevance of family variables and socioeconomic status. Concomitant personality disorders, suicide attempts, alcohol abuse, and low self-esteem were found to be negative predictors of outcome, whereas the role of comorbid depression was less clear.

Conclusions

The increased frequencies of eating disorders and people's awareness of these problems have greatly stimulated research. We have learned much about clinical phenomenology, epidemiology, treatment and outcome. Unfortunately, most of this knowledge stems from studies of adult patients. This is surprising because anorexia nervosa typically begins during adolescence, and more studies of this age group are needed.

As in other fields of psychiatry, rather loosely tailored aetiological models are trying to integrate a large body of diverse factors and assumptions. With the advancement of molecular genetics (see McGuffin & Rutter, Chapter 12), the identification of those individuals who are particularly vulnerable to eating disorders should be possible. This may also contribute to a revised system of classification in terms of valid subtypes. Furthermore, a longitudinal study set up in the framework of developmental psychopathology should shed more light on disorder-specific risk factors, potential protective factors within the individual and the social environment, their interaction and their timing. This approach might not only address the emergence but also the maintenance of the eating disorders and should include psychological, psychosocial and biological parameter and constructs.

There is an urgent need to tailor therapeutic interventions to the needs of young patients and to evaluate the various approaches. Given the high costs of medical treatment, regardless of setting and approach, and given the high relapse and chronicity rates, both the patients and society must have an interest in the question of which patients are most apt to profit best from certain well-evaluated treatment approaches. Studies of this kind should be connected with outcome studies that must concentrate on longer follow-up periods.

Clinical treatment rests on both inpatient and outpatient programmes with special indications and combinations of various interventions. Family involvement is essential for any intervention with children and adolescents, and psychological interventions are a part of a broader team effort that should be adjusted to the developmental level of the child or the adolescent.

Finally, greater efforts should be directed towards the prevention of eating disorders. However, given the limited knowledge on the precise aetiology and the large number of non-specific risk factors, expectations should be tempered. So far, empirical tests of several prevention studies revealed only minimal or

even counterproductive results (Franko & Orosion-Weine 1998). Further research into creative and carefully designed programmes is clearly warranted.

Definition: the concept and current issues

Obsessive-compulsive disorder was once considered rare in childhood, but recent advances in diagnosis and treatment have led to recognition that the disorder is a common cause of distress for children and adolescents. Obsessive-compulsive disorder (OCD) is characterized by the presence of obsessions (unwanted repetitive or intrusive thoughts), and compulsions (unnecessary repetitive behaviours or mental activities). Because the obsessive thoughts and compulsive rituals are recognized by the child as nonsensical, they are often kept hidden for as long as possible—from both parents and practitioners. This secrecy may have contributed to the fact that until recently, OCD was unfamiliar to most child psychiatrists, even though classic descriptions of the disorder featured cases with childhood presentation (Janet 1903). The recognition that OCD was more common in adults than previously believed, and retrospective reports that one-half to one-third of adult subjects had their onset in childhood or adolescence, focused the attention of the child psychiatric community on this chronic and often disabling disorder (Karno *et al.* 1988).

Until the mid-nineteenth century, obsessive-compulsive phenomena were considered to be a variant of insanity. However, as the disorder was better defined, it came into focus as one of the neuroses. The descriptions of repetitive unwanted thoughts or rituals often characterized by magical thinking, and usually kept private by the sufferer, were relatively constant observations in those early reports. Debate about core deficits and the relative importance of volitional, intellectual and emotional impairments (all of which are in some way abnormal in OCD) have flourished for over 100 years (Berrios 1989).

Freud (1909, 1913) provided some of the most interesting and creative speculations on the similarity between obsessive-compulsive phenomena, children's games and religious rites. Although psychoanalytic theory has not added usefully to the treatment or understanding of the aetiology of severe OCD, the broad questions raised by Freud about continuity and discontinuity within individual development and OCD, as well as with secular and religious rituals, remain fascinating issues. In addition, the observations of association between certain neurological disorders and OCD have led to the most intriguing aspects of current neurobiological research: the possible localization of brain circuits mediating obsessive-compulsive behaviours, as well as mechanisms for behavioural encoding. Over the past decade, interest in these social and developmental questions,

together with increased recognition of paediatric OCD, has generated an astonishing amount of clinical observation, and basic science and clinical research (Rapoport 1989a,b; King & Scahill 1999).

Epidemiology

The Epidemiological Catchment Area (ECA) study of over 18 500 adult individuals in five different sites in the USA included OCD as a separate category and provided the first large-scale information on the prevalence of this disorder (Robins *et al.* 1981). Using the Diagnostic Interview Schedule (DIS), a structured interview designed for lay interviewers, lifetime prevalence rates ranged from 1.9 to 3.3% across the sites. Even when other disorders were excluded, the rates were 1.2–2.4%. These rates were 25–60 times greater than had been estimated on the basis of clinical populations (Karno *et al.* 1988). The mean age of onset across the sites ranged from 20 to 25 years, with 50% developing symptoms in childhood or adolescence (Karno & Golding 1990), providing further support for retrospective accounts of the frequent paediatric onset of this disorder (Black 1974).

The ECA findings have been criticized on the grounds that interviewers were not trained clinicians and the validity of the DIS is uncertain (see discussion in Karno *et al.* 1988). To address these criticisms, and assess the rates of OCD in a younger population, Flament *et al.* (1988) used trained mental health professionals and previously validated instruments to assess obsessive-compulsive symptomatology in an adolescent population. As part of a two-stage study of 5596 adolescents (Whitaker *et al.* 1990), the Leyton Obsessional Inventory was administered (together with other questionnaires on general mental health, anxiety and eating disorders) to the entire high school population of a county 80 miles from New York City (Flament *et al.* 1988). Adolescents scoring above the clinical cut-off were interviewed by child psychiatrists with extensive clinical experience with OCD. Clinical vignettes were compiled on the basis of these semistructured interviews and a high agreement for OCD, compulsive personality and subclinical OCD was obtained (overall kappa of 0.85). A total of 20 subjects received a lifetime diagnosis of OCD (18 current and two with past illness). The weighted prevalence figure (without exclusion) for OCD was 1.9%, a figure that is in close agreement with the ECA estimates for adults. Two-year follow-up demonstrated

that the obsessive-compulsive symptoms were clinically significant, as the majority of subjects remained symptomatic (Berg *et al.* 1989).

In recent years, several additional epidemiological studies have been conducted (see Zohar 1999 for review), with prevalence rates ranging from 0.5 to 4% (Anderson *et al.* 1987; Lewinsohn *et al.* 1993; Reinherz *et al.* 1993; Wittchen *et al.* 1998; Rapoport *et al.*, 2000). In virtually all of these reports, the rates ascertained from direct child reports were higher than those derived from parent reports, supporting clinical data that children with OCD often hide their illness. The secrecy, and difficulties of utilizing lay interviewers, may have contributed to the low (0.5%) prevalence of OCD found by Wittchen *et al.* (1998) in a sample of 3021 adolescent subjects in Munich, Germany. Other investigators, such as Valleni-Basile *et al.* (1996) in south-eastern USA, Douglass *et al.* (1995) in New Zealand and Zohar *et al.* (1992) in Israel, used mental health interviewers and semistructured clinical interviews, and found more comparable rates of 2.9, 4.0 and 2.3%, respectively. Of note in the Israeli investigation, an additional 4% of the adolescents had subclinical obsessive-compulsive symptomatology, defined by the presence of obsessions and compulsions which were not of sufficient severity to meet DSM-III-R criteria. This group, as well as those meeting diagnostic criteria for OCD, remained symptomatic at 2-year follow-up evaluation (Zohar *et al.* 1992).

The frequency, chronicity and secrecy of paediatric OCD suggest that mental health professionals should make special efforts to question paediatric patients about symptoms of OCD.

Phenomenology and classification

OCD is defined in both ICD-10 and DSM-IV as repetitive intrusive thoughts and/or rituals that are unwanted and which interfere significantly with function or cause marked distress. The severity criteria avoid confusion with the many childhood habits which are a part of normal development, and the content and relative insight into the unreasonableness of the behaviours differentiate OCD from other disorders. The ICD and DSM-IV criteria differ in their inclusion or exclusion of comorbid psychotic disorders, such as schizophrenia. A change was made in DSM-III-R (American Psychiatric Association 1987) and continued in DSM-IV (American Psychiatric Association 1994) which allowed patients to receive a diagnosis of OCD, even in the presence of schizophrenia. This change was made because of the broad comorbidity of OCD (Karno *et al.* 1988) and convincing evidence of coexistence with schizophrenia (Lewis *et al.* 1991). DSM-IV urges the use of multiple diagnoses as appropriate, and both Karno *et al.* (1988) and our own experience (Swedo *et al.* 1989b), suggest that over 50% of OCD subjects will also merit another Axis I diagnosis, often an anxiety or affective disorder.

Current debates about diagnostic criteria—including whether obsessions are inevitably present, and what degree of

insight is required concerning the irrationality of symptoms—are of particular importance for childhood OCD. Both DSM-IV and ICD-10 state that compulsions are designed to neutralize or prevent some dreaded event. This may be an error. While some children may not be willing or able to verbalize their obsessive thoughts, long-term contact has demonstrated that about 40% of children do not have obsessive thoughts—they steadfastly report the presence of only compulsive rituals accompanied by a vague sense of discomfort if the rituals are not carried out (Swedo *et al.* 1989b). In fact, over one-third of adults also deny that their compulsions are driven by an obsessive thought (Karno *et al.* 1988), suggesting that neutralization is not an essential feature of OCD at any age.

The degree of insight needed for the diagnosis is also in dispute as some patients, at least some of the time, ‘believe’ their obsessions. Again, children generally do not differ from adults in this respect. While in theory it might seem that young children would be particularly prone to ‘believe’ their obsessional thoughts, experience to date suggests that the DSM-IV adult criteria are appropriate for the diagnosis in childhood (Rapoport 1989a; Swedo *et al.* 1989b; King & Scahill 1999). It seems that for both adults and children, diagnostic criteria must acknowledge that compulsions can and do occur in the absence of obsessions, and that partial ‘belief’ in the necessity for these thoughts/behaviours is seen, particularly in severe cases.

Recent research has suggested that subtyping of OCD may be useful. Leckman *et al.* (1997) suggest that symptom clusters divide OCD into four phenomenological subtypes, including those with ‘just right’ phenomena, as well as those with primarily cognitive symptoms. The presence or absence of a comorbid tic disorder also appears to define phenomenology and symptom course; in addition, children with comorbid tics often benefit from low-dose neuroleptic augmentation of serotonin uptake inhibitors. Aetiological investigations suggest that there are at least three subtypes of OCD: familial (possibly genetic), non-familial and environmentally triggered (e.g. post-infectious). One example of the latter subgroup has been identified by research at the National Institute for Mental Health (NIMH) which revealed a subgroup of paediatric patients in whom symptom exacerbations are triggered by streptococcal infections; the subgroup is identified by the acronym PANDAS (paediatric autoimmune neuropsychiatric disorders associated with streptococcal infections; Swedo *et al.* 1998). The postulated aetiopathophysiology of symptoms in the PANDAS subgroup is similar to that of Sydenham chorea (the neurological manifestation of rheumatic fever), in which streptococcal infections trigger the production of antibodies which cross-react with neuronal tissue to produce an ‘autoimmune’ reaction situated mainly within the basal ganglia (Swedo 1994). The resulting inflammation results in a variety of neuropsychiatric symptoms, including obsessions, compulsions and tics, among others. Several clinical characteristics define the PANDAS subgroup, including prepubertal onset (mean age of 7.4 ± 2.7 year), episodic (‘sawtoothed’) course, presence of neurological abnormalities, such as choreiform movements or motoric hyperactivity, and a

Table 35.1 Presenting symptoms in 70 consecutive children and adolescents with primary obsessive-compulsive disorder. (Categories adapted from Goodman *et al.* 1989.)

Reported symptoms at initial interview	<i>n</i>	Percentage
<i>Obsessions</i>		
Concerns with dirt, germs or environmental toxins	28	40
Something terrible happening (e.g. fire, death or illness of self or loved one)	17	24
Symmetry, order or exactness	12	17
Scrupulosity (religious obsessions)	9	13
Concern or disgust with bodily wastes or secretions (urine, stool, saliva)	6	8
Lucky or unlucky numbers	6	8

Hoarding/collecting rituals	8	11
Rituals of cleaning household or inanimate objects	4	6

Multiple obsessions and compulsions are possible, thus the total exceeds 70.

temporal association between symptom exacerbations and streptococcal infections (Perlmutter *et al.* 1998; Swedo *et al.* 1998). When a young child presents with the acute onset of OCD and/or tics, consideration of a relationship between streptococcal infections and symptom onset may provide unique opportunities for intervention (see section on Investigative Treatments).

Clinical presentation

Childhood onset OCD has been documented as early as age 2, but more typically begins later in childhood or early adolescence (Despert 1955; Adams 1973; Rapoport 1989c). Children with an early age at onset (below age 6) usually begin their rituals or obsessions in easily recognizable fashion, such as excessive hand-washing or ritualized checking and repeating (Swedo 1989). However, in some cases the clinical presentation is altered by the child's developmental immaturity. For example, one 6-year-old boy, who was compelled to draw zeros repetitively, had started at age 3 to circle manhole covers on city streets. His tantrums when the circling was interrupted, his subjective distress during the behaviour and his lack of other psychosocial abnormalities (such as autism or pervasive developmental disorder) led to the diagnosis of OCD. Another child presented at age

7 with clinically significant checking compulsions, but had been evaluated previously at 3 years of age when he developed a 'compulsion' to walk only on the edges of floor tiles. Cleaning rituals in children too young to reach the water faucet might present as excessive hand-wiping or licking.

In general, the symptoms of OCD in children mirror those in adult patients, and include a wide variety of obsessive thoughts and compulsive rituals (Despert 1955; Adams 1973; Goodman *et al.* 1989; Swedo 1989; Thomsen & Mikkelsen 1991; Toro *et al.* 1992; Maina *et al.* 1999). Obsessive thoughts centre on contamination concerns, danger to self or others, symmetry or moral issues. Common compulsions include washing, checking and repeating—particularly until the child experiences a feeling of 'getting it just right'. Most children have a combination of rituals and obsessions, and 'pure' obsessives are rare compared with the more frequent 'pure' ritualizers.

The presenting symptoms of 70 children and adolescents consecutively evaluated at the NIMH are summarized in Table 35.1 (Swedo 1989). As with other OCD patients, rituals were more frequently the presenting complaint than were obsessions. Washing compulsions were by far the most common symptom in the NIMH sample, occurring at some time during the course of the illness in 85% of patients. Hand-washing was slightly more frequent than was showering, and the two activities

accounted for virtually all of the washing rituals (no subject took prolonged baths), although a few children cleaned their hands with chemicals, such as alcohol or detergents, provoking eczematoid dermatitis.

Secrecy appears to be a hallmark of childhood onset OCD. The children recognize that their symptoms are nonsensical and are embarrassed by them, so they go to great lengths to hide them. Hand-washing might be disguised as more frequent voiding, and rituals are carried out in private, so that children are often symptomatic for months before their parents are aware of a problem. Teachers and peers become aware only with much greater severity. As with Tourette disorder, children may expend great effort 'controlling' their behaviours in public and 'let go' when at home. This partial voluntary control of symptoms often baffles and angers parents (see section on Family Education below).

Approximately one-third of paediatric patients report that certain stimuli trigger their rituals, and that avoidance of the trigger 'protects' them from the obsessive-compulsive symptoms (Swedo 1989). For example, a 16-year-old girl with elaborate front door touching and stepping rituals could 'sneak' into her house by a side door, avoiding the sight of the front door, and successfully avert the compulsions. Several hoarders would close their eyes to avoid seeing scraps of paper on the street that would set off the collecting urge. From an ethological perspective, the compulsions might be conceptualized as 'fixed action patterns' released by key environmental stimuli (Modell *et al.* 1989; Swedo 1989; Winslow 1989), perhaps mediated through the striatum (Rapoport & Wise 1988; Wise & Rapoport 1989). An ethological bias on OCD still leaves entirely open the question of what sort of innate programmes could serve to focus the developing child's attention on particular aspects of environmental stimulation that forms blocks of behavioural organization, later 'released' as OCD. Adaptive significance of such innate specification is assumed, but runs the danger of teleological argument. While evidence of selective response to certain stimuli has been demonstrated in normal infants (e.g. response to mother's voice), no studies have yet been carried out on trigger stimuli in childhood OCD. Such studies, particularly with high-risk groups, would be of great interest.

Course and natural history

There are no prospective data available to determine mean age at onset of OCD. In epidemiological studies, over 50% of adults with OCD report that their symptoms started during childhood or adolescence, with males generally having earlier onset than females (Rasmussen & Tsuang 1984). The demographics of the NIMH paediatric clinic support these retrospective data, as the mean age of onset was 10.1 (± 3.5) years in the OCD cohort, with eight of the 70 patients having symptom onset prior to age 7. Among those who had symptom onset prior to puberty, males outnumbered females by nearly 3:1. Of interest to our efforts to interpret retrospective data, parents of nearly half of the NIMH sample revealed that their children had displayed 'micro

episodes of OCD' several years before developing full-blown symptoms. During the episodes, excessive rigidity and repetitive rituals (e.g. wearing the same clothes for a month, refusal to take a different path through the house) were a source of concern, albeit briefly (Swedo *et al.* 1989b).

The clinical course of the disorder indicates some developmental influence on symptoms over time. The primary obsessions and compulsions changed over time in 90% of the NIMH paediatric patients (Rettew *et al.* 1992). Most children began with a single obsession or compulsion, continued with this for several months to years, and then gradually acquired different thoughts or rituals. Although the primary symptom would change (e.g. from counting to washing and then checking), the earlier symptoms often remained problematic, although at a lesser degree. The nature of the compulsive rituals also changed over time. A study of adolescents demonstrated that counting and symmetry were most prominent during grade-school years, but were replaced by washing rituals during early and mid-adolescence (Maina *et al.* 1999). As adolescence progressed, sexual thoughts or rituals became common; these dissipated by 18 years of age and were supplanted by more general ruminations and doubts. For a significant number of children, however, the presenting symptom continued unchanging throughout the course of the illness, such as the adolescents who report having an intrusive 'song stuck in my head' (Swedo 1989; Flament *et al.* 1990; Zungu-Dirwayi *et al.* 1999).

The clinical course of childhood onset OCD is usually described as chronic and unremitting, although epidemiological studies of adults suggest that spontaneous remissions occur in as many as one-third of patients (Karno & Golding 1990). Among children with comorbid tic disorders, symptom severity may fluctuate over time, similar to the waxing and waning course described for Tourette disorder (Leonard *et al.* 1992). An episodic course has also been described for the PANDAS subgroup of patients, but it is characterized as relapsing/remitting, rather than fluctuating in severity (Perlmutter *et al.* 1998). These variations in clinical course are intriguing, but it is not yet clear whether they reflect differences in underlying pathophysiology, or are merely the result of individual differences in clinical presentation.

The long-term prognosis of childhood onset OCD is unknown, as prospective follow-up studies are rare. Epidemiological studies suggest that symptoms remain problematic for the majority of childhood onset cases (Karno & Golding 1990). These findings are consistent with those from adult patients with childhood onset OCD, who report that their symptoms have remained problematic throughout adolescence and adulthood (Berman 1942; Warren 1965; Hollingsworth *et al.* 1980; Zeitlin 1986; Honjo *et al.* 1989; Hanna 1995). The availability of improved psychological and pharmacological therapies appears to have done little to improve the long-term outcome of childhood onset OCD. Leonard *et al.* (1993) carried out a 2–7 years prospective follow-up of 54 children participating in a clomipramine treatment trial. They found that 20 (37%) still met criteria for OCD and only 18 (33%) were symptom-free,

despite ongoing drug treatment (Leonard *et al.* 1993). Thomsen & Mikkelsen (1991) conducted a similar longitudinal evaluation in 23 Danish children and adolescents, and demonstrated that over 50% still met severity criteria for an OCD diagnosis at 1.5–5 years follow-up.

Associated disorders

In adults, OCD has a broad range of comorbidity similar to that seen for other major Axis I disorders (Karno *et al.* 1988). The patterns of comorbidity among childhood onset cases are generally comparable to those for adult samples, with tic disorders and specific developmental disorders appearing more frequently in the paediatric populations. In the NIMH sample, only 26% of the paediatric subjects had OCD as a single diagnosis (Swedo *et al.* 1989b). Tic disorders (30%), major depression (26%) and specific developmental disabilities (24%) were most common. Rates were also increased for simple phobias (17%), overanxious disorder (16%), adjustment disorder with depressed mood (13%), oppositional disorder (11%), attention deficit disorder (10%), conduct disorder (7%), separation anxiety disorder (7%) and enuresis/encopresis (4%). Riddle *et al.* (1992) reported similar findings, with the majority of children and adolescents in their sample having comorbid diagnoses, including anxiety disorders (38%), mood disorder (29%) or tic disorder (24%).

Epidemiological studies have also found similar comorbidity patterns. Zohar *et al.* (1992) found increased rates of phobias (33%), overanxious disorder (2%) and tic disorders (8%) among adolescents with OCD identified from a population of 861 Israeli adolescents. Other community-based studies have not evaluated the rate of comorbid tic disorders, but have found increased rates of affective and anxiety disorders. In a study in the south-eastern USA, Valleni-Basile *et al.* (1996) found that the majority of adolescents with OCD had a comorbid disorder, including depression (45%), separation anxiety disorder (34%) and/or phobia (29%). Lewinsohn *et al.* (1993) noted increased rates of panic disorder (33%), overanxious disorder (33%) and social phobia (33%) in their Oregon sample, and reported that over two-thirds of the adolescents with OCD had a second anxiety disorder. Eating disorders are also increased in frequency among children and adolescents with OCD, as demonstrated in the epidemiological study by Whitaker *et al.* (1990).

Increased incidence of neurological ‘soft’ signs in childhood anxiety disorder has been reported by Shaffer *et al.* (1985). Early studies at the NIMH reported a lack of normal cerebral laterality and a high rate of age-inappropriate synkinesias and left hemibody signs (Rapoport *et al.* 1981; Behar *et al.* 1984). Subsequent studies, utilizing structured neurological examinations, revealed that over 80% of the subjects had minor neurological abnormalities, including left hemisindrome, neurodevelopmental ‘immaturity’ and choreiform movements (Denckla 1989). Neuropsychological abnormalities included poor visuospatial skills and abnormal speech prosody (Cox *et al.* 1989). In a group of adult patients with OCD examined by

Hollander *et al.* (1990), increased neuropsychological abnormalities were found to correlate significantly with poor treatment response.

Choreiform movements were also found in one-third of the NIMH paediatric sample (Denckla 1989). The absence of these movements on follow-up examination 2–5 years later has been interpreted to mean that they are a marker of a pathological process aetiological to OCD (Leonard *et al.* 1993). Further support for this postulate comes from recent studies in children with infection-triggered OCD, in which over 90% demonstrated choreiform movements during periods of symptom exacerbation (Swedo *et al.* 1998).

Compulsive personality disorder appears to be less frequent (11%) among paediatric patients (Swedo 1989) than among adult patients (Rasmussen & Tsuang 1984; Black *et al.* 1988), although more systematic studies of personality disorder indicated that the prevalence of compulsive personality disorder in adult OCD patients may be less than previously believed (Joffe *et al.* 1988). Limitations of standardized instruments for assessing personality disorders and the lack of paediatric indication for this diagnosis have obscured this issue. Further, it is possible that compulsive personality disorder may develop as a secondary or adaptive response to very early onset OCD. Evidence supporting this postulate comes from follow-up to the NIMH epidemiological study, which found a number of adolescents no longer met criteria for OCD but did have features of the personality disorder—rigidity, excessive attention to details and social isolation, among others (Berg *et al.* 1989). The boundary is further obscured by a Harvard study of adult patients with OCD which demonstrated that features of the personality disorder remitted with successful treatment of the primary disorder (Ricciardi *et al.* 1992).

Case illustrations

Case 1

A 14-year-old boy, whose symptoms had begun gradually, recalls at a very early age having to wash his hands repetitively. He was unable to associate an obsessive thought with this ritual, but he felt compelled to perform it. By age 6 years he had developed an obsessive fear of tornadoes. He would repeatedly check the sky for clouds, listen to all weather reports and query his mother about approaching storms.

The tornado obsession faded over time and was replaced by a generalized fear of harm coming to himself or his family. He responded with extensive protective ritualization to keep his family safe and to protect himself. Particularly at times of separating, such as bedtime or leaving for school, the patient would be compelled to repeat actions perfectly or to check repetitively. When asked how many times he would have to repeat an action, he replied, ‘It depends. The number isn’t always the same, I just have to do it *right*.’ When asked how he knew when it was right, he said, ‘I don’t know, it just *feels* right.’

As the patient entered puberty, he became obsessed with

acquired immunodeficiency syndrome (AIDS) and was convinced he would acquire it through his mouth. He began spitting in an effort to cleanse his mouth, and would spit every 15–20 s. In addition, he began extensive washing rituals. Despite these cleansing and washing compulsions, his personal appearance was slovenly and dirty. He never tied his shoelaces because they had touched the ground and were ‘contaminated’; if he tied them, his hands would be ‘dirty’ and he would have to wash until they were ‘clean’ again. Remarkably, although his family was aware that ‘something has been wrong for a long time’, most of the content of his obsessions was kept secret. This case illustrates the contamination concerns common to adolescents, and the variety and evolution of obsessive-compulsive symptoms during development.

Case 2

A 16-year-old girl had symptoms that began abruptly, shortly after the onset of menses. She called herself ‘a prisoner of my own mind’. Her obsessions centred around fear of harm to her parents. She was plagued by recurrent thoughts of her mother dying in a car accident, her father being killed by an intruder, or both her parents dying of burns received in a house fire. Always a light sleeper, she began to get up during the night to check. She spent hours checking that the doors were locked, that the coffee pot was unplugged, and that the family dog was safely ensconced in the garage. Despite her obsessions about fire, however, she did not check the smoke detector, an excellent example of the irrationality of this superficially rational disorder.

She involved her family in her rituals. Her mother made a checklist that the daughter carried to school, and both parents had to check the 24 items on the list, signing that they had done so. At night she would wake her father to help her check. The family involvement was so profound that behavioural treatment could only take place after a period of family counselling in which the parents were helped to separate from their daughter’s illness.

Differential diagnosis

The broad comorbidity of OCD and array of associated features make the diagnosis in theory seem difficult; in practice, however, it is usually quite straightforward.

The diagnosis of OCD must be made only if the ‘obsessive worries’ are true obsessions, rather than symptoms of another disorder such as depressive ruminations or phobic avoidance. For example, when OCD is comorbid with bulimia or anorexia, the content of the obsessions or compulsions must be typical, e.g. washing, arranging, counting, and not fixed overfocused ideas about food, diet, etc. Depressive ruminations and psychotic preoccupations are also distinguished by content and associated symptomatology. Phobic disorders are not only distinguished by the content of the preoccupation (more often heights, spiders, the dark, etc.), but also by the absence of discomfort when the patient is not confronted with their phobic

object. It may be more difficult to separate the obsessional concerns of OCD from the fears and worries of generalized anxiety disorder, particularly in a child with comorbid disorders (Brown *et al.* 1993). Comorbidity of OCD and other anxiety disorders is common, so assigning specific symptoms to a specific disorder may be less important than identifying the presence of OCD in a child presenting with generalized anxiety or separation anxiety disorder.

Asperger disorder can be differentiated from OCD by its lack of ego dystonicity, and in addition, by the content of the preoccupations. For example, in Asperger disorder, concerns about danger or contamination occur only rarely, while these are common among children with OCD. Autistic patients also may exhibit obsessive-compulsive symptoms, but these occur within the context of cognitive and psychosocial abnormalities, and should not be confused with symptoms of OCD.

The differential diagnosis from Tourette is the most problematic, and the relationship between the two disorders remains obscure. Distinguishing between a compulsion or a tic may be difficult, as patients with Tourette syndrome often have a complex behavioural overlay on their tics. Some 20–80% patients with clear Tourette have been reported to have obsessive-compulsive symptoms or OCD (Frankel *et al.* 1986; Pauls *et al.* 1986; Grad *et al.* 1987); while 24–67% of children with primary OCD have been observed to have comorbid tics (Leonard *et al.* 1992; Riddle 1990; Zohar *et al.* 1992). Tics are seen more often in younger patients, those with acute illness and in males (Leonard *et al.* 1992). It is unknown just how the pattern and severity of obsessive-compulsive symptoms differ between patients with Tourette syndrome and those with primary OCD, but preliminary impressions are that compulsions associated with Tourette syndrome may be more likely to involve symmetry, rubbing, staring and blinking rituals, or touching than washing and cleaning (Baer 1994; Holzer *et al.* 1994; Leckman *et al.* 1995) and may be less severe than in non-tic OCD.

The overlapping clinical profiles makes it tempting to speculate that some cases of OCD may represent an alternative form of Tourette disorder and family studies provide partial support for such a construct. In Tourette, there is an increased familial rate of OCD, independent of the presence of obsessive-compulsive symptoms in the proband (Pauls *et al.* 1995). Increased familial rates of Tourette and tics also are seen with OCD probands, particularly for their male relatives (Leonard *et al.* 1992). Any Tourette/OCD formulation, however, is likely to be oversimplified, as both tic disorders and OCD may be manifestations of basal ganglia dysfunction secondary to a number of causes, including genetic, toxic, traumatic and infectious agents.

Theories of aetiology and current research

Psychological factors

Over the past two decades, it has become clear that OCD is not

caused solely by psychological factors, as had been posited by Kanner (1962) when he cited ‘an “overdose” of parental perfectionism’ as the source of obsessional neuroses. Instead, accumulated evidence suggests that OCD is caused by a combination of biological and psychological factors, with both nature and nurture playing a part (Esman 1989). Although no predisposing psychological factors have been identified in OCD (Anna Freud 1965), a role for psychological dysfunction is suggested by the overwhelming anxiety experienced by the patients, and the variable nature of their symptoms. For example, one 10-year-old boy developed an obsessive fear of ‘doing something wrong and going to Hell’ after hearing a minister preach that ‘the wages of sin are eternal damnation’. Another 10-year-old attributed his obsessive fear of vomiting in public to having witnessed a classmate’s humiliation. Both boys were able to pinpoint a specific event as the precipitant for their symptom onset, despite acknowledging that ‘I know it won’t really happen, but I can’t stop worrying about it.’ A particularly compelling example of post-traumatic OCD was recently reported by Boudreaux *et al.* (1998) who noted the onset of compulsive hand-washing and genital scrubbing in several patients following instances of rape or incest.

The effectiveness of cognitive-behaviour therapy (CBT) for OCD provides additional evidence of psychological dysfunction in the disorder. CBT is based on a conceptualization of the obsessions as intrusive and unwanted thoughts that trigger a significant and rapid increase in anxiety or distress, and compulsions as ritualized behaviours or cognitions (mental rituals) that serve to reduce the negative feelings (Piacentini 1999). In essence, the anxiety is a ‘learned response’ to the obsession, and the CBT is a means of teaching a new pattern of response (and ‘unlearning’ the old one).

Analogies have often been drawn between the obsessions and compulsions of OCD, and normal developmental rituals or superstitions, and several authors have suggested that OCD is merely ‘part of typical experience’ (Pollock & Carter 1999). The magical thinking and ritualistic behaviours of common superstitions, although brief, ego-syntonic and non-interfering, hold obvious features in common with OCD. Superstitious rituals before sports events are particularly similar to obsessive-compulsive rituals. However, it is not clear what such analogy really implies for OCD. Leonard *et al.* (1990), for example, found that superstitious beliefs or behaviours of children with OCD were no more severe or numerous than those of normal peers. Moreover, when ‘micro episodes’ of OCD were removed from consideration, normal childhood developmental rituals also were not exaggerated. A recent report by Evans *et al.* (1999) confirmed this separation between obsessive fears and ‘contextual’ fears of normal childhood. Obsessive-compulsive symptoms also appear to be discontinuous from normative cultural rituals and beliefs, with individuals in rural Ghana exhibiting ‘typical’ OCD cleaning compulsions, despite unique cultural attitudes towards hygiene (Field 1960). Thus, it would appear that OCD is not on a continuum with normal behaviours and beliefs.

Biological factors in OCD

Basal ganglia dysfunction

Understanding the aetiological role of the frontal lobe–basal ganglia circuitry in OCD is one of the most exciting challenges of psychiatry. Clues provided by historical reports of association with basal ganglia disease, brain-imaging techniques such as computed tomography (CT) and positron emission tomography (PET) and results of neurotransmitter and hormonal manipulations must be integrated into a neuropathological framework determined by basic scientific research. For reviews, see Wise & Rapoport (1989), Rapoport (1991) and Fitzgerald *et al.* (1999).

Association with basal ganglia disorders

The best description of neurologically based OCD comes from Constantin von Economo’s treatise (1931) on post-encephalitic Parkinson disease, which followed an outbreak of encephalitis lethargica in 1916–17. Von Economo noted the ‘compulsory nature’ of the motor tics and ritual-like behaviours that his patients exhibited. Von Economo’s patients, like OCD patients, described ‘having to’ act, while not ‘wanting to’: they experienced a neurologically based loss of volitional control. The neuropathological examinations revealed primarily basal ganglia destruction.

Basal ganglia dysfunction is also associated with OCD, as evidenced by the increased incidence of motor tics and choreiform movements in children with OCD (Denckla 1989) and the association of obsessive-compulsive symptoms with known basal ganglia disorders, such as Tourette disorder (discussed earlier) and Sydenham chorea (Swedo 1989, 1994). Sydenham chorea (SC), the neurological manifestation of rheumatic fever, is a post-streptococcal ‘autoimmune’ disorder which affects primarily the basal ganglia. Although the precise pathophysiology of SC is unknown, it is thought that the streptococcal bacteria induce the production of ‘cross-reactive’ antibodies recognizing the basal ganglia. Husby *et al.* (1976) demonstrated antibodies in the serum of patients with SC that not only recognized components of the streptococcus cell wall, but also reacted with the cytoplasm of the subthalamic and caudate nuclei. Kiessling *et al.* (1994) replicated these findings in children with OCD and tic disorders, as well as those with SC.

Osler (1894) was the first to note ‘perseverativeness of behaviour’ in children with SC. Over 50 years later, Chapman *et al.* (1958) observed obsessive-compulsive symptoms in 4 of 8 children acutely ill with SC. Grimshaw (1964) and Freeman *et al.* (1965) extended these findings by demonstrating an increased rate of childhood SC in patients with obsessional neuroses, as compared with other psychiatric disorders. In the late 1980s, the first systematic study of obsessive-compulsive symptoms in SC revealed significantly increased OCD and obsessive-compulsive symptoms in the 23 children with SC, as compared to a group of 14 children with rheumatic carditis (RF) (Swedo *et al.* 1989a). It is particularly noteworthy that the increase in

Table 35.2 Regional effects of basal ganglia disease and association with obsessive-compulsive disorder (OCD).

Disease	Cause	Basal ganglia area most affected	Most prominent signs	Association with OCD
Sydenham chorea	Autoimmune cross-reaction in streptococcus A/B	Caudate and putamen	Chorea	+++
Huntington chorea	Genetic	Caudate and putamen	Chorea	+
Wilson disease	Genetic	Putamen and caudate	Tremor and rigidity	?
Vascular disease	Vascular	Putamen	Dystonia	+
Parkinson disease				
Idiopathic	Unknown	SNC	Akinetic rigidity	-
Post-encephalitic	Infection	SNC	Akinetic rigidity	++
Seqawa dystonia	Genetic	Unknown	Dystonia	++
Tourette disorder	Genetic	Unknown	Motor/vocal tics	+++

compulsive behaviours and obsessive thoughts occurred selectively in the SC patients, as SC differs from RF only in the presence of basal ganglia dysfunction in SC and its absence in RF. Prospective studies have confirmed these findings, demonstrating obsessive-compulsive symptoms occur in two-thirds (Asbahr *et al.* 1999) to three-quarters of SC patients (Swedo 1994). Interestingly, the obsessive-compulsive symptoms appear to begin 2–4 weeks before the chorea appears, and wax and wane in severity in association with the choreatic movements, suggesting that the basal ganglia inflammation producing the SC also might be responsible for the OCD.

As seen in Table 35.2, a number of basal ganglia disorders are associated with OCD. Specific basal ganglia lesions in individuals also have resulted in obsessive-compulsive behaviours (Laplane *et al.* 1984; Rapoport 1991). Indirect evidence for basal ganglia involvement in OCD is provided by the efficacy of psychosurgical lesions which serve to disconnect the basal ganglia from the frontal cortex (Chiocca & Martuzzi 1990; Mindus 1991; Jenike 1998). Currently, the preferred psychosurgeries for OCD are capsulotomy and cingulectomy. In capsulotomy, bilateral basal lesions are made in the anterior limb of the internal capsule in order to interrupt frontocingulate projections; however, the surgical target lies within the striatum, near the caudate nuclei. In order to perform a cingulectomy, the surgeon lesions the anterior portion of the cingulate gyrus, interrupting tracks between the cingulate gyrus and the frontal lobes and destroying all of the efferent projections of the anterior cingulate cortex. Both procedures result in significant reduction of obsessions and compulsions. The success of psychosurgery is not conclusive evidence of a basal ganglia defect in OCD, as the lesions could be anywhere ‘upstream’ from the site of treatment, but it does contribute to a biological model and focuses interest on frontostriatal tracts.

Perhaps the best evidence for basal ganglia–frontal lobe dysfunction in OCD comes from neuroimaging studies (for reviews see Rauch & Baxter 1998 or Fitzgerald *et al.* 1999). Structural brain imaging studies have revealed volumetric abnormalities in frontostriatal circuitry, particularly in the caudate (Luxenberg *et al.* 1988), putamen (Rosenberg *et al.* 1997) and globus

pallidus (Giedd *et al.* 2000). Of note, Giedd *et al.* (2000) studied children in the PANDAS subgroup during acute symptom exacerbations and found increased volumes of the basal ganglia structures, while Luxenberg *et al.*'s (1988) study demonstrated decreased caudate size in a group of 10 young adult males with early childhood onset of symptoms. One possible explanation for these findings is that the early basal ganglia enlargements reflect inflammatory oedema, while the later studies are reflecting the resultant ‘atrophy’. Although some evidence supporting this hypothesis is provided by a single case study which demonstrated normalization of basal ganglia volumes following immunomodulatory treatment (Giedd *et al.* 1996), further supportive data are needed.

Functional neuroimaging studies utilizing 18-fluorodeoxyglucose positron emission tomography (¹⁸FDG PET) have found regional glucose metabolism in OCD to be elevated in the orbital frontal cortex, cingulate gyri and/or caudate nuclei of the OCD patient groups (see Rauch *et al.* 1997 for review). These metabolic abnormalities ‘normalize’ with successful drug or behaviour therapy (Baxter *et al.* 1992; Swedo *et al.* 1992b) and are exacerbated by tasks stimulating obsessive-compulsive symptomatology (Rauch *et al.* 1994, 1997). These findings are consistent with the hypothesized basal ganglia–frontal lobe dysfunction of OCD (Wise & Rapoport 1989; Insel 1992). Moreover, the findings are both replicable and the particular pattern appears specific to OCD (Baxter *et al.* 1987).

Although the evidence for basal ganglia–frontal lobe dysfunction in OCD is compelling, it fails to account for the behavioural specificity of the disorder—why washers wash and checkers check. It also fails to explain the varied patterns of comorbidity, ranging from generalized anxiety and depression to attention deficits and Tourette disorder. Despite these limitations, the notion of obsessive and compulsive behaviour as an expression of basal ganglia dysfunction has been most useful, accounting for a wide variety of observations and predicting others.

Genetic vulnerabilities

Despite the relatively high prevalence of OCD, and the fact

that the role of heredity in OCD has long been suspected by clinicians (Lewis 1936), genetic studies of this disorder have lagged behind those of other major neuropsychiatric disorders. The results of published twin studies are consistent in reporting substantive concordance differences between monozygotic and dizygotic twins, although the total number of twins studied is small, and there are no adoption and separation studies. There are more family studies of OCD (Lenane *et al.* 1990), and the two largest and most methodologically rigorous found that the risk of OCD was substantially greater in the parents of OCD probands compared to the parents of controls (16 vs. 3%) (Black *et al.* 1992), and that the risk of OCD was overall greater in the first-degree relatives of OCD patients compared to the relatives of psychiatrically assessed controls (10 vs. 1.9%) (Pauls *et al.* 1995).

There are two published segregation analyses of OCD. Nicolini *et al.* (1991) studied 24 families of probands with OCD and Cavalini *et al.* (1995, 1999) performed segregation analysis on families of 92 OCD probands. Nicolini *et al.* (1991) concluded that their family data are most consistent with a highly penetrant dominant major gene, although the affected phenotype under analysis included disorders other than OCD (hypothesized, but not tested, as aetiologically related to OCD). The segregation models were consistent with a gene or genes of major effect, although the mode of inheritance was not established. The findings of Cavalini *et al.* (1999), using a much larger sample and an analysis focused solely on OCD, were consistent with a complex genetic model which included a significant single major locus intermediate in nature (neither dominant nor recessive).

Most studies report a lack of association of candidate genetic variants with OCD (note that most of these used the relatively weak population-based design susceptible to population stratification artefacts), including one that examined the coding region of the tryptophan hydroxylase gene in OCD patients (Han *et al.* 1999). Another study, examining a functional variant of the catechol-O-methyltransferase (*COMT*) gene, found an association that was stronger in male than female OCD patients (Karayiorgou *et al.* 1997).

It is likely that the genetics of childhood onset OCD will be found to be closely related to the genetics of Tourette disorder. A number of studies have demonstrated increased rates of both OCD and tic disorders in first-degree relatives of probands with OCD (reviewed in Pauls & Alsobrook 1999), and also for relatives of probands with Tourette disorder (Pauls *et al.* 1991). Given this overlap, and the frequent comorbidity of tics and obsessive-compulsive symptoms, it is likely that what is 'transmitted' between generations is the OCD/Tourette disorder pattern, rather than a particular OCD subtype. In fact, Pauls *et al.* (1986, 1991) have hypothesized that the two disorders may not be separate, but rather are alternate expressions of the same genetic defect(s). However, a number of well-designed studies have failed to identify the gene(s) responsible. This may be caused, at least in part, by our lack of meaningful phenotypic separations. For example, the children in the PANDAS subgroup were found to have increased rates of familial OCD and tic disorders similar

to those reported for other paediatric samples (Lougee *et al.*, 2000), despite their presumed post-infectious aetiology. The families were also notable for increased rates of immunological disorders and rheumatic fever (unpublished data), suggesting that we can expect genetic heterogeneity within the early onset cases.

Serotonin and other neurotransmitters

The serotonergic hypothesis of OCD comes from the selective efficacy of drugs that have specific serotonergic activity (Insel *et al.* 1985), and challenge tests with metachlorophenylpiperazine (mCPP), a serotonergic agonist (Murphy *et al.* 1989; Pigott *et al.* 1991). Challenges with mCPP (Zohar *et al.* 1987, 1988; Pigott *et al.* 1991) show that OCD symptoms may be exacerbated by this serotonin agonist; metergoline, a serotonin antagonist, may protect against mCPP's behavioural effects (Pigott *et al.* 1991).

Medications that block serotonin reuptake, such as the selective serotonin reuptake inhibitors (SSRIs) fluoxetine, fluvoxamine, sertraline, paroxetine and citalopram, have been shown to be the most effective pharmacological treatments for OCD (see section on Drug Treatment). Clomipramine is a tricyclic antidepressant which is a *relatively* selective and potent inhibitor of active serotonin uptake in the brain (it also blocks histamine H₂-receptors, cholinergic and β-receptors, and has antidopaminergic properties). Its metabolite, desmethyl-clomipramine, also effectively blocks serotonin reuptake. The response of childhood OCD to clomipramine and not to the equally effective antidepressant desipramine (Leonard *et al.* 1989) indicates a remarkable specificity of effect for the serotonin uptake inhibitors for this condition. No unselected group of depressed patients, for example, would show such a differential response. Thus, the profile of drug response in OCD differs from that seen in depression or anxiety disorders which respond to a broad array of antidepressants and anti-anxiety agents and which highlight a unique role for serotonin blockers in this disorder.

Additional evidence for the serotonergic hypothesis is provided by several studies in children and adolescents with OCD. The first, conducted by Flament *et al.* (1985, 1987), demonstrated that response to clomipramine correlated with pretreatment platelet serotonin concentration. A high pretreatment level of serotonin was a strong predictor of clinical response and, within this sample, platelet serotonin concentrations were lower in the more severely ill patients. However, there were no differences in serotonin concentration from age- and sex-matched controls. A study of cerebrospinal fluid monoamines in 43 children and adolescents with OCD revealed that 5-hydroxyindole acetic acid, the major metabolite of serotonin, correlated most strongly with response to clomipramine therapy: the most successful responders had the highest levels of 5-hydroxyindole acetic acid in the cerebrospinal fluid (Swedo *et al.* 1992a). A more recent study, employing PET and serotonergic ligands, found evidence for decreased serotonin synthesis in

Table 35.3 Selected studies of cognitive-behaviour therapy for obsessive-compulsive disorder (OCD) in children and adolescents.

Study	<i>n</i>	Age range	Methods	Comments
Piacentini <i>et al.</i> (1994)	3	9–13	Psychoeducation for child and family Concurrent family sessions to disengage family from the OCD 10 2-h sessions weekly	All improved Gains maintained at 1 year follow-up
March <i>et al.</i> (1994)	15	8–18	Initial education re OCD as an illness Anxiety management training + ERP Parent training diaries	14 also on drug 10/15 had ≥50% improvement 3 non-responders
Scahill <i>et al.</i> (1996)	7	10–15	Visits 1–4 Self monitoring, triggering stimuli ranked, hierarchy established Visits 5–13 ERP (child selects provoking stimuli) Child and parent education weekly Families as cotherapists and informants	5/7 on drug All improved (30–90%) 14 sessions, mostly weekly Booster sessions within 6 months post-Rx
Wever & Rey (1997)	82	7–19	Training therapists Family/child workbook Family as cotherapist Modified to fit patient's cognitive/ developmental level Taped exposure to obsessions 10 sessions across 2 weeks, then monthly reviews across 6 months, then 6-monthly follow-ups	57 had combined treatment of which 22 (39%) weaned off drugs
Franklin <i>et al.</i> (1998)	14	10–17	Non-random assignment 7: weekly Rx over 4 months 7: 18 sessions over 1 month Parental involvement or individualized	8 on concurrent drugs 12/14 had 50% reduction in Y-BOC score Both weekly and daily sessions effective Maintained at 9 months follow-up

ERP, exposure with response prevention; Y-BOC, Yale–Brown Obsessive Compulsive Scale.

the ventral prefrontal cortex and caudate nucleus in treatment naïve OCD patients aged 8–13 years (Rosenberg *et al.* 1998). The latter study provides support for both the serotonergic hypothesis of OCD, and also for dysfunction within the basal ganglia–frontal cortex circuitry.

The serotonergic hypothesis is undoubtedly too simplistic to account for the complexity of OCD. If the defect were limited to serotonergic dysfunction, clomipramine and the SSRIs should be effective in eliminating symptoms in all patients; unfortunately, this is not the case. The medications are quite effective for many patients with OCD, but usually cause only partial symptom remission. Different patients also have different patterns of response, suggesting that the non-serotonergic properties of the medications may also have key roles, and that the antiobsessional effect may actually result from an alteration in the balance of serotonin and other monoamines, and/or changes in receptor functions (Murphy *et al.* 1989).

Other neurotransmitters

Dopaminergic dysfunction in OCD is suggested not only by the obsessive-compulsive symptoms in patients with basal ganglia disorders (Table 35.3), but also by the increase in obsessive-compulsive symptoms following high-dose stimulant administration (Frye & Arnold 1981), and occasional amelioration of symptoms following dopamine-blocking agents (Goodman *et al.* 1990; McDougle 1997). High-dose stimulant administration has been thought to result in simple stereotypies, rather than in more complex compulsive or obsessive behaviour; however, ‘compulsive’ symptoms following high-dose amfetamines have been observed in children with attention deficit disorder and hyperactivity (ADHD; Borcharding *et al.* 1990), particularly compulsive ritualization with high-dose *d*-amfetamine (1 mg/kg) and methylphenidate (2 mg/kg) administration. For example, a 7-year-old boy spent several hours each evening

vacuuming the carpet in his home, and another played with Lego blocks for 2 days, stopping only to eat and sleep. As in OCD, these children may become overly concerned with details and erase holes in their papers trying to get a single letter perfectly shaped. However, the obsessive-compulsive behaviours are not ego-dystonic in these stimulant-induced cases, leading to speculation that repetitive thoughts and behaviours (obsessions and compulsions) may result from dopaminergic overactivity and that serotonin dysregulation is required for ego dystonicity.

Tourette disorder and OCD may be at opposite ends of a spectrum of dopamine-serotonin disequilibrium. In Tourette disorder, dopaminergic overactivity overcomes serotonergic inhibition and results primarily in motor and vocal tics. By contrast, OCD is primarily a serotonergic defect. Here, a primary lack of serotonin results in an inability to inhibit normal dopaminergic activity and fixed action patterns (obsessions and compulsions) are inappropriately released. Ego dystonicity could then be related to the primary serotonin defect, or secondary to the loss of volitional control (Swedo & Rapoport 1990).

Neuroendocrine dysfunction

Although most OCD investigations concentrate on hormonal aberrations as secondary rather than primary to the disorder, case reports and anecdotal experience suggest that hormonal dysfunction and OCD may be aetiologically related (Swedo 1989). OCD symptoms often begin during early puberty, and some female patients experience an increase in obsessive thoughts and rituals immediately before their menses. Other hints at an influence of gonadal steroid on obsessive-compulsive symptomatology include the increased frequency of OCD during the post-partum period (Rasmussen & Eisen 1992), and reports of successful antiandrogen therapy for obsessive-compulsive symptoms (Casas *et al.* 1986). In the latter study, 5 out of 5 patients with OCD experienced a remission in their symptoms following treatment with cyproterone acetate, a potent antiandrogen. At the NIMH, two boys (ages 8 and 15) and a 14-year-old girl were treated with spironolactone, a peripheral antiandrogen particularly antitestosterone agent, and testolactone, a peripheral antioestrogen medication. All experienced a temporary reduction of obsessions and compulsions, but relapsed within 3–4 months (Salzberg & Swedo 1992).

Leckman *et al.* (1994) have suggested that oxytocin abnormalities may be involved in OCD, citing oxytocin-mediated mating behaviours in animals as a possible model (Leckman & Mayes 1999), and finding abnormal concentrations of oxytocin in cerebrospinal fluid oxytocin from a small group of children with OCD and tic disorders. In a larger group of 43 children and adolescents studied at the NIMH (Swedo *et al.* 1992a), cerebrospinal fluid oxytocin levels were not significantly correlated with OCD severity, but were correlated with depressive symptoms. Interestingly, arginine vasopressin concentrations were inversely related to OCD severity, and decreased following treatment with clomipramine (Altemus *et al.* 1994).

At present, there is not sufficient evidence to implicate hormonal dysfunction as a direct cause of OCD. However, some intriguing data build a circumstantial case for an association between OCD and growth hormone abnormalities, perhaps through the serotonergic system. In the epidemiological study of OCD in high school students cited earlier (Flament *et al.* 1988), males with OCD were noted to be smaller and lighter than the community normal controls and males with other psychiatric illnesses (Hamburger *et al.* 1989). There were no differences in the size of females with and without OCD. The small size of the OCD males could result from an effective lack of growth hormone, or from a delay in the pubertal growth spurt, although no causality is demonstrated by the relationship. To address the issue of causality, future studies might employ direct assays, hormonal challenges or therapeutic interventions.

Treatment approaches

Family education

Treatment begins with family education about the disorder. Parents need guidance about how to handle their child's behaviours, which may be severely disruptive to family life, and how to avoid punitive responses or the alternative 'enabling' that happens when families become enmeshed in rituals. Suggested readings for families include *OCD in Children and Adolescents: a Cognitive-Behavioural Treatment Manual* (March & Mulle 1998), which is commonly used by practitioners in the USA and other countries. (The original version of this manual was entitled *How I Ran OCD Off My Land.*)

In Europe, as well as in the USA, various OCD patient groups provide information, advocacy for services, and support for both patients and parents. The groups also provide children with an opportunity to meet others with OCD, which is important in dispelling the sense that the child is the 'only one' affected by the disorder. Over the past decade, support groups have added considerably to the care of OCD and should be considered for all cases. For a model support group, see Black & Blum (1992). In the USA, the Obsessive-Compulsive Foundation (North Branford, CT) provides such information and support. On the Internet, www.ocdresource.com is a useful source of information about the disorder, including community resources and lists of relevant publications.

School

Certain perfectionistic and repeating rituals may impair school performance. For example, the need to form letters or numbers 'perfectly' or a compulsion to reread sentences or entire paragraphs may stop the child from completing assignments. In some cases, special arrangements with the school need to be made, such as allowing the child untimed tests or doing alternate projects (Shafron 1998). Occasionally, teachers may be helpful in the child's behavioural programme.

Choosing a therapy

In adults, behavioural and drug treatments have been shown to be effective for OCD, both singly and in combination. Several excellent reviews have been published recently for both behavioural treatment (Marks 1997) and drug therapy (Pato *et al.* 1998; Pigott & Seay 1999). Behavioural treatment is now being used successfully in children (March 1995; Shafron 1998), although drug treatment remains more commonly used (DeVane & Sallee 1996; Emslie *et al.* 1999).

The choice of first-line treatment will depend on the symptom pattern and severity, as well as the patient and family's preference. Whatever is tried, it is important to urge flexibility, as a combination of drug and behavioural treatment may be needed (Greist 1996; Park *et al.* 1997; Wever & Rey 1997; O'Connor *et al.* 1999; see Rapoport & Inoff-Germain 2000 for review).

Cognitive-behavioural therapy

Since an earlier review (Wolff & Rapoport 1988), there have been extensive reports on how to adapt these techniques to paediatric OCD populations. These are summarized in Table 35.3, and are discussed in relevant sections of the text.

CBT for OCD encompasses three treatment types:

- 1 exposure and response prevention (ERP);
- 2 cognitive therapy, and
- 3 relaxation training.

Of the three, ERP is in the forefront for effectiveness in symptom reduction (Baer & Greist 1997; Shafron 1998). Cognitive therapy (e.g. changing false beliefs regarding risk and responsibility, challenging the reality of obsessions and the necessity for compulsions; Emmelkamp & Beens 1991) is generally viewed as ineffective as a *sole* treatment for OCD, although it may be helpful in individual cases and if it encourages exposure in a broader CBT programme (Shafron & Somers 1998). Relaxation therapy is used mainly to manage affect during exposure (March 1995) but it has no direct benefits for the obsessive-compulsive symptoms.

ERP for OCD was developed in adults, and the methodology is still undergoing regular refinement (March 1995; Greist 1996). It involves:

- 1 daily exposure to cues avoided because of their inducing discomfort and rituals; and
- 2 maintaining exposure and not ritualizing for at least an hour or until the discomfort slowly subsides.

A minimal trial consists of 10–20 h of treatment with ERP (Baer & Greist 1997), with *in vivo* (as opposed to fantasy) exposure being optimal (Foa *et al.* 1985). Although gains from ERP persist beyond its discontinuation, booster treatment may help for long-term progress, and additional treatment may be needed for migration of symptoms and for lapses brought on by stress (Greist 1996).

Because most clinicians are not trained in behavioural treatment and because of its expense, interactive computer-administered self-assessment and self-help programmes for

behaviour therapy (e.g. BT-STEPS; Baer & Greist 1997) may be useful (see also Clark *et al.* 1998 for a pilot study of computer-assisted ERP in adults) as it can be used by anyone having a touch telephone. No report of computer-assisted ERP with adolescents has yet appeared but, for some, this could be a particularly promising approach.

ERP has been adapted for use with children, and appears to confer similar benefits in the paediatric population as in adults (March 1995; Greist 1996; Marks 1997; King *et al.* 1998; March & Mulle 1998; Shafron 1998). The child's ability to understand the treatment and tolerate the intensity of affect are important considerations (Shafron 1998). Programmes that help the child to externalize the OCD help to empower the child and decrease his or her anxiety, as does allowing the child control over the gradient for exposure to anxiety-provoking stimuli (see March & Mulle 1998 for more details).

CBT must be tailored to specific symptoms; for example, ERP is not generally appropriate for scrupulosity and moral guilt or pathological doubt, where cognitive therapy may be helpful. Contamination fears, symmetry rituals, counting/repeating, hoarding, and aggressive urges are more amenable to ERP. Obsessional slowness appears not to respond well to either behavioural or pharmacotherapy (Wolff & Rapoport 1988). Pure obsessions are also difficult to treat with CBT, although cognitive therapy strategies that help the adolescent patient obtain benign interpretations of intrusive thoughts may be useful (Shafron & Somers 1998).

Although none of the behavioural studies described above is truly systematic and controlled, they provided sufficient evidence (March *et al.* 1994) to justify a comprehensive study of the effectiveness of CBT in paediatric OCD populations. An ongoing random-assignment collaborative treatment trial being carried out by Drs Edna B. Foa (University of Pennsylvania, PA, USA) and John March (Duke University, NC, USA) comparing CBT, drug therapy, their combination, and placebo, is now in its third year. Importantly, there will be a sizeable group without concurrent drug treatment, and outcome ratings are 'blind' to treatment condition. These data will be essential for guiding future treatment in children with OCD.

Drug treatment

The recent attention of psychiatry to drug treatment of OCD is unique in that much of the early work was carried out with children (Rapoport 1998). Subsequent adult studies demonstrated the utility of a variety of serotonergic agents for OCD. Although the paediatric trials of SSRIs have lagged behind those in adults, there is now extensive substantiation of the utility of pharmacotherapy in paediatric patients (see also Heyman & Santosh, Chapter 59).

An initial trial of a serotonin reuptake inhibitor (SRI), most often an SSRI, is the treatment of choice. If there is no or only partial response to an SSRI at 10–12 weeks, another SSRI may be tried. In adults, augmentation with other agents is effective in

Table 35.4 Pharmacological treatment for obsessive-compulsive disorder.

Drug	Adult dosage	Child/adolescent dosage from controlled study (or best available information)	Duration (weeks)
<i>First-line agents</i>			
Clomipramine	Up to 250 mg/day	Up to 150–200 mg/day* (3 mg/kg upper limit)	>10
Fluoxetine	Up to 100 mg/day	20 mg/day†	>10
Fluvoxamine	Up to 300 mg/day	Up to 200 mg/day‡	>10
Sertraline	Up to 200 mg/day	Up to 200 mg/day§	>10
Paroxetine	Up to 60 mg/day	Not known¶	>10
<i>Augmenting agents</i>			
Clonazepam	Up to 5 mg/day	Not known	>4
Haloperidol	Up to 3 mg/day	(Up to 2 mg/day)**	>3
Risperidone	(0.5–2.0 mg/day)	(1.5–2.5 mg/day)††	?

partial responders, and some reports suggest augmentors are also useful for children.

Serotonin reuptake inhibitors

Clomipramine was the first SRI antidepressant shown to be effective for OCD, with subsequent controlled trials documenting antiobsessional effects of the SSRIs—in order of increasing selectivity), fluoxetine, fluvoxamine, sertraline and paroxetine. All have been studied in multicentre double-blind trials in adults (Pigott & Seay 1999). Citalopram has been found to be effective for OCD in adults (Montgomery *et al.* 2001), but this is not yet a labelled indication. Controlled trials with children have been carried out for clomipramine, fluoxetine, fluvoxamine and sertraline (Table 35.4). Although the comparable study of paroxetine in children is still in progress, uncontrolled reports are also positive (Emslie *et al.* 1999).

Table 35.4 gives the dosage range of SRIs for adults, the most systematically obtained dosage data for children, and the recommended duration for a treatment trial. Low initial doses, with slow upward titration, are the rule. Patients should be told that trials of more than one agent may be needed, and the possibility of augmenting agents also should be suggested early. Not only may it be necessary to switch from one serotonin inhibitor to another, but combinations of SRIs seem to help counterbalance differing adverse effects, although no systematic studies are available to document this widely held clinical belief (see below).

Augmenting strategies for partial responders

Up to 50% of child (and adult) cases show no or only partial response to initial SRI treatment, even if two different SRIs are used (Geller *et al.* 1998). Because of this, a variety of treatment modifications and augmentation strategies have evolved (see Rasmussen & Eisen 1997 for a review).

Augmentation of SRIs with other agents

There have been no randomized allocation trials of the utility of augmentation strategies for paediatric OCD. However, based on positive results in adult patients, augmentation of an SRI might be considered for paediatric patients with a partial response or intolerance to higher doses. In adults, two agents, clonazepam (Pigott *et al.* 1992) and haloperidol (McDougle *et al.* 1994) have been shown effective in controlled augmentation trials (see McDougle 1997 for a review).

Clonazepam is a benzodiazepine with anxiolytic properties and serotonergic effects (Pigott *et al.* 1992; Park *et al.* 1997; March & Leonard 1998). Clonazepam augmentation in childhood onset OCD has been described for a patient with onset of OCD symptoms at age 7 years but who, other than psychotherapy, had no treatment for OCD until age 14 (Leonard *et al.* 1994). A variety of drug treatments, including buspirone augmentation, had been tried. At age 20, clonazepam (at dosage gradually increasing to 6 mg/day) was instituted as an augmentor to fluoxetine (60 mg/day). Dramatic reduction in symptom severity was reported within 1 month and was maintained by 4 mg/day, as evaluated 1 year later.

Neuroleptic augmentation has been shown to be particularly useful in cases with comorbid tic disorders. *Haloperidol* has been reported to have significant benefits as an augmentor for adult patients with tics or a family history of tics (McDougle *et al.* 1994). Paediatric experience with haloperidol has been limited in OCD, although it is used frequently in children and adolescents with tic disorders. Because of the long-term risks of neuroleptics administration, these should only be considered if atypical antipsychotics, such as risperidone, are ineffective.

Two controlled trials have documented the utility of *risperidone augmentation* of SSRIs among adult refractory OCD patients (McDougle *et al.* 1995; Ravizza *et al.* 1996). Risperidone augmentation in paediatric OCD requires further study (Mandoki 1995). However, risperidone was used in an 11-week open trial (Lombroso *et al.* 1995) for treatment of Tourette Disorder (TD) tics in seven children and adolescents, three of whom also had OCD. One of these three had a 100% decrease in her OCD symptom severity—as measured by her endpoint Children's Yale–Brown Obsessive Compulsive Scale (CY-BOCS) score, compared to baseline—the other two had slight but not significant improvements. These three (ages: 12, 13 and 16) were given a SRI and risperidone (1.5–2.5 mg/day). The risperidone was added to their concurrent SRI at 0.5 mg orally at bedtime, with scheduled increases of 0.5 mg every 5 days as tolerated, up to a maximum of 2.5 mg/day in divided doses. The maintenance dose was generally achieved by 3 weeks and given on a twice-daily schedule. Weight gain ranging from 3.5 to 6.5 kg occurred in all patients.

Addition of a second concurrent SRI has been used as an augmenting strategy in adults (Ravizza *et al.* 1998) and, to a limited extent, in children. In an open treatment trial of six adolescents (Simeon *et al.* 1990), combined fluoxetine and clomipramine allowed lower dosage of both medicines and produced fewer side-effects. Figueroa *et al.* (1998) described an open series of seven patients, aged 9–23, given clomipramine and either fluoxetine, sertraline, fluvoxamine or paroxetine and followed through 5–22 months. Combination therapy appeared more effective than monotherapy for all cases, but double-blind controlled studies are needed.

Maintenance treatment

OCD is often chronic and long-term maintenance is to be anticipated. For example, in a 9–14 year follow-up study of 15 cases initially treated for OCD in adolescence (primarily with behaviour and family therapy), 43% still met diagnostic criteria for OCD (Bolton *et al.* 1995). In adults, long-term improvement is maintained on drugs and lower doses may suffice (Ravizza *et al.* 1998). For such patients, drug discontinuation leads to relapse in 80% of cases at 2-year follow-up (Dolberg *et al.* 1996). However, concomitant CBT may lead to medication discontinuation for some patients (Stanley & Turner 1995; Wever & Rey 1997).

In children, the need for long-term maintenance was documented by an 8-month study of 26 children and adolescents with

severe OCD who had received clomipramine for a mean of 17.1 months (Leonard *et al.* 1991); a 2-month double-blind desipramine substitution resulted in 89% of the substituted (vs. 18% of the non-substituted) subjects relapsing during the substitution phase.

When discontinuation is attempted, tapering should be gradual, usually over several weeks. Long-term (indefinite) drug maintenance is suggested after 2–4 relapses.

Adverse effects of drug treatment

The SSRIs are recommended over clomipramine because of the anticholinergic, cardiovascular, sexual and sedative effects of the tricyclic. Clomipramine may be helpful when a tricyclic antidepressant may benefit other psychiatric comorbidities, and it is also less likely than SSRIs to cause insomnia, akathisia, nausea or diarrhoea (March & Leonard 1998; Riddle 1998; Thomsen 1998). Because clomipramine has the potential for tricyclic antidepressant (TCA)-related cardiotoxic effects, monitoring is recommended (Geller *et al.* 1999).

The side-effects of SSRIs are generally well-tolerated, and include drowsiness or insomnia, nausea, weight gain, agitation and a host of less common events that should be reviewed with the patient and family. While most adverse events occur within the first months of treatment, they can occur at any time. It is important for the family to be aware of this so that they remain vigilant to potentially adverse effects of the medications.

For excellent reviews on the safety of SRIs see:

Clomipramine (DeVaugh-Geiss *et al.* 1992; Geller *et al.* 1999)
Fluoxetine (Riddle *et al.* 1992; Geller *et al.* 1995)
Fluvoxamine (Riddle *et al.* 1996; Goodman *et al.* 1997)
Sertraline (March *et al.* 1998; Alderman *et al.* 1996, 1998)
Paroxetine (Gunasekara *et al.* 1998).

Augmenting agents

There is concern over dependency on clonazepam, although at the low dosage used (see Table 35.2), this is rare. While haloperidol raises the concern of risk for tardive dyskinesia, the very low dosage (often as low as 0.5 mg/day) and yearly 6-week drug holidays reduce this risk. Atypical agents, such as risperidone, may not be quite as effective augmenting agents for OCD and have their own risks of drowsiness and weight gain (Lombroso *et al.* 1995). In paediatric cases, risperidone may be more likely to cause dystonic reactions (Lombroso *et al.* 1995).

Drug treatment and comorbidities

Mania

SSRIs can appear to trigger manic symptoms in adults (Berk *et al.* 1996) and children (Go *et al.* 1998; Diller & Avci 1999) treated for OCD. Alternately, a subgroup of OCD cases may be 'prebipolar', independent of drug treatment. Additional investigation is needed to understand when such cases reflect

drug effects or the unmasking of underlying bipolar mood disorder (Berk *et al.* 1996).

Attention deficit hyperactivity disorder

The high rate of comorbid ADHD means that stimulant drug treatment may be ongoing during OCD treatment. There is some evidence that stimulants may have an adverse effect on OCD (Joffe *et al.* 1991), even triggering some compulsive or ritualistic behaviours (Borcherding *et al.* 1990). Thus, stimulants should be used with caution, and only in cases where other treatments for the ADHD symptoms are not indicated.

Psychosis

Patients with schizophrenia being treated with clozapine (Baker *et al.* 1992) or risperidone (see Saxena *et al.* 1996 and SRI augmentation section above) may have exacerbation of OCD; addition of typical neuroleptics may alleviate this complication (Baker *et al.* 1992; Patel & Tandon 1993).

Tic disorders

Tic disorders will often necessitate trials of dopamine-blocking agents. However, these may worsen anxiety symptoms (Blin 1999) and will have to be discontinued. The data on clonidine, which would be a logical alternative, are mixed (Hollander *et al.* 1991; Hewlett *et al.* 1992).

Substance abuse

OCD may be either worsened or alleviated by drugs of abuse and alcohol (Delgado & Moreno 1998; Crum & Anthony 1993; Burke *et al.* 1994; Fals-Stewart & Angarano 1994; Bolla *et al.* 1998). Where suspected or when the patient is non-responsive, substance abuse should be considered and may need to be the prime target of treatment.

Investigative treatments

Tramadol: an opioid agonist

Recent research suggests that OCD may be, in part, mediated by the opioid system (Insel & Pickar 1983; Shapira *et al.* 1997). Because the opioid antagonist naloxone exacerbates OCD in some patients, an open trial of the opioid agonist tramadol was carried out for seven treatment-refractory adult OCD patients (with a variety of comorbidities including tics or TD) (Shapira *et al.* 1997). Six of the seven cases completed at least 2 weeks of treatment, with mean dosage of 25 mg/day tramadol (in 3–4 divided doses), and all six reported a diminution in obsessive thoughts and in the urge to perform their compulsions. One, who had a history of panic attacks, discontinued medication during week 6 after experiencing a panic attack. The dose-limiting side-effect was sedation, but the drug was generally

well tolerated in this small group of adult patients. There are no paediatric data available. It is interesting that although the primary action of tramadol is as an opioid agonist, it also inhibits the reuptake of norepinephrine and serotonin, which may contribute to its effectiveness in OCD. If the results of the Shapira *et al.*'s (1997) trial are replicated, and the mechanism of action is shown to be distinct from the SRIs, tramadol may prove valuable for use in OCD.

Intravenous clomipramine

Recent research in adults (Sallee *et al.* 1997, 1998) including one placebo controlled study (Fallon *et al.* 1998) indicates that intravenous administration both speeds initial response and converts non-responders. Oral maintenance is still required. The hypothesized mechanism involves the greater bioavailability of the more serotonergic parent compound clomipramine vs. the more noradrenergic metabolite desmethylclomipramine, as a result of bypassing first-pass hepatoenteric metabolism.

In children, there have been a few small open trials of intravenous clomipramine use in adolescents with depression, or depression and OCD. In the first study, three of the five cases (age range 16–19 years) studied had OCD as well as major depressive disorder, and parenteral clomipramine infusions of up to 200 mg/dose (1 mg/min) were administered without major adverse incident (Sallee *et al.* 1989). One patient terminated the infusion as a result of nausea and vomiting. Two others had nausea after an initial 75 mg test dose during the first 15–20 min of infusion, but not during the second infusion (on night 2) of 200 mg. Drowsiness and sedation up to 18 h later were also reported. In addition to amelioration of depression, the three with concurrent OCD had an immediate decrease in obsessive-compulsive symptoms. Follow-up at 6 months (on 350 mg/day clomipramine) showed continued amelioration of OCD symptoms and no signs of depression.

In a later controlled trial, two of 16 adolescents had OCD among their comorbidities; one of these was in the single-dose 200 mg intravenous clomipramine treatment group. This case showed a decrease in depression and a 50% decrease in Y-BOCS score by the sixth day (Sallee *et al.* 1997). These reports justify systematic paediatric studies of intravenous clomipramine; however, at present, the treatment remains experimental.

Immunomodulatory therapies

For the PANDAS subgroup, the aetiology of the OCD symptoms is presumed to be related to inflammation in the basal ganglia. This postulate led to a trial of two immunomodulatory agents: intravenous immunoglobulin (IVIG) and plasma exchange (PEX) for severe acutely ill children with streptococcal-triggered OCD and tic disorders (Perlmutter *et al.* 1999). A total of 29 children (age 5–14) received IVIG ($n=9$), PEX ($n=10$), or placebo IVIG ($n=10$). At both 1 and 12 months after therapy, the results indicated striking and sustained improvement on active treatment, with virtually no placebo effect. In some cases,

these improvements were paralleled by reduction in basal ganglia volume (Giedd *et al.* 2000). While these results are exciting, they await replication before being recommended as standard therapy for severely ill children in the PANDAS subgroup. Further, it should be noted that PEX produced no improvements in a group of five children and adolescents with chronic treatment-refractory OCD with *no* evidence of post-streptococcal exacerbation (Nicholson *et al.* 2000). Clearly, the immunomodulatory therapies will not be useful in all cases of childhood onset OCD, and it is unclear how many children belong in the PANDAS subgroup.

At present, the PANDAS subgroup is defined by clinical criteria—no biological markers have been identified that can reliably distinguish children with post-streptococcal OCD or tic disorders. The children in the PANDAS subgroup have an abrupt prepubertal onset of symptoms; the acuity of onset and symptom exacerbations is in striking contrast to the typical OCD patient's gradual onset and waxing and waning symptom course. Because medical records often fail to document a relationship between the neuropsychiatric symptom exacerbations and streptococcal infections, it is often necessary to follow a child for several months to determine whether or not he or she is a member of the PANDAS subgroup. The observation period should reveal that symptom relapses follow bouts of streptococcal pharyngitis or scarlet fever (or are associated with rising anti-streptococcal titres) and that symptom remissions occur during intervals of streptococcal negativity. Thus, in theory, prevention of these infections should result in a decrease in antineuronal antibody titres, and a gradual improvement in neuropsychiatric symptom severity. This hypothesis led to a trial of penicillin prophylaxis, similar to that used for prevention of rheumatic fever recrudescences (Garvey *et al.* 1999). The pilot study with oral penicillin V-K (250 mg orally twice daily) failed to achieve an adequate level of streptococcal prophylaxis and was therefore inconclusive. However, for individual subjects who were adequately protected against streptococcal infections, some benefits of penicillin therapy were observed. These findings warrant further investigation but, at the present time, there is no justification for the use of penicillin prophylaxis. In fact, because a number of asymptomatic infections were documented during the pilot study, it is possible that prophylaxis might worsen neuropsychiatric symptoms by masking symptoms of pharyngitis and preventing appropriate diagnosis and treatment of the streptococcal infection.

Transcranial magnetic stimulation

Transcranial magnetic stimulation (TMS), involving non-invasive and focal stimulation of the brain, uses powerful magnetic fields to alter brain activity. It is a promising research tool and therapeutic agent for a variety of disorders involving mood and anxiety (George *et al.* 1999). In adult OCD patients (Greenberg *et al.* 1997; Cora-Locatelli *et al.* 1998), a single session of right prefrontal repetitive TMS (rTMS) decreased compulsive urges for 8 h (Greenberg & Rauch, *in press*). Long-term use has

not yet been investigated. TMS has also not been applied to treatment refractory cases, and there are no data for children, but the preliminary data are of sufficient interest to warrant further studies.

Conclusions

In recent years, great progress has been made in the recognition and treatment of childhood onset OCD. Structured instruments, such as the CY-BOCS, allow for the accurate diagnosis of this once hidden disorder. SSRI and behaviour therapy techniques (particularly ERP), provide relief from both compulsive rituals and obsessional anxiety. Advances in neuroimaging and neurophysiological technologies have opened new vistas for understanding the biological basis of OCD, while increased knowledge of the genetics of the disorder and novel pathophysiological models hold promise for the development of better strategies for treatment and prevention of OCD. Until that time, it is important to maximize the recognition and treatment of this troublesome disorder by educating parents and primary care physicians about the symptoms of OCD, and mental health professionals about the wide range of effective therapies.

Introduction

Tic disorders are transient or chronic conditions associated with difficulties in self-esteem, family life, social acceptance or school or job performance that are directly related to the presence of motor and/or phonic tics. Although tic symptoms have been reported since antiquity, systematic study of individuals with tic disorders dates only from the nineteenth century with the reports of Itard (1825) and Gilles de la Tourette (1885). Gilles de la Tourette, in his classic study, described nine cases characterized by motor ‘incoordinations’ or tics, ‘inarticulate shouts accompanied by articulated words with echolalia and coprolalia’ (Gilles de la Tourette 1885). In addition to identifying the cardinal features of severe tic disorders, his report noted an association between tic disorders and obsessive-compulsive symptoms as well as the hereditary nature of the syndrome in some families. Recently, Kushner (1999) has published a compelling account of the many ‘histories’ of tic disorders.

In addition to tics, individuals with tic disorders may present with a broad array of behavioural difficulties including disinhibited speech or conduct, impulsivity, distractibility, motoric hyperactivity and obsessive-compulsive symptoms (Leckman & Cohen 1998). Alternatively, a sizeable portion of children and adolescents with tics will be free of coexisting developmental or emotional difficulties. Scientific opinion has been divided on how broadly to conceive the spectrum of maladaptive behaviours associated with Tourette syndrome (Comings 1988; Shapiro *et al.* 1988). This controversy is fuelled in part by the genuine frustration that parents and educators encounter when they attempt to divide an individual child’s repertoire of problem behaviours into those that are ‘Tourette-related’ and those that are not. Population-based epidemiological studies and family genetic studies have begun to clarify these issues, but much work remains to be done.

In this chapter, a presentation of the phenomenology and classification of tic disorders precedes a review of the aetiology, neurobiological substrates, assessment and management of these conditions. The general perspective that will be presented is that Tourette syndrome and related disorders are model neurobiological disorders in which to study multiple interactive genetic and environmental (epigenetic) mechanisms that interact over the course of development to produce a distinctive range of complex syndromes of varying severity.

Definitions and classifications

Phenomenology of tics

A tic is a sudden repetitive movement, gesture or utterance that typically mimics some aspect or fragment of normal behaviour. Usually of brief duration, individual tics rarely last more than a second. Many tics tend to occur in bouts with brief inter-tic intervals (Peterson & Leckman 1998). Individual tics can occur singly or together in an orchestrated pattern. They vary in their intensity or forcefulness. Motor tics vary from simple abrupt movements, such as eye blinking, head jerks or shoulder shrugs, to more complex purposive-appearing behaviours, such as facial expressions or gestures of the arms or head. In extreme cases, these movements can be obscene (copropraxia) or self-injurious, e.g. hitting or biting. Phonic or vocal tics can range from simple throat-clearing sounds to more complex vocalizations and speech. In severe cases, coprolalia (obscene or socially unacceptable speech) is present.

By the age of 10 years, most individuals with tics are aware of premonitory urges that may be experienced either as a focal perception in a particular body region where the tic is about to occur (like an itch or a tickling sensation) or as a generalized awareness felt throughout the body (Lange 1991; Leckman *et al.* 1993). Most patients also report a fleeting sense of relief after a bout of tics has occurred. These premonitory and consummatory phenomena contribute to an individual’s sense that tics are a habitual, yet partially intentional, response to unpleasant sensory stimuli. Indeed, most adolescent and adult subjects describe their tics either as ‘voluntary’ or as having both voluntary and involuntary aspects. In contrast, many young children are oblivious to their tics and experience them as wholly involuntary movements or sounds. Most tics can also be suppressed for brief periods of time. The warning given by premonitory urges may contribute to this phenomenon.

Clinicians characterize tics by their anatomical location, number, frequency and duration. The intensity or ‘forcefulness’ of the tic can also be an important characteristic as some tics call attention to themselves simply by virtue of the exaggerated fashion in which they are performed or uttered. Finally, tics vary in terms of their ‘complexity.’ Complexity usually refers to how simple or involved a movement or sound is, ranging from brief meaningless abrupt fragments (simple tics) to ones that are longer more involved and seemingly more goal-directed in character (complex tics). Each of these elements has been

incorporated into clinician rating scales that have proven to be useful in monitoring tic severity (Leckman *et al.* 1989).

Diagnostic categories

Diagnostic categories can be useful to families, educators and other professionals. They provide a common basis for discussion and are an essential tool in epidemiological and clinical research. Several widely used diagnostic classifications currently include sections on tic disorders. These include both the DSM-IV classification system published by the American Psychiatric Association (1994) and the ICD-10 criteria by the World Health Organization (1996). A third classification system, the Classification of Tic Disorders (CTD), has been offered by the Tourette Syndrome Classification Study Group (1993). Although clear differences exist when comparing these classification schemes, they are broadly congruent with each containing three major well-specified categories:

- 1 Tourette syndrome or its equivalent;
- 2 chronic motor or vocal tic disorder or its equivalent; and
- 3 transient tic disorder or its equivalent.

Current classification of tic disorders in ICD-10 includes transient tic disorder (F95.0), chronic motor or vocal tic disorder (F95.1), combined vocal and multiple tic disorder (Tourette syndrome) (F95.2) and residual categories (F95.8 and F95.9). The ICD-10 diagnostic descriptions are largely based on the diagnostic criteria contained in DSM-IV. The ICD-10 descriptions focus on the phenomenology and natural history of the disorder and are readily applied in clinical settings. Objections can be raised to the statement contained in the description of Tourette syndrome that ‘tics disappear during sleep’. Based on several empirical studies, it appears that although tics are diminished during the sleep of children and adolescents with Tourette syndrome, they do not disappear (Glaze *et al.* 1983; Jankovic & Rohaidy 1987). The statement that ‘symptoms [tics] frequently worsen during adolescence’, is not well supported by empirical data (Leckman *et al.* 1998a). The ICD-10 description of Tourette syndrome also overlooks the frequent presence of premonitory urges, the bout-like occurrence of tics, the waxing and waning character of the disorder (with variations in the repertoire of tics occurring over weeks to months), and the usual amelioration of the condition that occurs during mid- to late adolescence and early adulthood.

With the publication of DSM-IV in 1994, a notable difference between the CTD and DSM classification schemes emerged: the DSM-IV requirement that the tic symptoms need to ‘cause marked distress or significant impairment in social, occupational or other important areas of functioning’. This criterion is based on a conceptualization of mental disorder articulated by the framers of the DSM-IV and was intended to distinguish between normality and pathology. Unfortunately, in the case of tic disorders, this criterion is vague and open to varying interpretation. The DSM-IV text is currently under revision and the impairment criterion has been dropped. With this change,

less controversy will exist about who has Tourette syndrome, and individuals who have adjusted well to the presence of tics can still be considered to have the diagnosis even if their symptoms are not a major source of distress.

At present, the CTD is a rarely used system that emphasizes whether or not the tic symptoms in question have been ‘witnessed by a reliable observer directly...or recorded by videotape or cinematography’. Other differences include the retention of an age of onset of 21 years or less. However, until more objective diagnostic tests are developed, differences among clinical experts are likely to persist.

To minimize error in case ascertainment and produce an instrument measuring lifetime likelihood of having had Tourette syndrome, clinical members of the American Tourette Syndrome Association International Genetic Collaboration have developed the Diagnostic Confidence Index (DCI) (Robertson *et al.* 1999). The DCI produces a score from 0 to 100 that is a measure of the likelihood of having or ever having had Tourette syndrome. However, the DCI, together with the ICD-10, DSM-IV and CTD diagnostic groupings, suffer from uncertainties on how best to categorize conditions that potentially encompass a broad range of symptoms that wax and wane in severity. As the current nosological boundaries are set by convention and clinical practice, they may not reflect true aetiological differences.

Prevalence

Transient tic behaviours are commonplace among children. Community surveys indicate that 1–13% of boys and 1–11% of girls manifest ‘frequent ‘tics, twitches, mannerisms or habit spasms’’ (see Zohar *et al.* 1998 for a review). The instability of these estimates are in part because of the wording of items on symptom inventories, the identity of the informant and the demographic characteristics of the sample studied. Children between the ages of 7 and 11 years appear to have the highest estimated prevalence rates that are in the range of 5%. Indeed, children are 5–12 times more likely to be identified as having a tic disorder than adults (Burd *et al.* 1986a,b). Although boys are more commonly affected with tic behaviours than girls, the male:female ratio in most community surveys is less than 2:1. For example, in the Isle of Wight study of 10–11 year olds, approximately 6% of boys and 3% of girls were reported by their parents to have ‘twitches, mannerisms, tics of face or body’ (Rutter *et al.* 1970). Similar estimates have been reported from Quebec and from North Carolina (Costello *et al.* 1996; Breton *et al.* 1999). Urban living may be associated with elevated rates (Rutter *et al.* 1974). Although most reports on tics have come from European, American and Asian sources, race and socioeconomic status have not been shown to influence the point prevalence of tics.

Less is known concerning the prevalence of Tourette syndrome. Once thought to be rare, current estimates vary 100-

fold, from 2.9 in 10 000 (Caine *et al.* 1988) to 299 in 10 000 (Mason *et al.* 1998). In the largest study to date, Apter *et al.* (1993) have reported a prevalence rate of 4.5 in 10 000 for full-blown Tourette syndrome among 16–17 year olds in Israel. Using a similar design, Costello *et al.* (1996) examined 4500 children aged 9, 11 and 13 years in rural North Carolina. The children were directly examined, as was one parent and both were asked about the last 3 months. Altogether, 10 in 10 000 children met criteria for Tourette syndrome: 13 in 10 000 for boys, and 7 in 10 000 for girls.

More recently, Mason *et al.* (1998) completed a study of all pupils aged 13–14 years in a mainstream secondary school in the UK. Students were investigated using a two-stage procedure employing standardized questionnaires completed by parents, teachers and pupils. Trained personnel to identify tics carried out classroom observations. Those pupils identified as having tics underwent a semistructured interview to determine whether they had Tourette syndrome. Five subjects were identified as having Tourette syndrome, yielding a prevalence estimate of 299 in 10 000 pupils in this age group. The results of this study suggest that Tourette syndrome in the community as a whole is more common and milder than earlier population-based studies would suggest.

Clinical descriptions and natural history

With the exception of Tourette syndrome (Shapiro *et al.* 1988; Goetz *et al.* 1992; Leckman *et al.* 1998a) relatively few cross-sectional or longitudinal studies of tic disorders have been performed so that most of the information provided below is based on clinical experience and anecdotal reports.

Transient tic disorder

Almost invariably a disorder of childhood, transient tic disorder is usually characterized by one or more simple motor tics that wax and wane in severity over weeks to months. The anatomical distribution of these tics is usually confined to the eyes, face, neck or upper extremities. Transient phonic tics, in the absence of motor tics, can also occur, although more rarely. The age of onset is typically 3–10 years and boys are at greater risk. The initial presentation may be unnoticed. If medical consultation is sought, GPs, paediatricians, allergists and ophthalmologists are typically the first to see the child. Missed diagnoses are common, particularly as the symptoms may have completely disappeared by the time of the consultation. As prescribed by the prevailing diagnostic criteria, the subsequent natural history of this condition is limited to fewer than 12 consecutive months of active symptomatology. As such, this is often a retrospective diagnosis as the clinician is unable to know with certainty which children will show progression of their symptoms and which children will display a self-limiting course.

Chronic motor or vocal tic disorder

This chronic condition can be observed among children and adults. As with other tic disorders, it is characterized by a waxing and waning course and a broad range of severity. Chronic simple and complex motor tics are the most common manifestations. Most tics involve the eyes, face, head, neck and upper extremities. Although some children may display other developmental difficulties, such as attention deficit hyperactivity disorder (ADHD), the disorder is not incompatible with an otherwise normal course of childhood. This condition can also appear as a residual state, particularly in adulthood. In such instances, a predictable repertoire of tic symptoms may only be seen during periods of heightened stress or fatigue.

Chronic vocal tic disorder, by all accounts, is a rare condition. Some authors exclude ‘chronic cough of adolescence’ from this category (Shapiro *et al.* 1988).

Tourette syndrome

The most severe tic disorder is best known by the eponym, Gilles de la Tourette syndrome. Typically, the disorder begins in early childhood with transient bouts of simple motor tics, such as eye blinking or head jerks. These tics may initially come and go, but eventually they become persistent and begin to have adverse effects on the child and his or her family. The repertoire of motor tics can be vast, incorporating virtually any voluntary movement by any portion of the body. Although some patients have a ‘rostral–caudal’ progression of motor tics (head, neck, shoulders, arms, torso), this course is not predictable. As the syndrome develops, complex motor tics may appear which typically accompany simple motor tics. Often they have a ‘camouflaged’ or purposive appearance, e.g. brushing hair away from the face with an arm, and can only be distinguished as tics by their repetitive character. They can involve dystonic movements. In a small fraction of cases (<5%), complex motor tics have the potential to be self-injurious and to further complicate management. These self-injurious symptoms may be relatively mild, e.g. slapping or tapping, or quite dangerous, e.g. punching one side of the face, biting a wrist or gouging eyes to the point of blindness.

On average, phonic tics begin 1–2 years after the onset of motor symptoms and are usually simple in character, e.g. throat-clearing, grunting and squeaks. More complex vocal symptoms such as echolalia (repeating another’s speech), palilalia (repeating one’s own speech) and coprolalia occur in a minority of cases. Other complex phonic symptoms include dramatic and abrupt changes in rhythm, rate and volume of speech.

Motor and phonic tics tend to occur in bouts. Their frequency ranges from non-stop bursts that are virtually uncountable (>100 tics/min) to rare events that occur only a few times a week. Single tics may occur in isolation or there may be orchestrated combinations of motor and phonic tics that involve multiple muscle groups. The forcefulness of motor tics and the volume of

phonic tics can also vary tremendously from behaviours that are not noticeable (a slight shrug or a hushed guttural noise) to strenuous displays (arm thrusts or loud barking) that are frightening and exhausting. During periods of waxing tic symptoms, clinicians may find themselves under extreme pressure to intervene medically. Although such interventions may be warranted, it is often the case that the tic symptoms will wane substantially within a few weeks.

By the age of 10, most children and adolescents have some awareness of the premonitory urges that frequently precede both motor and vocal tics (see above). These urges add to the subjective discomfort associated with having a tic disorder. They may also contribute to an individual's ability to suppress their tics for longer periods of time.

The factors that determine the degree of disability and handicap vs. resiliency are largely unknown (see below). They are likely to include the presence of additional developmental, mental and behavioural disorders; the level of support and understanding from parents, peers and educators; and the presence of special abilities (as in sports) or personal attributes (intelligence, social abilities and personality traits). The behavioural and emotional problems that frequently complicate Tourette syndrome range from impulsive, 'disinhibited' and immature behaviour to compulsive touching or sniffing. At present there are no clear dividing lines between these disruptive behaviours and complex tics on the one hand, and comorbid conditions of ADHD and obsessive-compulsive disorder (OCD) on the other. As described below, some of these conditions may be alternate expressions of the same underlying vulnerability (e.g. OCD), others may be intimately related by virtue of shared pathophysiological mechanisms (e.g. ADHD) and still others may be the consequence of having a chronic disorder that is socially disfiguring (e.g. affective and anxiety syndromes). Defining the limits of tic disorders vis-à-vis other forms of psychopathology remains one of the most controversial and difficult areas for families, clinicians and researchers. Some investigators believe that the 'spectrum' of Tourette syndrome includes attentional deficits, impulsivity, hyperactivity, disruptive behaviour, learning disabilities, pervasive developmental disorders, affective and anxiety disorders, as well as tics and OCD (Comings 1988).

Although most children with Tourette syndrome are loving and affectionate, maintaining age-appropriate social skills appears to be a particularly difficult area for many patients (Dykens *et al.* 1990; Stokes *et al.* 1991; Bawden *et al.* 1998). Whether this is because of the stigmatizing effects of the tics, the patient's own uneasiness, or some more fundamental difficulty linked to the neurobiology of this disorder is unknown.

Consistent with available epidemiological data, tic disorders tend to improve in late adolescence and early adulthood. In many instances, the phonic symptoms become increasingly rare or may disappear altogether, and the motor tics may be reduced in number and frequency. Complete remission of both motor and phonic symptoms has also been reported (Shapiro *et*

al. 1988; Goetz *et al.* 1992; Leckman *et al.* 1998a). In contrast, adulthood is also the period when the most severe and debilitating forms of tic disorder can be seen. The factors that influence the continuity of tic disorders from childhood to adolescence to adulthood are not well understood but probably involve the interaction of normal maturational processes occurring in the central nervous system with the neurobiological mechanisms responsible for Tourette syndrome, the exposure to cocaine, other central nervous system stimulants, androgenic steroids and the amount of intramorbidity emotional trauma and distress experienced by affected individuals during childhood and adolescence. In addition, it should be emphasized that tic disorders may be aetiologically separable so that some of these factors, such as activation of the immune system or exposure to heat stress, may influence the pathogenesis and intramorbidity course for some tic disorders but not others. Other factors, such as psychological stress, may have a more uniform adverse impact.

Coexisting conditions

The past decade has seen a renewed emphasis on the range of neurological and psychiatric symptoms seen in Tourette syndrome patients (Leckman & Cohen 1998). Symptoms associated with OCD and ADHD have received the most attention.

Obsessive-compulsive symptoms

Clinical and epidemiological studies indicate that more than 40% of individuals with Tourette syndrome experience recurrent obsessive-compulsive symptoms (Leckman *et al.* 1994, 1997a; Swerdlow *et al.* 1999). Genetic, neurobiological and treatment response studies suggest that there may be qualitative differences between tic-related forms of OCD and cases of OCD in which there is no personal or family history of tics. Specifically, compared with non-tic-related OCD, tic-related OCD has a male preponderance, an earlier age of onset, a poorer level of response to standard antiobsessional medications, and a greater likelihood of first-degree family members with a tic disorder (Miguel *et al.* 2001).

Symptomatically, the most common obsessive-compulsive symptoms encountered in Tourette syndrome patients are:

- 1 obsessions about aggression, sex, religion and the body, as well as related checking compulsions; and
- 2 obsessions concerning a need for symmetry or exactness, repeating rituals, counting compulsions, and ordering/arranging compulsions (Leckman *et al.* 1997a).

Attention deficit hyperactivity disorder

Clinical and epidemiological studies sharply differ on rates of ADHD seen among individuals with Tourette syndrome (Walkup *et al.* 1998). Clinical studies vary according to setting

and established referral patterns, but it is not uncommon to see reports of 50% or more of referred children with Tourette syndrome diagnosed with comorbid ADHD. In contrast, epidemiological studies typically indicate a much lower rate of comorbidity (Apter *et al.* 1993). Although the aetiological relationship between Tourette syndrome and ADHD is in dispute, it is clear that those individuals with both Tourette syndrome and ADHD are at a much greater risk for a variety of untoward outcomes (Carter *et al.* 2000). Uninformed peers frequently tease individuals with Tourette syndrome. They are often regarded as less likeable, more aggressive and more withdrawn than their classmates (Stokes *et al.* 1991). These social difficulties are amplified in a child with Tourette syndrome who also has ADHD (Bawden *et al.* 1998). In such cases, their level of social skill is often several years behind their peers (Dykens *et al.* 1990).

Negative appraisal by peers in childhood is a strong predictor of global indices of psychopathology (Hinshaw 1994). This appears to be particularly true for children with Tourette syndrome and ADHD. Longitudinal studies confirm that these individuals are at high risk for anxiety and mood disorders, oppositional defiant disorder and conduct disorder (Carter *et al.* 1994, 2000). Much of this negative impact appears to be a result of the ADHD, as children who only have Tourette syndrome tend to fare far better (Spencer *et al.* 1998; Carter *et al.* 2000). Surprisingly, levels of tic severity are less predictive of peer acceptance than is the presence of ADHD (Bawden *et al.* 1998). Furthermore, the rates of subsequent psychiatric morbidity seen in Tourette syndrome plus ADHD subjects are nearly identical to those seen in prior cross-sectional and longitudinal studies of ADHD subjects who do not have tics (Greene *et al.* 1997; Mannuzza *et al.* 1998).

Other developmental disorders

Children with a range of developmental disorders appear to be at increased risk for tic disorders. Kurlan *et al.* (1994) reported a fourfold increase in the prevalence of tic disorders among children in special educational settings in a single school district in upstate New York. These children were not mentally retarded but did have significant learning disabilities or other speech or physical impairments.

Children with autism and other pervasive developmental disorders are also at higher risk for developing Tourette syndrome. In a recent survey of 447 pupils from nine schools for children and adolescents with autism, 19 children were found to have definite Tourette syndrome, yielding a prevalence rate of 4.3% (Baron-Cohen *et al.* 1999). Although this figure exceeds available population-based estimates, it should be viewed with caution. Complex motor tics can be difficult to distinguish from motor stereotypies. Differentiation among these behaviours may be especially problematic among retarded individuals with limited verbal skills. Further study is required to elucidate the relationship between Tourette syndrome and other disorders of central nervous system development.

Neuropsychological findings

Although motor and phonic tics constitute the core elements of the diagnostic criteria for Tourette syndrome, perceptual and cognitive difficulties are also common. These neuropsychological symptoms are potentially informative about the pathobiology of the disorder. Moreover, these associated difficulties can be more problematic for school and social adjustment than the primary motor symptoms (Dykens *et al.* 1998; Walkup *et al.* 1998).

Neuropsychological studies of Tourette syndrome have focused on a broad array of functions. Review of the literature suggests that the most consistently observed deficits occur on tasks requiring the accurate copy of geometric designs ('visuomotor integration') or 'visuographic' ability (see Schultz *et al.* 1998 for a review). There was no evidence to suggest that comorbid ADHD or depressive symptomatology could account for the observed group differences. Even after controlling statistically for visuoperceptual skill, intelligence and fine motor control, children with Tourette syndrome continued to perform worse than controls on the visuomotor tasks, suggesting that the integration of visual inputs and organized motor output is a specific area of weakness in individuals with Tourette syndrome.

Aetiology and pathogenesis

During the course of the past decade, Tourette syndrome and related conditions have emerged as model disorders for researchers interested in the interaction of genetic, neurobiological and environmental (epigenetic) factors which shape clinical outcomes from health to chronic disability over the life span.

Genetic factors

Twin and family studies provide evidence that genetic factors are involved in the vertical transmission within families of a vulnerability to Tourette syndrome and related disorders (Pauls & Leckman 1986). The concordance rate for Tourette syndrome among monozygotic twin pairs is greater than 50%, while the concordance of dizygotic twin pairs is about 10% (Price *et al.* 1985; Hyde *et al.* 1992). If cotwins with chronic motor tic disorder are included, these concordance figures increase to 77% for monozygotic and 30% for dizygotic twin pairs. Differences in the concordance of monozygotic and dizygotic twin pairs indicate that genetic factors have an important role in the aetiology of Tourette syndrome and related conditions. These figures also suggest that non-genetic factors are critical in determining the nature and severity of the clinical syndrome.

Other studies indicate that first-degree family members of Tourette syndrome probands are at substantially higher risk for developing Tourette syndrome, chronic motor tic disorder and OCD than unrelated individuals (Hebebrand *et al.* 1997; Pauls *et al.* 1991; Walkup *et al.* 1996). Overall, the risk to male first-

degree family members approximates 50% (18% Tourette syndrome, 31% chronic motor tics and 7% OCD) while the overall risk to females is less (5% Tourette syndrome, 9% chronic motor tics and 17% OCD). These rates are substantially higher than might be expected by chance in the general population, and greatly exceed the rates for these disorders among the relatives of individuals with other psychiatric disorders except OCD.

The pattern of vertical transmission among family members has led several groups of investigators to test whether or not mathematical models of specific genetic hypotheses could be rejected. While not definitive, most segregation analyses could not rule out models of autosomal transmission (Pauls & Leckman 1986; Walkup *et al.* 1996). These studies prompted the identification of large multigenerational families for genetic linkage studies. However, subsequent efforts to identify susceptibility genes within these high-density families using traditional linkage strategies have met with little success (Barr & Sandor 1998).

More recently, non-parametric approaches using families in which two or more siblings are affected with Tourette syndrome have been undertaken (Tourette Syndrome International Consortium for Genetics 1999). This sib-pair approach is suited for diseases with an unclear mode of inheritance and has been used successfully in studies of other complex disorders, such as diabetes mellitus and essential hypertension. In this study, two areas are suggestive of linkage to Tourette syndrome: one on chromosome 4q and another on chromosome 8p. Currently, this international consortium of researchers is actively completing high-density maps of several genomic regions in an effort to refine and extend their preliminary results. In addition, several studies have implicated a region on 11q23 (Merrette *et al.* 2000; Simonic *et al.* 2001).

It is also noteworthy that none of the chromosomal regions (e.g. 3 [3p21.3], 8 [8q21.4], 9 [9pter] and 18 [18q22.3]) in which cytogenetic abnormalities have been found to cosegregate with Tourette syndrome showed any convincing evidence for linkage in the sib-pair study. It is still possible that rare susceptibility genes may be found in one or more of these regions using molecular cytogenetic techniques. Furthermore, none of the regions associated with candidate genes, such as *DRD2* [11q22] and *DRD4* [11p15], were supported by the results of the sib-pair study. Future progress is anticipated and clarity about the nature and normal expression of even a few of the Tourette syndrome susceptibility genes is likely to provide a major step forward in understanding the pathogenesis of this condition.

Neural circuits

The basal ganglia are key structures in the assembly and activation of cognitive, emotive and motor routines (habits) that are expressed in response to specific environmental cues (Graybiel 1998). The basal ganglia are subcortical nuclei that process information from the cortex before passing it along to thalamic nuclei that in turn project information back to more restricted

cortical regions (Parent & Hazrati 1995). These corticostriato-thalamocortical (CSTC) neural loops have long been a focus of Tourette syndrome and OCD research (see Leckman & Riddle 2000 for a review). Specifically, it has been hypothesized that Tourette syndrome and aetiologically related forms of OCD are associated with a failure to regulate sensorimotor and orbitofrontal subsets of the CSTC minicircuits, respectively (Leckman *et al.* 1991a, 1997b). Preliminary evidence in support of this hypothesis includes the ameliorative effects on tic and obsessive-compulsive behaviours following neurosurgical ablation or high-frequency electrical stimulation of thalamic nuclei and following procedures that isolate regions of the prefrontal cortex (Rauch *et al.* 1995; Lippitz *et al.* 1999; Vandewalle *et al.* 1999). In Tourette syndrome, volumetric magnetic resonance imaging (MRI) studies have also provided preliminary evidence of volume differences within the basal ganglia and cortical regions (Peterson *et al.* 1993; Peterson *et al.* 2001; Singer *et al.* 1993). Recent functional MRI studies present a more complex picture in which altered patterns of activation and/or deactivation of prefrontal cortex likely influence voluntary tic suppression or active ticking (Peterson *et al.* 1998a). If confirmed, these findings are consistent with the view that prefrontal cortex–basal ganglia circuits participate in the shaping of the inhibitory output of the basal ganglia. A similar picture has emerged in the study of individuals with OCD using functional neuroimaging techniques (Baxter *et al.* 1992).

Other aspects of the circuitry of the basal ganglia may provide important clues concerning the anatomical distribution of motor tics and the ‘choice’ of obsessive themes frequently encountered in forms of OCD related to Tourette syndrome. Specifically, the unidirectional input from the amygdala and the bed nucleus of the stria terminalis to widespread areas of the nucleus accumbens and ventral portions of the caudate and putamen appears to overlap those areas most affected in Tourette syndrome and related forms of OCD (Nauta 1982; Russchen *et al.* 1985). Studies in primates and humans have also shown that stimulation of the amygdala produces motor and vocal activity reminiscent of the symptoms of Tourette syndrome (McLean & Delgado 1953; Baldwin *et al.* 1954).

Reciprocal connections between midbrain sites (periaqueductal grey, substantia nigra and the ventral tegmental area), portions of the hypothalamus and structures in the basal ganglia and amygdala are likely to have a critical role in the genesis and maintenance of the symptoms of Tourette syndrome. These connections may also contribute to the stress sensitivity, including sensitivity to thermal stress observed in a limited number of subjects, and to the more frequent expression of Tourette syndrome in males than females, as many of these structures contain receptors for gonadal steroids and are responsive to alterations in their hormonal environment (see below).

Recent studies using transcranial magnetic stimulation have reported altered patterns of cortical inhibition/excitation. Specifically, following focal transcranial magnetic stimulation to the motor cortex, Ziemann *et al.* (1997) have documented that the cortical silent period was shortened and the intracor-

tical inhibition reduced in Tourette syndrome patients. This suggests either disinhibited thalamic input or impaired intracortical inhibition directly at the level of the motor cortex.

Neurochemical and neuropharmacological data

Extensive immunohistochemical studies of the basal ganglia have demonstrated the presence of a wide spectrum of classic neurotransmitters, neuromodulators and neuropeptides (Parent 1986; Graybiel 1990). The functional status of a number of these systems has been evaluated in Tourette syndrome (see Anderson *et al.* 1998 for a review). In the following section, the current status of a select group of these compounds is reviewed with special attention to those that are related to medications currently used to treat tics and related conditions.

Dopaminergic systems

Inputs from ascending dopamine pathways originating in the substantia nigra pars compacta play a crucial role in co-ordinating the output from the striatum (Aosaki *et al.* 1994). Explicit 'dopamine' hypotheses for Tourette syndrome posit either an excess of dopamine or an increased sensitivity of D₂ dopamine receptors. These hypotheses are consistent with multiple lines of empirical evidence as well as emerging data from animal models of habit formation. Data implicating central dopaminergic mechanisms include the results of double-blind clinical trials in which haloperidol, pimozide, tiapride and other neuroleptics that preferentially block dopaminergic D₂ receptors have been found to be effective in the temporary suppression of tics for most patients (see Chappell *et al.* 1997 for a review). Tic suppression has also been reported following administration of agents such as tetrabenazine that reduce dopamine synthesis (Shapiro & Shapiro 1988 for a review). Increased tics have been reported following withdrawal of neuroleptics or following exposure to agents that increase central dopaminergic activity, such as L-dopa and central nervous system stimulants, including cocaine (see Anderson *et al.* 1998 for a review). Preliminary positron emission tomography (PET) studies of brain dopamine D₂ receptors provide some evidence that the density and/or binding of D₂ receptors in the striatum are associated with current levels of tic severity (Wolf *et al.* 1996; Wong *et al.* 1997). Post-mortem brain and ligand-based neuroimaging studies have reported alterations in the number or affinity of presynaptic dopamine carrier sites in the striatum (Singer *et al.* 1991; Malison *et al.* 1995) or the presynaptic processing of dopamine (Ernst *et al.* 1999). However, a recent assessment of the number of striatal vesicular monoamine transporter type 2 sites found no differences between Tourette syndrome patients and controls (Meyer *et al.* 1999).

In summary, while the evidence that dopaminergic pathways are intimately involved in the pathobiology of Tourette syndrome is compelling, the exact nature of the abnormality remains to be elucidated.

Excitatory amino acid systems

The excitatory neurotransmitter, glutamate, is released upon depolarization by the corticostriatal, corticosubthalamic, subthalamic and thalamocortical projection neurones. As such, these excitatory neurones are key players in the functional anatomy of the basal ganglia and the CSTC loops. While the activity of these neurones are likely to be important in Tourette syndrome, only limited data are available to evaluate their role in this disease. For example, Anderson *et al.* (1992) have hypothesized that the disinhibition of thalamocortical projection neurones may be partly caused by a failure of the subthalamic nucleus to activate the inhibitory output neurones of the basal ganglia. However, this speculation is based on the results of an examination of just four post-mortem brain specimens.

Inhibitory amino acid systems

Neurones containing inhibitory amino acid neurotransmitters, particularly gamma-aminobutyric acid (GABA), also form major portions of CSTC loops. These include GABAergic medium spiny neurones of the striatum that project to the internal segment of the globus pallidus and the pars reticulata of the substantia nigra within the 'direct pathway'. GABAergic neurones are also present in the 'indirect pathway' that relays information from the striatum to the external segment of the globus pallidus and from there to the internal segment of the globus pallidus. An imbalance between the direct and indirect pathways has been hypothesized in Tourette syndrome (Leckman *et al.* 1991a). However, there is very little direct evidence available to support this hypothesis. Clinical studies have shown that benzodiazepines, which enhance the inhibitory effects of GABA, have some value in the treatment of tics (Gonce & Barbeau 1977). But thus far, post-mortem and other studies have failed to detect any significant abnormalities in these cells compared to controls (see Anderson *et al.* 1998 for a review).

Cholinergic systems

The large aspiny interneurones found throughout the striatum are likely to be critically involved in the co-ordination of striatal response through interactions with central dopaminergic and GABAergic neurones (Aosaki *et al.* 1994). Cholinergic projections from the basal forebrain are found throughout the cortex and within key structures of the basal ganglia and mesencephalon, including the internal segment of the globus pallidus, the pars reticulata of the substantia nigra and the locus caeruleus. Evidence of cholinergic involvement in the pathobiology of Tourette syndrome concerns the reported potentiation of D₂ dopamine receptor blocking agents through the use of transdermal nicotine or nicotine gum (Sanberg *et al.* 1997) and more recent reports of the usefulness of a non-competitive cholinergic agonist, mecamylamine (Silver *et al.*, 2000). Unfortunately, the efficacy of these agents has yet to be evaluated in a double-blind trial. Further, none of the post-mortem

or cerebrospinal fluid studies has detected differences between patients and controls (see Anderson *et al.* 1998 for a review).

Endogenous opioid peptides

Endogenous opioid peptides (EOPs) are localized in structures of the extrapyramidal system, are known to interact with central dopaminergic and GABAergic neurones, and are likely to be importantly involved in the gating of motor functions. Two of the three families of EOPs, dynorphin and met-enkephalin, are highly concentrated and similarly distributed in the basal ganglia and substantia nigra. In addition, significant levels of opiate receptor binding have been detected in both primate and human neostriatum and substantia nigra.

EOPs have been directly implicated in the pathophysiology of Tourette syndrome. Haber *et al.* (1986) reported decreased levels of dynorphin A(1–17) immunoreactivity in striatal fibres projecting to the globus pallidus in post-mortem material from a small number of Tourette patients. This observation, coupled with the neuroanatomical distribution of dynorphin, its broad range of motor and behavioural effects, and its modulatory interactions with striatal dopaminergic systems, suggested that dynorphin might have a key role in the pathobiology of Tourette syndrome. However, subsequent studies have failed to confirm these initial observations (van Watum *et al.* 1999; also see Anderson *et al.* 1998 for a review).

Noradrenergic systems

Noradrenergic projections from the locus caeruleus project widely to the prefrontal and other cortical regions. Noradrenergic pathways are also likely to indirectly influence central dopaminergic pathways via projections to areas near the ventral tegmental area (Grenhoff & Svensson 1989). Speculation that noradrenergic mechanisms might be relevant to the pathobiology of Tourette syndrome was based initially on the beneficial effects of α_2 -adrenergic agonists including clonidine (Cohen *et al.* 1979). Although clonidine is one of the most widely prescribed agents for the treatment of tics, its effectiveness remains controversial (Goetz *et al.* 1987; Leckman *et al.* 1991b). In open trials another related α_2 -adrenergic agonist, guanfacine, has also been reported to reduce tics and improve ADHD symptoms (Chappell *et al.* 1995). At the level of receptor function, clonidine has been traditionally viewed as a selective α_2 -adrenoceptor agonist active at presynaptic sites, and its primary mode of action may be its ability to reduce the firing rate and the release of noradrenaline from central noradrenergic neurones. However, evidence of heterogeneity among the α_2 class of adrenoceptors and their distinctive distribution within relevant brain regions adds further complexity. Specifically, differential effects in cortical regions mediated by specific receptor subtypes may account for the differential responsiveness of particular behavioural features of this syndrome to treatment with clonidine vs. guanfacine (Arnsten 2000).

The involvement of the noradrenergic pathways may be one of the mechanisms by which stressors may influence tic severity. For example, a series of adult Tourette syndrome patients were found to have elevated levels of cerebrospinal fluid noradrenaline (Leckman *et al.* 1995) and to have excreted high levels of urinary noradrenaline in response to the stress of the lumbar puncture (Chappell *et al.* 1994a). These elevated levels of cerebrospinal fluid noradrenaline may also contribute to the elevation in cerebrospinal fluid corticotropin releasing factor levels seen in some Tourette syndrome patients (Chappell *et al.* 1996).

Serotonergic systems

Ascending serotonergic projections from the dorsal raphe have been repeatedly invoked as playing a part in the pathophysiology of both Tourette syndrome and OCD. The most compelling evidence relates to OCD and is based largely on the well-established efficacy of potent serotonin reuptake inhibitors (SRIs) such as clomipramine and fluvoxamine in the treatment of OCD (Greist & Jefferson 1998). However, some investigators have reported that the SRIs are less effective in treating tic-related OCD compared with other forms of OCD (McDougle *et al.* 1993). It is also doubtful that treatment with SRIs diminishes tic symptoms (Scahill *et al.* 1997). Additional evidence has come from pharmacological challenge studies in which serotonergic agonists such as metachlorophenyl-piperazine (mCPP) were found to exacerbate obsessive-compulsive symptoms in some patients (Zohar *et al.* 1987). However, not all OCD patients show this response (Goodman *et al.* 1995) and this agent does not appear to exacerbate tics in Tourette syndrome patients (Cath *et al.* 1999). Finally, preliminary post-mortem brain studies in Tourette syndrome have suggested that serotonin and the related compounds tryptophan (TRP) and 5-hydroxyindoleacetic acid (5-HIAA) may be globally decreased in the basal ganglia and other areas receiving projections from the dorsal raphe (Anderson *et al.* 1992).

Gender-specific endocrine factors

Males are more frequently affected than females with Tourette syndrome (Shapiro *et al.* 1988). While this could be caused by genetic mechanisms, frequent male-to-male transmission within families appears to rule out the presence of an X-linked vulnerability gene. This observation has led us to hypothesize that androgenic steroids act at key developmental periods to influence the natural history of Tourette syndrome and related disorders (Peterson *et al.* 1992). These developmental periods include the prenatal period when the brain is being formed, adrenarche when adrenal androgens first appear at age 5–7 years, and puberty. Androgenic steroids may be responsible for these effects or they may act indirectly through oestrogens formed in key brain regions by the aromatization of testosterone.

The importance of gender differences in expression of associated phenotypes is also clear given the observation that women are more likely than men to develop obsessive-compulsive

symptoms without concomitant tics (Pauls *et al.* 1991) and that boys are much more likely than girls to display disruptive behaviours (Comings & Comings 1987).

Surges in testosterone and other androgenic steroids during critical periods in fetal development are known to be involved in the production of long-term functional augmentation of subsequent hormonal challenges (as in adrenarche and during puberty) and in the formation of structural central nervous system dimorphisms (Sikich & Todd 1988). In recent years several sexually dimorphic brain regions have been described, including portions of the amygdala (and related limbic areas) and the hypothalamus (including the medial preoptic area that mediates the body's response to thermal stress) (Boulant 1998). These regions contain high levels of androgen and oestrogen receptors and are known to influence activity in the basal ganglia both directly and indirectly (Fehrbach *et al.* 1985). Indeed a proportion of Tourette syndrome patients appear to be uniquely sensitive to thermal stress such that when their core body temperature increases and they begin to sweat their tics increase (Lombroso *et al.* 1992). It is also of note that some of the neurochemical and neuropeptidergic systems implicated in Tourette syndrome and related disorders, such as dopamine, serotonin and the opioids, are involved with these regions and appear to be regulated by sex-specific factors.

Further support for a role for androgens comes from anecdotal reports of tic exacerbation following androgen use (Leckman & Scahill 1990) and from trials of antiandrogens in patients with severe Tourette syndrome and/or OCD (Casas *et al.* 1986; Peterson *et al.* 1998b; Altemus *et al.* 1999). In the most rigorous study to date, Peterson *et al.* (1998b) found that the therapeutic effects of the antiandrogen, flutamide, were modest in magnitude and these effects were short-lived, possibly because of physiological compensation for androgen receptor blockade.

Perinatal risk factors

The search for non-genetic factors which mediate the expression of a genetic vulnerability to Tourette syndrome and related disorders has also focused on the role of adverse perinatal events. This interest dates from the report of Pasamanick & Kawi (1956) who found that mothers of children with tics were 1.5 times more likely to have experienced a complication during pregnancy than the mothers of children without tics. Other investigations have reported that among monozygotic twins discordant for Tourette syndrome, the index twins with Tourette syndrome had lower birth weights than their unaffected cotwins (Leckman *et al.* 1987; Hyde *et al.* 1992). Severity of maternal life stress during pregnancy, severe nausea and/or vomiting during the first trimester have also emerged as potential risk factors in the development of tic disorders (Leckman *et al.* 1990). Whitaker *et al.* (1997) reported that premature and low birth weight children are at increased risk of developing tic disorders and ADHD. This appears to be especially true of children who had ischaemic parenchymal brain lesions. More recently, Burd *et al.* (1999) presented the results of a case-

control study in which low Apgar scores at 5 min and *more* prenatal visits were associated with a higher risk of Tourette syndrome. Finally, there is limited evidence that smoking and alcohol use, as well as forceps delivery, can predispose individuals with a vulnerability to Tourette syndrome to develop comorbid OCD (Santangelo *et al.* 1994).

Post-infectious autoimmune mechanisms

It is well established that group A β -haemolytic streptococci (GABHS) can trigger immune-mediated disease in genetically predisposed individuals (Bisno 1991). Speculation concerning a post-infectious (or at least a post-rheumatic fever) aetiology for tic disorder symptoms dates from the late 1800s (Kushner 1999). Acute rheumatic fever is a delayed sequela of GABHS, occurring approximately 3 weeks following an inadequately treated upper respiratory tract infection. Rheumatological fever is characterized by inflammatory lesions involving the heart (rheumatic carditis), joints (polymigratory arthritis), and/or central nervous system (Sydenham chorea; SC). SC and Tourette syndrome, OCD and ADHD share common anatomical targets—the basal ganglia of the brain and the related cortical and thalamic sites (Husby *et al.* 1976). Furthermore, SC patients frequently display motor and vocal tics, obsessive-compulsive and ADHD symptoms suggesting the possibility that, at least in some instances, these disorders share a common aetiology (Swedo *et al.* 1989; Mercadante *et al.* 1997).

It has been proposed that paediatric autoimmune neuropsychiatric disorder associated with streptococcal infection (PANDAS) represents a distinct clinical entity, and includes SC and some cases of Tourette syndrome and OCD (Swedo *et al.* 1998). The most compelling evidence that acute exacerbations of Tourette syndrome and OCD can be triggered by GABHS comes from two independent reports demonstrating that the vast majority of patients with childhood onset Tourette syndrome or OCD have elevated expression of a stable B-cell marker (Murphy *et al.* 1997; Swedo *et al.* 1997). The D8/17 marker identifies close to 100% of rheumatic fever patients (with or without SC) but is present at low levels of expression in healthy control populations. The identity of the D8/17 epitope is not yet known, but it can be expressed by several non-B-cell types (Kemeny *et al.* 1994). Further suggestive evidence comes from Swedo *et al.* (1998) who reported that in children who met PANDAS criteria, GABHS infection was likely to have preceded neuropsychiatric symptom onset for 44% of the children, whereas pharyngitis (no culture obtained) preceded onset for another 28% of the children. There were 144 episodes of symptom exacerbation among these 50 children. In addition to tic and obsessive-compulsive symptoms, cognitive deficits, oppositional behaviours and motor hyperactivity were reported to be 'particularly common' during periods of exacerbation. Thirty-one per cent of these exacerbations were associated with documented GABHS infection, and 42% with symptoms of pharyngitis or upper respiratory infection (no throat culture obtained). While these results are intriguing, they are preliminary.

As individuals were selected for having a recent or recurrent history of GABHS infections, the magnitude of some of the reported associations may have been biased upwards.

In summary, a substantial body of circumstantial evidence exists that links post-infectious autoimmune phenomena with Tourette syndrome, OCD and ADHD. However, these data are not compelling with regard to specific immunological mechanisms (Singer *et al.* 1998), nor do they establish where in the sequence of causal events these immune changes occur. These potentially important findings require replication in independent samples and warrant more intensive investigation.

Psychological factors

Tic disorders have long been identified as ‘stress-sensitive’ conditions (Jagger *et al.* 1982; Shapiro *et al.* 1988; Silva *et al.* 1995; Witzum *et al.* 1996). Typically, symptom exacerbations follow in the wake of stressful life events. As noted by Shapiro *et al.* (1988), these events need not be adverse in character. Clinical experience suggests that in some unfortunate instances a vicious cycle can be initiated in which tic symptoms are misunderstood by the family and teachers, leading to active attempts to suppress the symptoms by punishment and humiliation. These efforts can lead to a further exacerbation of symptoms and further increase in stress in the child’s interpersonal environment. Unchecked, this vicious cycle can lead to the most severe manifestations of Tourette syndrome and dysthymia as well as maladaptive characterological traits. Although psychological factors are insufficient to cause Tourette syndrome, the intimate association of the content and timing of tic behaviours and dynamically important events in the lives of children make it difficult to overlook their contribution to the intramorbidity course of these disorders (Carter *et al.* 1994, 2000).

In addition to the intramorbidity effects of stress and anxiety that have been well characterized, premorbid stress may also play an important part as a sensitizing agent in the pathogenesis of Tourette syndrome among vulnerable individuals (Leckman *et al.* 1984).

It is likely that the immediate family environment (e.g. parental discord) and the coping abilities of family members have some role (Leckman *et al.* 1990), and this may lead to a sensitization of stress-responsive biological systems such as the hypothalamic–pituitary–adrenal axis (see above, Chappell *et al.* 1994a, 1996; Leckman *et al.* 1995).

Differential diagnosis

The differential diagnosis of simple motor tics includes a variety of hyperkinetic movements: myoclonus, tremors, chorea, athetosis, dystonias, akathic movements, paroxysmal dyskinesias, ballistic movements and hyperekplexia (see Towbin *et al.* 1998 for a review). These movements may be associated with:

- genetic conditions, such as Huntington chorea or Wilson disease;

- structural lesions, as in hemiballismus (associated with lesions to the contralateral subthalamic nucleus);
- infectious processes, as in SC;
- idiopathic functional instability of neuronal circuits, as in myoclonic epilepsy; and
- pharmacological treatments, such as acute akathisia and dystonias associated with the use of neuroleptic agents.

Differentiation between these conditions and tic disorders is usually accomplished on clinical grounds and is based on the presentation of the disorder and its natural history. For example, although aspects of tics—such as their abruptness, their paroxysmal timing or their suppressible nature—may be similar to symptoms seen in other conditions, it is rare for all of these features to be combined in the absence of a bona fide tic disorder. Occasionally diagnostic tests are needed to exclude alternative diagnoses.

Complex motor tics can be confused with other complex repetitive behaviours, such as stereotypies or compulsive rituals. Differentiation among these behaviours may be difficult, particularly among retarded individuals with limited verbal skills. In other settings where these symptoms are closely intertwined, as in individuals with both Tourette syndrome and OCD, efforts to distinguish between complex motor tics and compulsive behaviours may be futile. In cases of a tic disorder, it is unusual to see complex motor tics in the absence of simple tics. Involuntary vocal utterances are uncommon neurological signs in the absence of a tic disorder. Examples include sniffing and brief sounds in Huntington disease and involuntary moaning in Parkinson disease particularly as a result of L-dopa toxicity. Complex phonic tics characterized by articulate speech typically can be distinguished from other conditions including voluntary coprolalia. Because of their rarity in other syndromes, phonic tics can have an important role in differential diagnosis.

Anamnesis, family history, observation and neurological examination are usually sufficient to establish the diagnosis of a tic disorder. There are no confirmatory diagnostic tests. Neuroimaging studies, electroencephalography-based studies and laboratory tests are usually non-contributory, except in atypical cases.

Assessment

Once the diagnosis has been established, care should be taken to focus on the overall course of an individual’s development, not simply on his or her tic symptoms. This may be a particular problem in the case of Tourette syndrome where the symptoms can be dramatic and there is the temptation to organize all of an individual’s behavioural and emotional difficulties under a single all-encompassing rubric.

The principal goal of an initial assessment is to determine the individual’s overall level of adaptive functioning and to identify areas of impairment and distress (Leckman *et al.* 1998b). Close attention to the strengths and weaknesses of the individual and his or her family is crucial. Relevant dimensions include the pres-

ence of comorbid mental, behavioural, developmental or physical disorders; family history of psychiatric and/or neurological disease; relationships with family and peers; school and/or occupational performance; and the history of important life events. Medication history is important, particularly if the disorder is long-standing or if medications have been prescribed for physical disorders. It may be necessary to evaluate the adequacy of the prior trials with pharmacological agents used to treat tic disorders. Inventories such as the Yale Child Study Center: Tourette Syndrome Obsessive-Compulsive Disorder Symptom Questionnaire (Leckman & Cohen 1998, Appendix 1) completed by the family prior to their initial consultation can be valuable ancillary tools to gain a long-term perspective of the child's developmental course and the natural history of the tic disorder. In addition, several valid and reliable clinical rating instruments have been developed to inventory and quantify recent tic symptoms including the Yale Global Tic Severity Scale (YGTSS; Leckman *et al.* 1989), the Tourette Syndrome Severity Scale (TSSS; Shapiro *et al.* 1988), the Hopkins Motor and Vocal Tic Scale (HMVTS), and some clinicians make regular use of standardized videotape protocols to assess current tic severity (Tanner *et al.* 1982; Shapiro *et al.* 1988; Walkup *et al.* 1992; Chappell *et al.* 1994b).

The YGTSS is a clinician-rated semistructured scale that begins with a systematic inventory of tic symptoms that the clinician rates as present or absent over the past week. Current motor and phonic tics are then rated separately according to number, frequency, intensity, complexity and interference on a 6-point ordinal scale (0, absent; 1–5 for severity) yielding three scores: Total Motor, Total Phonic and Total Tic Score. The scale concludes with an overall impairment rating. The YGTSS has shown excellent interrater agreement as well as other desirable psychometric properties (Leckman *et al.* 1989).

Because the YGTSS permits the clinician to incorporate direct observation with historical information, it requires both training with the instrument and clinical experience with tic disorders. At present most investigators consider the YGTSS to be state-of-the-art with regard to clinician ratings of tic severity.

Other clinician-rated scales include the TSSS (Shapiro *et al.* 1988); Tourette Syndrome Global Scale (TSGS; Harcherik *et al.* 1984); and the HMVTS (Walkup *et al.* 1992). Although both the TSSS and TSGS have been used in many published reports, both scales have unconventional scoring procedures and unstable psychometric properties. The HMVTS is a more recently developed instrument that combines self-report data with clinician assessment, resulting in a composite rating. This scale consists of a series of analogue scales that are tallied to yield a 1–5 score for motor, phonic and total score. This scale has shown promise as a global measure of tic severity in a preliminary study of 20 children, but has not entered into common use. When compared to other measures of tic severity, the HMVTS showed the strongest correlation with the YGTSS. In addition to clinician ratings, there are two other methods of estimating tic severity: self-reports (parent reports in the case of children) and direct observational methods, such as videotaped counts of tics for variable

periods of time. Each of these methods has advantages and disadvantages (Scahill *et al.* 1998). The validity of self-reports may be limited by inaccurate information about the nature of tics on the part of the child or parent leading to over- or underendorsement of symptoms. On the other hand, self-reports are efficient and potentially cost effective. At present, the most widely used self-report measure is the Tic Symptom Self-Report. It consists of a checklist of simple and complex motor and phonic tics over the prior week (Cohen *et al.* 1984).

Direct observational methods include videotape tic counting procedures (Chappell *et al.* 1994b; Goetz *et al.* 1999) or *in vivo* evaluation of tic symptoms (Nolan *et al.* 1994). These direct observational methods would appear to be the most objective measure of tic severity; however, the frequency of tics varies according to setting and activity. In addition, many individuals with Tourette syndrome can suppress their symptoms for brief periods of time. In practice, videotaped tic counting appears to be most useful for acute research procedures that take place over several hours. Clinically, videotaping can be quite valuable when the diagnosis is in doubt or when tics are not observed in the consultation room.

Treatment

Tic disorders are frequently chronic, if not lifelong, conditions. Continuity of care is desirable and should be considered before embarking on a course of treatment. Usual clinical practice focuses initially on the educational and supportive interventions with pharmacological treatments typically held in reserve. Given the waxing and waning course of the disorders, it is likely that whatever is done (or not done) will lead in the short term to some improvement in tic severity. The decision to employ psychoactive medications is usually made after the educational and supportive interventions have been in place for a period of months and it is clear that the tic symptoms are persistently severe and are themselves a source of impairment in terms of self-esteem, relationships with the family or peers, or the child's ability to perform at school.

Educational and supportive interventions

Educational activities are among the most important interventions available to the clinician. They should be undertaken first, not only with patients with Tourette syndrome but also with patients with milder presentations. Although the efficacy of these educational and supportive interventions has not been rigorously assessed, they appear to have positive effects by reshaping familial expectations and relationships (Cohen *et al.* 1988). This is particularly true when the family and colleagues have misconstrued the tic symptoms as being intentionally provocative. Families also find descriptions of the natural history comforting in that the disorders tend not to be relentlessly progressive and usually improve during adulthood. This information often contradicts the impressions gained from the available lay literature

on Tourette syndrome that typically focuses on the most extreme cases. Armed with this knowledge, patients and family members and colleagues can begin to understand why waiting before beginning medical treatment makes good sense. If a patient is in the midst of a bad period of tics, it is likely that whether or not a new medication is prescribed, the tics will probably get significantly better in the near future. This insight will also help patients and their families realize why at times in the past their medications have suddenly stopped working. These dialogues can be relieving and can interrupt a vicious cycle of recrimination that leads to further tic exacerbation, and it can help aggravated parents shift the focus from blame to problem-solving.

For children, contact with their teachers can be enormously valuable. By educating the educators, clinicians can make significant progress towards securing for the child a positive and supportive environment in the classroom. If possible, teachers need to respond to outbursts of tics with grace and understanding. Repeatedly scolding a child for his or her tics can be counterproductive. The child may develop a negative attitude to authority figures and may be reluctant to attend school, and classmates may feel freer to tease the child. If tics interfere with a student's ability to receive information in the classroom, it is imperative to find alternative ways to present the material. By helping the student find a way to function even during periods of severe tics, teachers model problem-solving skills that will foster future self-esteem. It is also important for teachers to know that unstructured settings, such as the cafeteria, gym, playground and school bus, tend to be very difficult. In these situations, peers who tease or taunt tend to take advantage of the lack of adult supervision. The assignment of a paraprofessional aide to accompany the student can be remarkably beneficial—particularly in situations where there is a history of teasing. Other useful strategies that teachers may consider include: providing short breaks out of the classroom to let the tics out in private; allowing students with severe tics to take tests in private so that a child does not have the pressure to suppress tics during the test period; and being flexible with regard to the scheduling of oral presentations so that the child is not expected to make an oral presentation at a point when his or her tics are severe (Bronheim 1991). A useful compendium of educational accommodations is available on the Internet at <http://www.tourettesyndrome.net>.

Educated peers are equally important. Many clinicians actively encourage patients, families and teachers to help educate peers and classmates about Tourette syndrome. It is remarkable what can be tolerated in the classroom and playground when teachers and peers simply know what the problem is and learn to disregard it.

Finally, it is important for clinicians to determine the family's awareness and potential interest in advocacy organizations such as the Tourette Syndrome Association, Obsessive-Compulsive Foundation, and the Children and Adults with Attention Deficit Disorder. In the USA, these organizations have made a positive contribution to the lives of many patients and their families by providing support and information. They can also be a valuable outlet for families—to advance research and raise the general

level of awareness among health care professionals, educators and the public at large. Readers are referred to their respective web sites for additional information: Tourette Syndrome Association (<http://www.tsa-usa.org/>); Obsessive-Compulsive Foundation (<http://www.ocfoundation.org/>) and Child and Adults with Attention Deficit (<http://www.chadd.org/>). It is likely with the expansion of the Internet that these organizations will have an increasingly important voice around the world.

Behavioural, cognitive and other psychotherapeutic treatments

The characteristic suppressibility of tic symptoms may have broad implications for treatment. Prior to seeking professional consultation, many families will have experimented with a variety of ad hoc behavioural approaches on their own. It is useful to elicit information concerning these efforts and their sequelae.

A variety of cognitive and behavioural approaches have been used with Tourette syndrome subjects (King *et al.* 1998). A battery of 'habit reversal training' techniques encompassing 'awareness' training, self-monitoring, relaxation training, competing response training (where a movement is performed that is opposite to a particular tic) and contingency management have been reported to reduce markedly tic symptoms at home and in a clinic setting (Azrin & Peterson 1990; Peterson & Azrin 1992). Additional studies are needed to confirm the effectiveness of these techniques.

The most frequently used component of this battery is some version of relaxation training which may employ tensing followed by relaxation, imagery or deep breathing. Some of these methods can be temporarily helpful; however, most families report that these techniques lose their effectiveness. Other techniques, such as massed negative practice (where the patient deliberately performs the tic movement as quickly and as forcefully as possible), have been studied with mixed results (Azrin & Peterson 1988).

Although not indicated for the treatment of tics, individual and family counselling may alleviate secondary symptoms such as low self-esteem, defiant and disruptive behaviour as well as family conflict. These interventions may also serve to reduce a significant source of psychological stress. Specifically, tic symptoms can have a powerful impact on the inner life of individuals with Tourette syndrome. They can emerge as important determinants of self-esteem and self-definition. Traditional psychotherapeutic approaches can be useful in helping patients and their families to understand and cope with their illness and to address intrapsychic conflicts that affect or result from tic symptoms.

Pharmacological treatments

The decision to begin medication is based on the level of symptoms and the clinical presentation of the individual case. Many cases of Tourette syndrome can be successfully managed without medication. When patients present with coexisting ADHD,

OCD, depression or bipolar illness it is often better to treat these 'comorbid' conditions first, as successful treatment of these disorders will often diminish tic severity.

Pharmacotherapy of tics

A variety of therapeutic agents are now available to treat tics (Chappell *et al.* 1997; Kurlan 1997; Leckman *et al.*, 2001). Each medication should be selected on the basis of expected efficacy and potential side-effects. Dopamine D₂ receptor antagonists remain the most predictably effective tic-suppressing agents in the short term. Documentation of the effectiveness of haloperidol in the early 1960s was a landmark in the history of Tourette syndrome as it called into question the prevailing view that tics were psychogenic in nature (Kushner 1998). The most widely used D₂ receptor antagonists are haloperidol, pimozide, fluphenazine and tiapride (not presently available in the USA or UK). Favourable data from double-blind clinical trials are available for haloperidol, pimozide and tiapride (Eggers *et al.* 1988; Shapiro *et al.* 1989; Sallee *et al.* 1997; Tourette Syndrome Study Group 1999). The US Food and Drug Administration has approved Tourette syndrome as an indication for haloperidol and pimozide use. Long-term experience has been less favourable, and the 'reflexive' use of these agents should be avoided (Silva *et al.* 1996; Kurlan 1997).

Typically, treatment is initiated with a low dose (0.25 mg haloperidol or 1 mg pimozide) given before sleep. Further increments (0.5 mg haloperidol or 1 mg pimozide) may be added at 7–14-day intervals if the tic behaviours remain severe. In most instances, 0.5–6.0 mg/day haloperidol or 1.0–10.0 mg/day pimozide administered over a period of 4–8 weeks are sufficient to achieve adequate control of tic symptoms. Common potential side-effects include tardive dyskinesia, acute dystonic reactions, sedation, depression, school and social phobias and/or weight gain. In many instances, by starting at low doses and adjusting the dosage upwards slowly, clinicians can avoid these side-effects. The goal should be to use as little of these medications as possible to render the tics 'tolerable'. Efforts to stop the tics completely often risk overmedication.

More recently, 'atypical' neuroleptics, including risperidone, ziprasidone and olanzapine, have been used to treat tic symptoms. These agents have potent 5-HT₂ blocking effects as well as more modest blocking effects on dopamine D₂. Initial favourable double-blind clinical trials have now been reported for both risperidone and ziprasidone, although ziprasidone is not currently available in the UK (Bruggeman *et al.* 2001; Sallee *et al.* 2000). Risperidone use often causes weight gain and complaints of sedation. Ziprasidone appears to have a more favourable side-effect profile, but more data are needed before a judgement can be made regarding its efficacy.

Clonidine is a potent α_2 -receptor agonist that is thought to reduce central noradrenergic activity. Although initial open studies were favourable, subsequent double-blind clinical trials have had mixed results (Goetz *et al.* 1987; Leckman *et al.* 1991b). Clinical trials indicate that subjects can expect on average a

25–35% reduction in their symptoms over an 8–12-week period. Motor tics may show greater improvement than phonic symptoms. The usual starting dose is 0.05 mg on rising. Further 0.05 mg increments at 3–4-h intervals are added weekly until a dosage of 5 μ g/kg is reached or the total daily dosage exceeds 0.25 mg. Although clonidine is clearly less effective than haloperidol and pimozide for immediate tic suppression, it is considerably safer. The principal side-effect associated with its use is sedation which occurs in 10–20% of subjects and which usually abates with continued use. Other side-effects include dry mouth, transient hypotension and rare episodes of worsening behaviour. Clonidine should be tapered and not withdrawn abruptly, to reduce the likelihood of symptom or blood pressure rebound. Initial results from a double-blind clinical trial with the closely related compound guanfacine are also promising (Scahill *et al.* 2001).

While many other medications have been used in the treatment of tics, with the exception of flutamide, an androgen receptor antagonist, none have been evaluated in double-blind randomized clinical trials (Peterson *et al.* 1998b). Promising agents include dopamine agonists that act presynaptically (pergolide) and agents that deplete presynaptic dopamine concentrations (tetrabenazine) (Gilbert *et al.* 2000; see also Carpenter *et al.* 1999 for a review). Cholinergic agents, including nicotine formulated as a patch and used in combination with a neuroleptic, have also been recommended (Sanberg *et al.* 1997). Building on its success in treating dystonia, reports concerning the benefits of botulinum toxin injections to temporarily weaken muscles associated with severe motor or vocal tics have also appeared (Jankovic 1994). Finally, GABAergic agents, particularly clonazepam, have also been widely used.

Pharmacotherapy of coexisting ADHD

The stimulants methylphenidate and dexamphetamine, are first-line agents for the medical management of ADHD (Dulcan 1997). However, the use of stimulants in ADHD associated with a tic disorder is controversial (Castellanos 1999). While many patients with both ADHD and a pre-existing tic disorder will do well on stimulants, data from clinical case reports and controlled studies indicate that some children with ADHD will exhibit tics *de novo* when exposed to a stimulant. In other cases, tics may increase to a level that warrants discontinuation of the stimulant. Commonly used non-stimulants for ADHD include:

- the tricyclic antidepressants, desipramine and nortriptyline;
- atypical antidepressants, such as bupropion;
- α_2 -agonists, clonidine and guanfacine (Dulcan 1997).

Compared to clonidine, guanfacine is less sedating and has a longer duration of action as well as being more specific for α_2 -receptors in the prefrontal cortex (Arnsten *et al.* 1998). Initial results from a double-blind clinical trial with guanfacine in subjects with both ADHD and coexisting tics are promising (Scahill *et al.* 2001).

Pharmacotherapy of coexisting OCD

Cognitive behavioural therapies, particularly exposure and response prevention alone or in combination with SRIs are the standard interventions for OCD (American Academy of Child and Adolescent Psychiatry 1998). Unfortunately, many patients with OCD and a coexisting tic disorder respond less well to these interventions. Investigators in controlled clinical trials have found that addition of small doses of the neuroleptic haloperidol, or the atypical neuroleptic risperidone increases the response to SRIs (McDougle *et al.* 1994, 2000).

Special populations: PANDAS

Post-infectious autoimmune mechanisms are likely to contribute to the pathogenesis of 10–20% of Tourette syndrome cases (Swedo *et al.* 1998). Preliminary evidence suggests that individuals with abrupt onset and coexisting ADHD and/or OCD may be at greater risk (Peterson *et al.*, 2000). As in SC, the precise mechanisms are in doubt. Clarification of these mechanisms is likely to lead to improved treatment and possibly preventive interventions. Although initial results from immunomodulatory treatments, including plasma exchange, are promising, caution is warranted (Perlmutter *et al.* 1999). It is also premature to recommend prophylactic antibiotic treatment (Garvey *et al.* 1999; Shulman 1999).

Future directions

Along with a deepening appreciation of the clinical phenomenology of Tourette syndrome and related disorders, recent progress in neuroanatomy, systems neuroscience and functional *in vivo* neuroimaging has set the stage for a major advance in our understanding of these disorders. Success in this area will lead to the targeting of specific brain circuits for more intensive study. Diagnostic and prognostic advances can also be anticipated. Which circuits are involved and to what degree? How does that degree of involvement affect the patient's symptomatic course and outcome?

Given this potential, Tourette syndrome can be considered a model disorder to study the dynamic interplay of neurobiological systems during development. It is likely that the research paradigms utilized in these studies may lead to the development of animal models that can be exploited to develop novel interventions. Findings from these and other empirical studies will likely be relevant to other disorders of childhood onset and will enhance our understanding of normal development.

Acknowledgements

We are indebted to members of the Yale Tourette Syndrome and Obsessive-Compulsive Disorder Research Group for their support and comments on an earlier version of this review. Mem-

bers of this research group include: David L. Pauls PhD, Bradley S. Peterson MD, Lawrence Scahill MSN PhD, Heping Zhang PhD, Alice S. Carter PhD, Paul J. Lombroso MD, Robert T. Schultz PhD, George M. Anderson PhD, John P. Alsobrook II PhD, Flora M. Vaccarino MD, Diane B. Findley PhD, Debra E. Bessen PhD, Syed A. Morshed MD PhD, Salina Parveen MD PhD, Robert W. Makuch PhD and Kenneth K. Kidd PhD. We are also grateful to the comments and suggestions of Yukiko Kano MD PhD, Marcos Mecedante MD PhD and Maria C. do Rosario Campos MD MS, who are currently on leave at the Child Study Center.

Portions of the research described in this review were supported by grants from the National Institutes of Health: MH18268, MH49351, MH30929, HD03008, NS16648 and RR00125, as well as by the Tourette Syndrome Association.

Introduction

Schizophrenia is one of the most devastating psychiatric disorders to affect children and adolescents. Although extremely rare before the age of 10, the incidence of schizophrenia rises steadily through adolescence to reach its peak in early adult life. An accumulating body of evidence now supports the view that schizophrenia presenting in childhood and adolescence shows continuity with the adult form of the disorder at the levels of symptoms, clinical course and underlying neurobiology. Like other disorders of presumed multifactorial origin (e.g. juvenile rheumatoid arthritis and diabetes), the early onset form of schizophrenia lies at the extreme end of a continuum of disease severity and genetic liability.

The clinical severity and poor prognosis of child and adolescent onset schizophrenia reinforces the need for early diagnosis and treatment and ultimately prevention before the onset of psychosis. The introduction of newer atypical antipsychotics has been an important recent advance with their greater efficacy against negative symptoms and a lower risk of producing extrapyramidal side-effects. The goal of early diagnosis and prevention depends on identifying clinical and biological markers that have good reliability and predictive validity. Longitudinal studies are essential here, in particular those that track the transition from high-risk status to active psychosis.

While knowledge of the fundamental causes and pathogenic mechanisms in schizophrenia remains elusive, over the last decade there have been important developments in the way the disorder is conceptualized. There is now broad support for the view that schizophrenia is a disorder of brain development. Although there has been a long-standing interest in the role of perinatal risk factors in schizophrenia, recent attention has shifted to adolescent brain development more proximal to the onset of psychosis. It is proposed that excessive synaptic elimination during adolescence may lead to abnormal neural connectivity and psychotic symptoms. There is growing evidence that symptoms of psychosis (hallucinations, delusions, disorganization of thought or behaviour) may be a final end-state for a variety of disorders including schizophrenia and represent non-specific indicators of severe mental illness. Meanwhile, the genetic and developmental vulnerability to schizophrenia may be manifest in a broader non-psychotic schizophrenic spectrum characterized by a range of subtle social and cognitive impairments. Hence, the search for the causes of schizophrenia may be better directed not at the end-state psychotic symptoms, but at

the more proximal developmental and cognitive processes that predispose to psychosis. The implication is that genetic and phenotypic vulnerability to schizophrenia is distributed on a continuum in the population with only a small proportion of the highest risk individuals crossing the threshold for the expression of psychotic symptoms. The concept of schizophrenia as a discrete disease category defined essentially by the presence or absence of psychotic symptoms may actually limit our ability to detect the genetic, developmental and pathophysiological origins of the disorder.

Concepts of schizophrenia

In the late nineteenth century, Kraepelin (1919) invoked the term 'dementia praecox' to distinguish patients with a psychosis that typically began in early adult life and ran a progressive and deteriorating course from the more benign and episodic course of manic depressive illness. Bleuler (1911) reformulated dementia praecox as schizophrenia, and described four fundamental symptoms: ambivalence, disturbance of association, disturbance of affect and preference of fantasy over reality. Bleuler viewed the fundamental deficit in schizophrenia as a 'splitting' or disconnection of normally integrated cognitive functions. Interestingly, the symptoms of hallucinations and delusions which are emphasized in modern diagnostic systems (DSM-IV and ICD-10) were not seen as fundamental in Bleuler's scheme, but rather as secondary consequences of the core schizophrenic deficits.

Bleuler's development of a theory of underlying deficits in schizophrenia contrasts with Kraepelin's atheoretical empirical observations. Bleulerian definitions of schizophrenia were largely abandoned by modern diagnostic systems (DSM and ICD) because they were seen as vague and had poor reliability. Instead, modern diagnostic constructs draw largely on the Kraepelian and Schneiderian tradition that views psychotic symptoms as fundamental to schizophrenia, with Schneider's first-rank symptoms given the greatest prominence. However, there is now good evidence that first-rank symptoms are neither specific nor valid indicators of schizophrenia (Peralta & Cuesta 1999). So has diagnostic reliability been achieved at the expense of validity? One approach to improving the validity of definitions of schizophrenia has been to link groups of symptoms (symptom dimensions) to underlying neurobiological processes.

Dimensions of psychopathology in schizophrenia

Although the concept of positive and negative symptoms was first expounded by the nineteenth century neurologist, Hughlings Jackson, it was not until the 1970s that these were applied to the symptoms of schizophrenia (Strauss *et al.* 1974). Factor analytical and correlational studies have now confirmed that schizophrenic symptoms consist of at least three dimensions (Liddle 1987a; Andreasen *et al.* 1995; Johnstone & Frith 1996; Lenzenweger & Dworkin 1996).

The 'positive' symptom dimension includes hallucinations and delusions and has been linked with temporal lobe function (Liddle *et al.* 1992). The 'negative' symptom dimension includes affective blunting, avolition and alogia and has been most clearly associated with poor performance on 'frontal lobe' tasks (Liddle 1987b; Liddle & Morris 1991) and hypofunction of the dorsolateral prefrontal cortex (Weinberger *et al.* 1986). The 'disorganization' dimension includes formal thought disorder and bizarre behaviour and has been linked to functional abnormalities of the ventral prefrontal cortex (predominantly on the right) and anterior cingulate (Liddle *et al.* 1992).

Recent work suggests that these dimensions are not unique to schizophrenic patients and can be identified (with added depressive and manic dimensions) in a broad spectrum of adult psychotic patients early in the course of their illness (van Os *et al.* 1996). This finding weakens the idea of clear categorical boundaries between psychotic diagnoses both at the symptomatic and neurobiological level.

Symptom dimensions in child and adolescent onset schizophrenia

Very few studies have examined symptom dimensions in child and adolescent schizophrenia and related psychoses. The evidence so far points to a broadly similar pattern of symptom dimensions in child and adolescent onset psychotic patients (Maziade *et al.* 1996; Hollis 1999). The main difference from studies in adult patients is the higher proportion of overall symptom variance explained by the negative symptom dimension in child and adolescent onset patients (Hollis 1999). Symptom dimensions in these younger patients show some expected associations with diagnostic categories: negative symptoms are specifically associated with schizophrenia and dimensions of mania and depression with affective psychoses. In contrast, the dimensions of disorganization and positive psychotic symptoms show less clear-cut associations with any specific diagnostic category. This lack of diagnostic specificity confirms that positive symptoms cannot be regarded as pathognomonic of schizophrenia. In terms of prognosis, the dimensions of disorganization and negative symptoms predict a poor adult outcome whereas affective symptoms predict a more benign course and outcome; positive symptoms (hallucinations–delusions and passivity–thought interference) have no prognostic value.

Two other findings from the Maudsley study (Hollis 1999) are of particular interest. First, the negative symptom dimension is

associated with premorbid developmental impairments, which suggests possible developmental and neurobiological continuity between these domains. Second, negative symptoms are associated with an increased familial risk of schizophrenia. Taken together, these findings suggest that negative symptoms may be the most direct expression of a genetic and developmental risk for schizophrenia. These findings also support the Bleulerian view that the fundamental features of schizophrenia are negative symptoms and cognitive deficits.

The schizophrenia spectrum: schizotypy and 'schizotaxia'

A dimensional view of a schizophrenia spectrum is consistent with multigene models in schizophrenia, yet runs counter to the categorical approach found in current diagnostic systems. Multigene models assume that multiple genes combine with one another and with environmental factors to produce schizophrenia, with the genetic liability for schizophrenia distributed on a continuum in the population. According to this model, individuals with a very high loading of risk factors may manifest schizophrenia, whereas those with a lesser loading may show signs of schizotypal personality disorder, negative symptoms or cognitive impairments. A further implication of multigene models is that those individuals with the greatest liability will develop the disorder earlier in life and will have an increased risk of schizophrenia spectrum disorders among biological relatives.

Schizotypal personality disorder is characterized by disturbances of perception and thinking that appear to represent a milder variant of schizophrenia. The biological relationship between schizotypal personality disorder and schizophrenia is supported by family and genetic studies (Kendler *et al.* 1993), similarities on measures of neuropsychological test performance (Kremen *et al.* 1994) and similar structural brain abnormalities (Cannon *et al.* 1993).

The term 'schizotaxia' was first introduced in the early 1960s (Meehl 1962) to describe the unexpressed genetic liability to schizophrenia. More recently, the concept has been reinvoked to refer to the subtle psychiatric and neurobiological features found in non-psychotic and non-schizotypal relatives of schizophrenic patients (Tsuang *et al.* 2000). These features include negative symptoms, executive cognitive impairments, deviant eye tracking and structural brain abnormalities (Faraone *et al.* 2001). Thus, schizotaxia lies on a continuum of genetic liability and neurobiological dysfunction that includes schizotypy with schizophrenia as its most extreme manifestation. It is estimated that features of schizotaxia occur in about 20–50% of first-degree relatives of patients with schizophrenia (Faraone *et al.* 1995). However, only about 10% of relatives will become psychotic and less than 10% will have schizotypal personality disorder (Battaglia & Torgersen 1996). Hence, most affected individuals with schizotaxia do not develop psychosis.

These findings are all consistent with the view that the biological risk for schizophrenia is expressed in non-schizophrenic individuals as part of a broader non-psychotic phenotype and may

also be apparent before the onset of psychosis in the form of pre-morbid social and cognitive impairments. In the following sections we will consider whether a premorbid phenotype of schizophrenia can be reliably identified, if progression to psychosis can be predicted and if intervention could prevent progression to full-blown psychosis.

Clinical phases of schizophrenia

Premorbid social and developmental impairments

Child and adolescent onset schizophrenia is associated with poor premorbid functioning and early developmental delays (Alaghband-Rad *et al.* 1995; Hollis 1995). Similar developmental and social impairments in childhood have been reported in adult onset schizophrenia using population-based cohorts free from referral biases (Done *et al.* 1994; Jones *et al.* 1994; Jones & Done 1997; Malmberg *et al.* 1998). Although age of onset comparisons are plagued by methodological difficulties, premorbid developmental impairments appear to be more common and severe in the child and adolescent onset forms of the disorder. In the Maudsley study (Hollis 1999) significant early delays were particularly common in the areas of language (20%), reading (30%) and bladder control (36%). Just over 20% of cases of adolescent schizophrenia had significant early delays in either language or motor development. A history of premorbid impairments may be even more common in the very earliest onset cases. Nicholson *et al.* (2000) reported significant premorbid speech/language, motor and social impairments in 50% of childhood onset patients with onset of psychosis before the age of 12 years. In contrast, a similar pattern of language and motor developmental delays has been reported in only about 10% of individuals destined to develop schizophrenia in adult life (Jones *et al.* 1994). A consistent characteristic in the premorbid phenotype is impaired sociability. In the Maudsley study of child and adolescent onset psychoses (Hollis 1999), about one-third of cases with schizophrenia had significant difficulties in social development affecting the ability to make and keep friends. Similar, but less frequent difficulties with premorbid sociability have been noted in representative population samples of adult schizophrenia (Malmberg *et al.* 1998).

Premorbid IQ also appears to be lower in child and adolescent onset schizophrenia than in the adult form of the disorder. The mean premorbid IQ lies in the mid to low 80s, 10–15 IQ points lower than in most adult studies (Asarnow *et al.* 1994a; Spencer & Campbell 1994; Alaghband-Rad *et al.* 1995; Hollis 2000). In the Maudsley study (Hollis 2000), one-third of child and adolescent onset cases had an IQ below 70 (mild learning disability range).

One interpretation of these findings is that a subgroup of adolescent schizophrenic cases has abnormal premorbid development with the rest developing normally. In fact, careful analysis shows that there is no abnormal developmental subgroup — this

is simply an artefact of using rather crude categorical measures of premorbid development. Continuous IQ measures show that the whole distribution of IQ is shifted down compared to both adolescent affective psychoses and adult schizophrenia.

These findings are consistent with the view that premorbid impairments are manifestations of a genetic/developmental liability to schizophrenia. It seems clear that the premorbid phenotype does not just represent non-specific psychiatric disturbance. Subtle problems of language, attention and social relationships are typical whereas, in contrast, conduct problems are rare. However, premorbid social and behavioural difficulties are not specific to schizophrenia. Premorbid deficits also occur in adolescent affective psychoses, at a lower rate than in schizophrenia, but higher than in non-psychotic psychiatric controls (van Os *et al.* 1997; Sigurdsson *et al.* 1999).

Are premorbid impairments a risk or precursor of psychosis?

Premorbid impairments could lie on a causal pathway for psychosis or, alternatively, they could be markers of an underlying neuropathological process, such as aberrant neural connectivity which may be the cause of both premorbid social impairment and psychosis. Causality is clearly implicit in ideas of primary prevention and the risk estimates provided by population-based epidemiological studies of prepsychotic impairments (Done *et al.* 1994; Jones *et al.* 1994; Malmberg *et al.* 1998). Frith (1994) has speculated on the possible cognitive mechanisms that might link deficits in social cognition or ‘theory of mind’ in a causal pathway to both positive and negative psychotic symptoms. If these characteristics are causally related then modifying the ‘primary’ cognitive or social deficits may reduce the risk of psychosis. Alternatively, cognitive and social deficits, although often present, may not be necessary in the pathogenesis. The fact that individuals may develop schizophrenia without obvious premorbid impairments supports this view. In these circumstances, an intervention aimed at the neurobiological level (e.g. antipsychotic medication) may be necessary. Only a high-risk longitudinal intervention study can adequately address the issue of causality, and this would require an intervention that had benefits for the majority of individuals with the premorbid phenotype who would not develop psychosis.

Prodromal symptoms and onset of psychosis

Although some individuals show relatively stable patterns of subtle social and neurocognitive impairments, those that develop schizophrenia typically enter a prodromal phase characterized by a gradual but marked decline in social and academic functioning that precedes the onset of active psychotic symptoms. An insidious deterioration prior to onset of psychosis is typical of the presentation of schizophrenia in children and adolescents (Werry *et al.* 1994). In the Maudsley study of adolescent psychoses (Hollis 1999), a pattern of insidious onset was found more often in cases of schizophrenia than in affective psychoses.

Non-specific behavioural changes including social withdrawal, declining school performance, uncharacteristic and odd behaviour began, on average, over a year before the onset of positive psychotic symptoms. In retrospect, it was often apparent that non-specific behavioural changes were early negative symptoms, which in turn had their onset well before positive symptoms such as hallucinations and delusions.

Hence, early recognition of disorder can be very difficult, as premorbid cognitive and social impairments gradually shade into prodromal symptoms before the onset of active psychotic symptoms (Hafner & Nowotny 1995). Prodromal symptoms can include odd ideas, eccentric interests, changes in affect, unusual experiences and bizarre perceptual experiences. Although these are also characteristic features of schizotypal personality disorder, in a schizophrenic prodrome there is usually progression to more severe dysfunction.

Diagnosis of schizophrenia in childhood and adolescence

Historical perspective

Both Kraepelin and Bleuler believed that schizophrenia presented in a similar form, albeit more rarely, during childhood and adolescence. Kraepelin (1919) found that 3.5% of cases of dementia praecox began before the age of 10 with a further 2.7% arising between the ages of 10 and 15. Bleuler (1911) suggested that about 5% of cases of schizophrenia had their onset prior to age 15.

However, from the 1930s until the early 1970s, the concept of 'childhood schizophrenia' as a distinct category was invoked. The definition of childhood schizophrenia was broadened to encompass autism and other developmental disorders that were seen as childhood manifestations of adult schizophrenia. This lumping together of different disorders under the diagnosis of childhood schizophrenia makes most research carried out during this period very difficult to interpret.

During the 1970s the pendulum swung back to reflect Kraepelin's and Bleuler's original views. Schizophrenia in childhood and adolescence was again seen as continuous with the adult form of the disorder and presented with essentially the same clinical picture (Kolvin 1971; Rutter 1972). From ICD-9 (World Health Organization 1978) and DSM-III (American Psychiatric Association 1980) onwards, the same diagnostic criteria have been used for schizophrenia regardless of the age of onset. The current international diagnostic systems (ICD-10 and DSM-IV) have continued this tradition, with no diagnostic distinction made for schizophrenia presenting in childhood and adolescence.

Developmental issues

Although the use of the same diagnostic criteria for schizophrenia aids comparability across the age range, it does not exclude

the possibility of some degree of symptom variation in childhood and adolescence. The main argument against the idea of developmental variants of schizophrenia is the finding that schizophrenia can be reliably identified in children as young as 7 years using unmodified adult diagnostic criteria (McKenna *et al.* 1994). However, if schizophrenia does show significant symptom variation in children and adolescents then applying unmodified adult criteria may result in a proportion of 'true' cases being missed (false-negative diagnoses). Conversely, some presentations of schizophrenia in early life could be phenocopies of adult schizophrenia (false-positive diagnoses) with a distinct aetiology and clinical course. Hence, there are two main issues to be addressed.

- 1 What is the validity of adult diagnostic criteria for schizophrenia when applied in childhood and adolescence?
- 2 Are there partial syndromes or variants of schizophrenia in childhood and adolescence that should be considered as part of a broader schizophrenic spectrum?

Diagnostic validity and stability

Good evidence for the validity of the diagnosis of schizophrenia in childhood and adolescence comes from the recent Maudsley Child and Adolescent Psychosis Follow-up Study (Hollis 2000). A DSM-III-R diagnosis of schizophrenia in childhood and adolescence predicted a significantly worse adult outcome compared with other non-schizophrenic psychoses (American Psychiatric Association 1987). The diagnosis of schizophrenia showed a high level of stability, with 80% having the same diagnosis recorded at adult follow-up. These findings challenge the belief that adolescent schizophrenic and affective psychoses are poorly differentiated and show a high degree of diagnostic instability from adolescence into adult life (Zeitlin 1986; Werry *et al.* 1991).

However, there remains the problem of resolving the status of 'partial syndromes' that share some diagnostic features, or prodromal symptoms, of schizophrenia but do not meet full DSM-IV (American Psychiatric Association 1994) or ICD-10 (World Health Organization 1992) diagnostic criteria. For example, in the USA the term 'multidimensionally impaired' (MDI) (Jacobsen & Rapoport 1998; Kumra *et al.* 1998a) has been coined to describe children that have multiple early impairments in cognitive and social functioning and then develop transient psychotic symptoms in late childhood and early adolescence. A higher than expected rate of schizophrenia among first-degree relatives suggests that MDI children may lie on the schizophrenia spectrum, but longer follow-up studies are needed to tell if these cases progress to more typical schizophrenic presentations (Kumra *et al.* 1998a). At present, cases with partial or contiguous syndromes, such as MDI or schizotypal personality disorder, require careful clinical follow-up to determine if they will develop schizophrenia. The question of how best to treat these presentations (e.g. should they be given low-dose antipsychotics) remains an important but unresolved question.

Diagnostic criteria for schizophrenia

The two dominant diagnostic systems (DSM and ICD) both require the clear evidence of psychosis (in the absence of predominant affective symptoms) with minimum duration criteria. A comparison of the current DSM-IV and ICD-10 criteria for schizophrenia is presented in Table 37.1.

It may appear confusing to have different, albeit quite similar definitions for a single disorder. However, although different definitions of schizophrenia continue to exist, it is helpful that they are explicit and clearly operationalized. The existence of alternative definitions also emphasizes that these definitions are arbitrary and provisional.

ICD-10 criteria are closer to the Schneiderian concept of schizophrenia and place more reliance than DSM-IV on the presence of first-rank symptoms. In contrast, the DSM-IV definition reflects Kraepelin's concept of a psychotic disorder with a chronic and deteriorating course (Maj 1998). An example of the different approaches of the two systems can be seen in how they categorize a hypothetical patient presenting with schizophrenic symptoms but only 2 months' duration of disturbance. This patient would be given a diagnosis of schizophrenia using ICD-10 but would not fulfil the DSM-IV criteria. DSM-IV stipulates a 6-month duration of disturbance, which makes it more restrictive than the 1-month duration criteria of ICD-10. The DSM-IV category of schizophreniform disorder is used for cases with the same symptoms but an overall duration of disturbance of less than 6 months. As a result, the DSM-III-R/DSM-IV definition of schizophrenia has greater specificity but lower sensitivity than ICD-10 in first-episode psychoses (Mason *et al.* 1997). Not surprisingly, cases of schizophrenia defined using DSM-IV have a worse prognosis than those defined using ICD-10.

DSM-IV describes various subtypes of schizophrenia defined by the most prominent symptomatology:

- 1 paranoid type, characterized by delusions and hallucinations;
- 2 disorganized type, characterized by disorganization of speech, behaviour and negative symptoms (i.e. flat or inappropriate affect);
- 3 catatonic type, characterized by motor abnormalities; and
- 4 residual type.

Clinical characteristics of schizophrenia in childhood and adolescence

Even if strict adult definitions of schizophrenia (DSM-III-R/DSM-IV or ICD-10) are applied, there appears to be evidence of some age-dependent variations in phenomenology. Child and adolescent onset cases are characterized by a more insidious onset, negative symptoms, disorganized behaviour, hallucinations in different modalities and fewer systematized or persecutory delusions (Garraida 1984; Asarnow & Ben-Meir 1988; Green *et al.* 1992; Werry *et al.* 1994). Using the DSM-III-R/DSM-IV scheme of subtyping schizophrenia, the disorganized subtype (hebephrenia in ICD-10) has a peak incidence

during adolescence, whereas the paranoid subtype more often presents first in adult life (Beratis *et al.* 1994).

In summary, early onset schizophrenia is characterized by greater disorganization (incoherence of thought and disordered sense of self) and more negative symptoms, whereas in later onset cases there is a higher frequency of systematized and paranoid delusions (Hafner & Nowotny 1995).

Course and outcome

Short-term course

Adolescent schizophrenia characteristically runs a chronic course with only a small minority of cases making a full symptomatic recovery from the first psychotic episode. In the Maudsley study of child and adolescent onset psychoses (Hollis 1999), only 12% of schizophrenic cases were in full remission at discharge compared with 50% of cases with affective psychoses. The short-term outcome for schizophrenia presenting in early life appears to be worse than that of first-episode adult patients (Robinson *et al.* 1999). If full recovery does occur then it is most likely within the first 3 months of onset of psychosis. In the Maudsley study, those adolescent onset patients who were still psychotic after 6 months had only a 15% chance of achieving full remission, whereas over half of all cases that made a full recovery had active psychotic symptoms for less than 3 months (Hollis 1999). The clinical implication is that the early course over the first 6 months is the best predictor of remission and that longer observation over 6 months adds relatively little new information.

Long-term outcome

A number of long-term follow-up studies of child and adolescent onset schizophrenia describe a typically chronic, unremitting, long-term course with severely impaired functioning in adult life (Eggers 1978; Werry *et al.* 1991; Schmidt *et al.* 1995; Eggers & Bunk 1997; Hollis 2000). Several common themes emerge from these studies.

- 1 The generally poor outcome of early onset schizophrenia conceals considerable heterogeneity. About one-fifth of patients in most studies have a good outcome with only mild impairment whereas, at the other extreme, about one-third of patients are severely impaired requiring intensive social and psychiatric support. Hence, for an individual patient, diagnosis alone is a relatively crude prognostic indicator.
- 2 After the first few years of illness there is little evidence of further progressive decline. This suggests that during the first 10–15 years of illness, at least, the course is relatively stable, although further progression may occur later in life.
- 3 Child and adolescent onset schizophrenia has a worse outcome than either adolescent onset affective psychoses or adult onset schizophrenia. This suggests that outcome and clinical severity are related to both diagnosis and the age at onset.

Table 37.1 Diagnostic criteria for schizophrenia in DSM-IV and ICD-10.

DSM-IV	ICD-10
<p>DSM-IV requires that six separate criteria (A–F) are met for a diagnosis of schizophrenia.</p> <p>A Five types of ‘characteristic’ symptoms are listed of which at least two types must be present for at least 1 month:</p> <ul style="list-style-type: none"> (i) <i>Delusions</i> of any kind (ii) <i>Hallucinations</i> of any kind in clear consciousness (excluding hallucinations secondary to substance misuse or an organic brain disorder) (iii) <i>Disorganized speech/formal thought disorder</i> (e.g. frequent derailments, loosening of association or incoherence) (iv) <i>Grossly disorganized or catatonic behaviour</i> (v) <i>Negative symptoms</i>, i.e. affective flattening, alogia or avolition. <p>NB: A single symptom of <i>bizarre delusions</i>, or specific types of auditory hallucination (voices commenting or conversing with each other) are sufficient on their own to fulfil criterion A.</p> <p>B Evidence of deterioration in social or occupational functioning. In childhood and adolescence this can mean failure to reach an expected level of social, academic or occupational achievement.</p> <p>C At least 6 <i>months</i> duration of disturbance. This period must include at least 1 month of ‘active symptoms’ (criterion A) and may include periods of prodromal or residual symptoms.</p> <p>D The exclusion of schizoaffective and other psychotic mood disorders. If affective symptoms occur, they must be relatively brief in relation to other active symptoms listed in criterion A.</p> <p>E Symptoms are not attributable to the effects of substance misuse, other medication or medical conditions.</p> <p>F In cases with a history of pervasive developmental disorder (autism), the diagnosis of schizophrenia can only be made with at least 1 month duration of hallucinations or delusions.</p>	<p>A Either <i>at least one</i> of the groups of symptoms (a–d) listed under (1) or <i>at least two</i> of the groups of symptoms (a–d) listed under (2) should be present for most of the time during a psychotic episode lasting for at least <i>1 month</i>.</p> <p>1. At least <i>one</i> of the following (a–d) must be present:</p> <ul style="list-style-type: none"> (a) thought echo/insertion/withdrawal/broadcasting (b) delusions of control, influence or passivity, delusional perception (c) auditory hallucinations giving a running commentary on the patient’s behaviour, or discussing the patient among themselves, or other types of hallucinatory voice coming from some part of the body (d) persistent delusions of other kinds that are culturally inappropriate or completely impossible (bizarre delusions) <p>2. Or at least two of the following (a–d):</p> <ul style="list-style-type: none"> (a) Persistent hallucinations in any modality, occurring every day for at least a month, accompanied by delusions without clear affective content, or accompanied by persistent overvalued ideas (b) Neologisms, breaks in the train of thought, resulting in incoherence or irrelevant speech (c) Catatonic behaviour such as excitement, posturing or waxy flexibility, negativism, mutism or stupor (d) ‘Negative’ symptoms, such as marked apathy, paucity of speech, and blunting or incongruity of emotional responses (it must be clear that these are not caused by depression or neuroleptic medication) <p>B Exclusion criteria:</p> <ul style="list-style-type: none"> (a) If the patient meets criteria for a manic or depressive episode, the criteria listed above, (1) and (2) must be present <i>before</i> the disturbance in mood developed (b) The disorder is not attributable to organic brain disease, or to alcohol- or drug-related intoxication, dependence or withdrawal.

4 Social functioning, in particular the ability to form friendships and love relationships, appears to be very impaired in early onset schizophrenia.

Taken together, these findings confirm that schizophrenia presenting in childhood and adolescence lies at the extreme end of a continuum of phenotypic severity.

Prognostic factors

The predictors of poor outcome in child and adolescent onset psychoses include premorbid social and cognitive impairments (Werry & McClellan 1992; Hollis 1999), a prolonged first psychotic episode (Schmidt *et al.* 1995), extended duration of untreated psychosis (Hollis 1999) and the presence of negative symptoms (Hollis 1999). Premorbid functioning and negative symptoms at onset provide better prediction of long-term outcome than categorical diagnosis (Hollis 1999). This finding suggests that premorbid social and cognitive impairments and negative symptoms lie at the core of a valid clinical concept of schizophrenia.

Mortality

The risk of premature death is increased in child and adolescent onset psychoses. In the Maudsley study (Hollis 1999), there were nine deaths out of the 106 cases followed-up (8.5%). The standardized mortality ratio (SMR) was 1250 (95% CI, 170–5500), which represents a 12-fold increase in the risk of death compared to an age- and sex-matched general UK population over the same period. Of the nine deaths in the cohort, seven were male and seven had a diagnosis of schizophrenia. Three subjects suffered violent deaths, two died from self-poisoning, and three had unexpected deaths caused by previously undetected physical causes (cardiomyopathy and status epilepticus) and were possibly associated with high-dose antipsychotic medication.

The death rate in child and adolescent onset schizophrenia and other psychoses appears to be significantly higher than in the adult form of the disorder. In adults the ‘all cause’ SMR for schizophrenia has been reported as 157 (95% CI, 153–160) (Harris & Barraclough 1997). In a Norwegian study of adolescent psychiatric inpatients, Kjelsberg (2000) reported an SMR for psychosis of 390 in male and 1130 in female patients.

Epidemiology

Incidence and prevalence

Good population-based incidence figures for child and adolescent onset schizophrenia are notably lacking because studies have used broad categories of psychosis, without standardized assessments. Gillberg *et al.* (1986) calculated age-specific prevalence for all psychoses (including schizophrenia, schizophreni-

form affective psychosis, atypical psychosis and drug psychoses) in the age range 13–18 years using case-register data from Goteborg, Sweden. Of the cases, 41% had a diagnosis of schizophrenia. At age 13 years, the prevalence for all psychoses was 0.9 in 10 000, showing a steady increase during adolescence, reaching a prevalence of 17.6 in 10 000 at age 18 years.

Sex ratio

Males are overrepresented in many clinical studies of childhood onset schizophrenia (Russell *et al.* 1989; Green *et al.* 1992; Russell 1994; Spencer & Campbell 1994). However, other studies of predominantly adolescent onset schizophrenia have described an equal sex ratio (Gordon *et al.* 1994; Werry *et al.* 1994; Hollis 2000). The interpretation of these studies is complicated by the possibility of referral biases to clinical centres. In an epidemiological study of first admissions for schizophrenia and paranoia in children and adolescents there was an equal sex ratio for patients under the age of 15 (Galdos *et al.* 1993; Lewine 1994). The finding of an equal sex distribution with adolescent onset is intriguing as it differs from the consistent male predominance (ratio 2:1) reported in incident samples of early adult onset schizophrenia (Castle & Murray 1991). Clearly, future studies require population-based incident samples free from potential referral biases.

Aetiology and risk factors

Pregnancy and birth complications

Pregnancy and birth complications (PBC) have been implicated as a risk factor in schizophrenia. In a meta-analysis of 20 case-control studies, subjects that developed schizophrenia were over twice as likely to have been exposed to PBCs as controls (Geddes & Lawrie 1995). However, the findings from two other large case-control studies suggest that the link between schizophrenia and PBCs may be much weaker than previously assumed (Kendall *et al.* 2000). In one case-control study of childhood onset schizophrenia, Matsumoto *et al.* (1999) reported an odds ratio of 3.5 for PBC, suggesting a greater risk in very early onset cases. However, in the National Institute for Mental Health (NIMH) study of childhood onset schizophrenia, PBCs were no more common in cases than in sibling controls (Nicholson *et al.* 1999). Even if there is a significant association, it remains unclear whether there is any causal connection between PBCs and schizophrenia. There is a strong argument that PBCs are *consequences* rather than *causes* of abnormal neurodevelopment (Goodman 1988). This view is supported by the finding that schizophrenic patients have smaller head size at birth than controls (McGrath & Murray 1995), which is likely to be a consequence of either defects in genetic control of neurodevelopment or earlier environmental factors such as viral exposure.

Puberty

The close temporal association between the onset of puberty and a marked increase in the incidence of schizophrenia suggests that biological (or social) events around puberty may be related to the expression of psychotic symptoms. Galdos *et al.* (1993) reported an association between the timing of menarche and onset of psychosis in girls. However, this finding has not been supported by subsequent studies. Frazier *et al.* (1997) found no relationship between the onset of psychosis and indices of puberty in cases recruited to the NIMH study of childhood onset schizophrenia. For both boys and girls the timing of pubertal events were the same for cases and controls.

Psychosocial risks

One possible explanation for an atypically early onset of schizophrenia could be differential exposure to psychosocial adversity, such as higher levels of parental hostility and criticism ('high EE'). High levels of expressed emotion (EE) among relatives of schizophrenic adults has been shown to be a predictor of psychotic relapse and poor outcome (Leff & Vaughn 1985). Although the role of high EE in precipitating the onset of schizophrenia has not been established, it is theoretically plausible that high EE might act to 'bring forward' the onset of the disorder in a vulnerable individual. Goldstein (1987) reported that parental EE measures of criticism and overinvolvement taken during adolescence were associated with an increased risk of schizophrenia spectrum disorders in young adulthood. However, a causal link was not proven, and the association may reflect either an expression of some common underlying trait or a parental response to premorbid disturbance in the preschizophrenic adolescent. More direct comparisons between the parents of adult and childhood onset schizophrenic patients fail to support the hypothesis of higher parental EE in childhood onset cases. Asarnow *et al.* (1994b) used the Five Minute Speech Sample to measure parental EE and found that those with childhood onset schizophrenia were no more likely to have 'high EE' parents than normal controls. Overall, there seems little evidence to suggest that the onset of schizophrenia in childhood can be explained by exposure to higher levels of parental criticism and hostility than that experienced by adult onset patients. Indeed, it appears that, on average, the parents of those with childhood onset schizophrenia generally express *lower* levels of criticism and hostility than parents of adult onset patients, caused by a greater tendency to attribute their childrens' behaviour to an illness which is beyond their control (Hooley 1987).

Neurobiology of schizophrenia

Neurodevelopmental models of schizophrenia

Over the last decade the concept of schizophrenia as a neurode-

velopmental disorder has taken a strong hold, although 'neurodevelopmental' is often used with a wide range of meanings. It is possible to distinguish 'early' and 'late' neurodevelopmental models, with a third 'risk' model incorporating ideas from developmental psychopathology (Hollis & Taylor 1997).

The 'early' neurodevelopmental model emerged from the ideas of Fish (1957) who proposed that the neuropathology in schizophrenia was of perinatal origin. The 'early' neurodevelopmental model views the primary cause of schizophrenia as a static 'lesion' occurring during fetal brain development (Murray & Lewis 1987; Weinberger 1987). The putative 'lesion' could be of either neurogenetic or environmental origin (e.g. virus infection or fetal hypoxia). Two main lines of evidence support the 'early' neurodevelopmental model. First, post-mortem studies of brain morphology (Jacob & Beckman 1986) report an absence of gliosis and possible abnormalities in neuronal migration that suggest that brain abnormalities are caused by aberrant neurodevelopment rather than neurodegeneration. Second, a more indirect line of evidence includes the association of schizophrenia with premorbid social and cognitive impairments (Foerster *et al.* 1991; Done *et al.* 1994; Jones *et al.* 1994), PBCs (Lewis & Murray 1987; McNeil 1995) and minor physical anomalies (Gualtieri *et al.* 1982; Guy *et al.* 1983). According to this 'early' model, during childhood this lesion is relatively silent giving rise only to subtle behavioural symptoms (premorbid social and cognitive impairments). However, in adolescence or early adult life, the lesion interacts with the process of *normal* brain maturation (e.g. myelination of corticolimbic circuits, and/or synaptic pruning and remodelling) to manifest itself in the form of psychotic symptoms.

There are several problems with the 'early' neurodevelopmental model. First, it fails to provide a satisfactory account of the long latency between the perinatal damage/lesion and the typical onset of symptoms in late adolescence/early adult life. Second, an early neurodevelopmental insult on its own cannot account for the finding of increased extracerebral (sulcal) cerebrospinal fluid space in schizophrenia. Diffuse loss of brain tissue limited to the prenatal or perinatal periods would result in enlargement of the lateral ventricles but not increased extracerebral cerebrospinal fluid space (Woods 1998).

The 'late' neurodevelopmental model, first proposed by Feinberg (1983, 1997), argues that the key neuropathological events in schizophrenia occur as a result of *abnormal* brain development during adolescence. The current formulation of the 'late' neurodevelopmental model proposes that *excessive* synaptic and/or dendritic elimination occurs during adolescence, producing aberrant neural connectivity and psychotic symptoms (Woods 1998; McGlashen & Hoffman 2000). This 'late' model characterizes schizophrenia as a *progressive* late onset neurodevelopmental disorder in contrast to the 'early' model that proposes a *static* lesion during the perinatal period. The 'late' model predicts that progressive structural brain changes and cognitive decline will be seen in adolescence around the onset of psychosis. The excessive synaptic pruning during adolescence proposed in

the ‘late’ model is simply an amplification of the normal process of neuronal remodelling with progressive pruning and elimination of synapses that begins in early childhood and extends through late adolescence (Huttenlocher 1979; Purves & Lichtman 1980). These major regressive changes in adolescence with remodelling of neural connections are likely to be under genetic control, with synaptic elimination in schizophrenia representing an extreme of normal variation (Feinberg 1983). In the ‘late’ model, premorbid abnormalities in early childhood are viewed as non-specific risk factors rather than early manifestations of an underlying schizophrenic neuropathology.

Both the ‘early’ and ‘late’ models suppose that there is a direct and specific expression of the eventual brain pathology as schizophrenic disorder. A third viewpoint, the ‘risk’ model, proposes that early and/or late brain pathology acts as a risk factor rather than a sufficient cause so that its effects can only be understood in the light of an individual’s exposure to other risk and protective factors (Hollis & Taylor 1997). This latter formulation provides a probabilistic model of the onset of schizophrenia in which aberrant brain development is expressed as neurocognitive impairments that interact with the environment to produce psychotic symptoms. The following sections will examine how well current neurobiological research evidence supports these competing neurodevelopmental models of schizophrenia.

Neuropathology

In the post-mortem brains of schizophrenic patients there is an absence of gliosis which is the necessary hallmark of neurodegeneration (Roberts *et al.* 1986). The prominent neuropathology in schizophrenia is not the classic form involving neuronal cell death, but instead a loss or reduction in dendritic spines and synapses which are the elements of neural connectivity (Glantz & Lewis 2000). As a result the brain in schizophrenia is characterized by increased neuronal density, decreased intraneuronal space and reduced overall brain volume. Furthermore, the decrease in dendritic spine density appears to be both region- and disease-specific, being found in the dorsolateral prefrontal cortex (layer 3 pyramidal cells), but not in the visual cortex of schizophrenic patients (Glantz & Lewis 2000). These findings are compatible with the hypothesis of reduced cortical and/or thalamic excitatory inputs to the dorsolateral prefrontal cortex in schizophrenia.

Structural brain abnormalities

Neuroimaging and post-mortem studies have shown that the brain as a whole, and the frontal and temporal cortices in particular, are smaller than in normal subjects (Andreasen *et al.* 1990; Nopoulos *et al.* 1995). Brain volume reductions in schizophrenia are specific to grey matter (Gur *et al.* 2000a), which supports neuropathological findings of increased neuronal density and reduced intraneuronal neurophil rather than neuronal loss (Selemon *et al.* 1995).

Across a range of neuroimaging studies, the volume of the hip-

pocampus and amygdala is reduced bilaterally by 4.5–10% (Nelson *et al.* 1998; Gur *et al.* 2000a). Prefrontal grey matter volume is reduced by about 10% (Gur *et al.* 2000b). Enlargement of the third and lateral ventricles is a consistent finding, with ventricular volume increased by about 40% bilaterally (Lawrie & Abukmeil 1998). Ventricular enlargement is associated with neuropsychological impairment and negative symptoms (Vita *et al.* 1991). Studies of the basal ganglia have produced more inconsistent results, possibly as a function of the increase in basal ganglia volume associated with the use of traditional antipsychotics. Interestingly, when patients are switched to the atypical antipsychotic clozapine there is a reduction in basal ganglia volume (Chakos *et al.* 1995).

The brain changes reported in childhood onset schizophrenia appear to be very similar to those described in adult schizophrenia, supporting the idea of an underlying neurobiological continuity. In the NIMH study of childhood onset schizophrenia (onset less than 12 years of age), subjects had smaller brains than controls, with larger lateral ventricles and reduced prefrontal lobe volume (Jacobsen & Rapoport 1998). Similar to findings from adult studies, reduced total cerebral volume is associated with negative symptoms (Alaghband-Rad *et al.* 1997). The midsagittal thalamic area is decreased while the midsagittal area of the corpus callosum is increased (Giedd *et al.* 1996), suggesting that the reduction in total cerebral volume in childhood onset schizophrenia is caused by relative reduction in grey matter with sparing of white matter. Childhood onset patients have a higher rate of developmental brain abnormalities than controls, including an increased frequency of an enlarged cavum septum pellucidum (Nopoulos *et al.* 1998). Abnormalities of the cerebellum have also been found, including reduced volume of the vermis, midsagittal area and inferior posterior lobe (Jacobsen *et al.* 1997a).

Progressive brain changes

Two different types of progressive brain change have been described in schizophrenia. First, treatment with traditional antipsychotics appears to cause progressive enlargement of the basal ganglia, with these structures returning to their original size when patients are transferred to the atypical antipsychotic clozapine (Frazier *et al.* 1996). Second, there is evidence of progressive volume reductions in the temporal and frontal lobes during the first 2–3 years after the onset of schizophrenia (Gur *et al.* 1998). In the NIMH study of childhood onset schizophrenia, longitudinal repeated magnetic resonance imaging (MRI) scans through adolescence have revealed a progressive increase in ventricular volume and progressive decrease in cortical volume, with frontal (11% decrease) and temporal lobes (7% decrease) disproportionately affected (Rapoport *et al.* 1997, 1999). Both patients and controls showed progressive reductions in frontal and parietal lobe volumes, with schizophrenic subjects showing a relatively greater loss of temporal lobe volume than controls (Jacobsen *et al.* 1998). The reduction seen in temporal lobe structures may occur rather later in the illness course than the re-

duction in frontal lobe and midsagittal thalamic structures. Progressive changes appear to be time-limited to adolescence, with the rate of volume reduction in frontal and temporal structures declining as subjects reach adult life.

Because progressive brain changes have been described *after* the onset of psychosis, it is possible that they are a consequence of neurotoxic effects of psychosis. Evidence that progressive brain changes precede the onset of psychosis is very limited. Pantelis *et al.* (2000) have provided a preliminary report of brain MRI findings in high-risk subjects scanned before and after the transition into psychosis. For those subjects that developed psychosis there were longitudinal volume reductions in the medial temporal region (hippocampus, entorhinal cortex, inferior frontal and fusiform gyrus). There were no significant longitudinal changes in cases that remained non-psychotic. These are exciting findings and, if replicated, provide strong support for the idea that excessive developmental reductions in temporal lobe volume have a key role in the onset of psychosis.

Functional brain imaging

The emergence of functional brain imaging technology has provided a unique opportunity to link symptoms and cognitive deficits in schizophrenia to underlying brain activity. Liddle *et al.* (1992) studied the relationship between symptom dimensions (negative, positive and disorganization) in adult schizophrenic subjects and regional cerebral blood flow (rCBF) using positron emission tomography (PET). Negative symptoms (e.g. affective blunting, avolition and alogia) were associated with reduced rCBF in the dorsolateral prefrontal cortex (DLPFC). Disorganization (e.g. formal thought disorder and bizarre behaviour) was associated with reduced rCBF in the right ventrolateral prefrontal cortex and increased rCBF in the anterior cingulate. Positive symptoms (e.g. hallucinations and delusions) were associated with increased rCBF in the left medial temporal lobe, and reduced rCBF in the posterior cingulate and left lateral temporal lobe. The most consistent association in the literature, across a variety of imaging methods, has been between negative symptoms and reduced frontal activity.

In a PET study in childhood onset schizophrenia using the Continuous Performance Test (CPT), Jacobsen *et al.* (1997b) reported reduced activation compared with healthy controls in the mid and superior frontal gyrus, and increased activation in the inferior frontal, supramarginal gyrus and insula. Clearly, a simple description of 'hypofrontality' does not capture the complex pattern of changes involving interconnected frontal areas. Likewise older localizationist models, based on focal cerebral dysfunction in schizophrenia, have tended to give way to more dynamic models of cerebral 'disconnectivity' based on dysfunctional neural networks or systems. Models of cerebral connectivity view normal higher brain function as depending on the integrated activity of widely distributed neurocognitive networks, rather than the activity of discrete brain areas in isolation (Bullmore *et al.* 1997). In normal individuals, the functional anatomy of a verbal fluency task (generation of words beginning

with a given letter) can be examined using PET and has consistently shown activation of the left DLPFC and reciprocal deactivation of the superior temporal gyrus (STG). A number of investigators have reported a failure of STG deactivation (disconnectivity) in schizophrenic patients during a verbal fluency task (Friston *et al.* 1995; Donlan *et al.* 1996). This left DLPFC–STG disconnectivity appears to be state-related, being only found in symptomatic patients, possibly associated with active auditory hallucinations (Spence *et al.* 2000). In contrast, schizophrenic patients in remission show reduced connectivity between the left DLPFC and anterior cingulate cortex relative to normal controls (Spence *et al.* 2000).

In summary, models of cerebral disconnectivity fit well with both neuropathological and functional neuroimaging findings. This may be one reason for inconsistent neuroanatomical findings in schizophrenia as 'lesions' in different areas of a widely distributed neural system could produce similar functional disturbance.

Magnetic resonance spectroscopy: abnormal neuronal metabolism

Magnetic resonance spectroscopy (MRS) is an imaging technique that can be used to extract *in vivo* information on dynamic biochemical processes at a neuronal level. Proton (^1H) MRS focuses on changes in the neuronal marker *N*-acetyl aspartate (NAA). Studies in adult schizophrenic patients have shown reductions in NAA in the hippocampal area and DLPFC. Similar reductions in NAA ratios specific to the hippocampus and DLPFC (Bertolino *et al.* 1998) and frontal grey matter (Thomas *et al.* 1998) have been reported in childhood onset schizophrenia, suggesting neuronal damage or malfunction in these regions.

Pettegrew *et al.* (1991) used ^{31}P MRS in first episode non-medicated schizophrenic patients and found reduced phosphomonoester (PME) resonance and increased phosphodiester (PDE) resonance in the prefrontal cortex. This result is compatible with reduced synthesis and increased breakdown of connective processes in the prefrontal cortex. A similar finding of reduced PME and increased PDE resonance has been reported in autistic adults, although they showed increased prefrontal metabolic activity which was not seen in schizophrenic subjects (Pettegrew *et al.* 1991). It is possible that excessive synaptic elimination is not specific to schizophrenia, but its timing, location and extent may have crucial implications for the development of executive functions in late childhood and adolescence.

Implications for neurodevelopmental models of schizophrenia

Taken together, the neuropathological and brain imaging findings provide considerable support for the idea of progressive neurodevelopmental changes in schizophrenia including excessive synaptic elimination resulting in aberrant neural connectivity. The progressive nature of brain volume reductions in adolescence, and the fact that reduced brain volume is not

accompanied by reduced intracranial volume, suggests that a static prenatal or perinatal brain insult is insufficient to account for this process. Although early random events in fetal neurodevelopment (e.g. hypoxia, viruses, etc.) may affect baseline synaptic density, genetically determined excessive synaptic elimination as proposed by the ‘late’ neurodevelopmental model may be the neurobiological process underlying disorders in the schizophrenia spectrum (McGlashen & Hoffman 2000). What is unclear is whether excessive synaptic elimination in the prefrontal cortex (and possibly other brain regions) is a sufficient cause for psychosis to occur, or whether it provides a vulnerable neurocognitive substrate that must interact with environmental stressors (e.g. cognitive or social demands) to produce psychotic symptoms.

Genetics of schizophrenia

Multigene models of risk

Twin studies have suggested the heritability of schizophrenia to be as high as 83% (Cannon *et al.* 1998). However, one of the most significant implications of twin, adoption and family studies in schizophrenia has been the challenge the results pose to traditional qualitatively distinct categories of disorder (Rutter & Plomin 1997). Quantitative genetic studies have shown that the genetic liability to schizophrenia extends to schizotypal personality disorders and other conditions viewed as lying on the broader schizophrenia spectrum (Kendler *et al.* 1993, 1995; Erlenmeyer-Kimling *et al.* 1995). These results suggest that what is inherited in schizophrenia is unlikely to be a discrete disorder but normal dimensions of personality that determine liability to disorder. Non-psychotic relatives of schizophrenic patients show eye-tracking deficits that correlate with subtle frontal lobe dysfunction (O’Driscoll *et al.* 1999). Hence, reduced prefrontal activation may be one expression of a genetic susceptibility to schizophrenia.

While the mode of inheritance in schizophrenia remains unknown, the most widely accepted models are polygenic. These models propose that schizophrenia results from the combined action of multiple genes of small effect which confer susceptibility to the schizophrenic phenotype. Susceptibility to the disorder is expressed as a dimension in the population: the risk of schizophrenia in the population is distributed normally not binomially (a continuously distributed risk vs. a risk of 0 or 1). Because there are likely to be multiple genes involved, each conferring only a small part to the susceptibility to schizophrenia, there is little prospect of identifying ‘the gene for’ schizophrenia. Hence, the genetics of schizophrenia is moving away from the rather simplistic (albeit attractive) notion of finding a gene for the disorder, towards a search for genes that confer susceptibility traits (described earlier as ‘schizotaxia’). Susceptibility alleles may be quite common in the population and hence the predictive value of any individual allele will be low.

Because genes affect brain development and resultant cogni-

tive function, susceptibility to schizophrenia is most likely to lie at the levels of aberrant brain development and neurocognitive deficits. According to the neurodevelopmental ‘risk’ model, it is the interaction of neurodevelopmental and cognitive deficits with environmental factors that will result in the expression of the schizophrenic phenotype (Hollis & Taylor 1997). It is commonly assumed that genes affecting brain development in schizophrenia are only expressed during fetal neurodevelopment. However, genes can affect ‘late’ as well as ‘early’ brain development. Hence, it is quite possible that while some susceptibility genes for schizophrenia may affect fetal brain development, other genes do not exert their effect until adolescence, possibly causing excessive or aberrant synaptic pruning with reduction in temporal and frontal lobe volume (Feinberg 1997).

Molecular genetic strategies are attempting to identify susceptibility genes for schizophrenia and current interest is focusing on chromosomes 15, 10 and 5. However, despite many claims of linkage, there has been little replication across studies (DeLisi & Crow 1999). The association between schizophrenia and chromosomal deletions offers another possible clue to the location of candidate genes. The velocardiofacial syndrome (VCFS) microdeletion on chromosome 22q11 is associated with learning difficulties, short stature, palate abnormalities, cardiac anomalies and parkinsonism (see Skuse & Kuntsi, Chapter 13). VCFS has also been associated with schizophrenia, occurring at a rate of 2% compared to 0.02% in the normal population (Karayiorgou *et al.* 1995). VCFS appears to be associated with an earlier age of onset of schizophrenia in adults (Cohen *et al.* 1999). In the NIMH study of childhood onset schizophrenia, five cases out of 47 (10.6%) had previously undetected cytogenetic abnormalities (Nicholson *et al.* 1999). These included 3 of 47 (6.3%) with VCFS, one with Turner syndrome (deletion of a long arm of one X chromosome), and one with a balanced translocation of chromosomes 1 and 7. One study has reported an association, found only in males, between childhood onset schizophrenia and an excess of CAG/CTG trinucleotide expansions (Burgess *et al.* 1998). These findings point to genetic heterogeneity in early onset forms of schizophrenia.

Genetic risk and early onset schizophrenia

If there is a continuum of transmitted liability for schizophrenia then, as with other disorders of presumed multifactorial origin, early onset cases of schizophrenia should be associated with a greater genetic loading (Childs & Scriver 1986). Pulver *et al.* (1990) found an increased morbidity risk of schizophrenia in relatives of male probands under the age of 17. Meanwhile, Sham *et al.* (1994) found an increased morbidity risk in females under age 21 compared with males or later onset females. Although both these studies suggest an inverse relationship between age at onset and transmitted liability, albeit with different gender specific effects and age cut-offs, it would be dangerous to simply extrapolate these age trends to a younger childhood onset population. Unfortunately, there is a dearth of genetic studies of childhood onset schizophrenia which have used ad-

equate methodology. In the only major twin study of childhood onset schizophrenia, Kallman & Roth (1956) reported an uncorrected monozygotic concordance rate of 88.2% and a dizygotic concordance rate of 22.9%. Adult onset schizophrenia clustered in the families of childhood onset probands, providing support for a similar genetic aetiology. Data from family studies suggest that childhood and adolescent onset schizophrenia carries a greater familial risk of psychosis than adult onset schizophrenia. In the Maudsley study, Hollis (1999) found 20% of child and adolescent onset schizophrenia cases had at least one first-degree relative with schizophrenia, and 50% had a first-degree relative with psychosis. These rates are somewhat higher than those reported by Sham *et al.* (1994) for adult schizophrenia probands (13% of adult probands had a first-degree relative with schizophrenia and 23% had a first-degree relative with any psychosis). Data from the Maudsley study (Hollis 1999) also showed that the presence of negative symptoms in the proband predicted a family history of schizophrenia. This provides further support for the idea that negative symptoms may represent the genetically transmitted phenotype in schizophrenia (Tsuang 1993).

Neuropsychology of schizophrenia

Pattern of cognitive deficits

There is growing awareness that cognitive deficits in schizophrenia are a core feature of the disorder and cannot simply be dismissed as secondary consequences of psychotic symptoms (Breier 1999). The degree of cognitive impairment is greater in child and adolescent onset than in adult onset patients. A consistent finding is a mean IQ of between 80 and 85 (1 SD below the population mean), with about one-third of cases having an IQ below 70 (Jacobsen & Rapoport 1998; Hollis 1999). This represents a mean IQ score about 10 points lower than the mean IQ in adult schizophrenia. These findings raise several important questions.

- 1 Are the cognitive deficits specific or generalized; are some aspects of cognitive functioning affected more than others?
- 2 Which deficits precede the onset of psychosis and could be causal, and which are consequences of psychosis?
- 3 Is the pattern of deficits specific to schizophrenia or shared with other developmental and psychotic disorders?
- 4 Are cognitive impairments progressive or static after the onset of psychosis?

Recent research (Asarnow *et al.* 1994a, 1995) suggests that children with schizophrenia have specific difficulties with cognitive tasks that make demands on short-term working memory and selective and sustained attention and speed of processing. These deficits are similar to the deficits reported in adult schizophrenia (Nuechterlein & Dawson 1984; Saykin *et al.* 1994). Deficits of attention and of short-term and recent long-term memory have also been reported in adolescents with schizophrenia (Friedman *et al.* 1996). In contrast, well-established

'overlearned' rote language and simple perceptual skills are unimpaired in child and adolescent onset schizophrenia. Asarnow *et al.* (1991, 1995) have shown that children with schizophrenia have impairments on the span of apprehension task (a target stimulus has to be identified from an array of other figures when displayed for 50 ms). Performance on the task deteriorates markedly when increasing demands are made on information processing capacity (e.g. increasing the number of letters in the display from 3 to 10). Furthermore, evoked-potential studies using the span of apprehension task in both children and adults with schizophrenia, when compared with age-matched controls, show less negative endogenous activity measured between 100 and 300 ms after the stimulus. Similar findings of reduced event-related potentials have been found during the CPT in both childhood and adult onset schizophrenia (Strandburg *et al.* 1999). These findings indicate a deficit in the allocation of attentional resources to a stimulus (Strandburg *et al.* 1994; Asarnow *et al.* 1995). As with adults, children and adolescents with schizophrenia show high basal autonomic activity and less autonomic responsivity than controls (Gordon *et al.* 1994), with attenuated increases in skin conductance following the presentation of neutral sounds (Zahn *et al.* 1997). Childhood onset patients, like adults, show increased reaction times with a loss of ipsimodal advantage compared with healthy controls (Zahn *et al.* 1998). Abnormalities in smooth pursuit eye movements (SPEM) have also been found in adolescents with schizophrenia (mean age 14.5), which suggests continuity with the finding of abnormal SPEM in adults with schizophrenia (Iacono & Koenig 1983). Children with schizophrenia also show similar impairments to adult patients on tests of frontal lobe executive function such as the Wisconsin Card Sorting Test (WCST; Asarnow *et al.* 1994a).

In summary, whereas basic sensorimotor skills, associative memory and simple language abilities tend to be preserved in children with schizophrenia, deficits are most marked on tasks that require focused and sustained attention, flexible switching of cognitive set, high information processing speed and suppression of prepotent responses (Asarnow *et al.* 1995). Similar deficits have also been found in children genetically at 'high-risk' for schizophrenia (Erlenmeyer-Kimling & Cornblatt 1992) and non-psychotic relatives of schizophrenic probands (Park *et al.* 1995). This strengthens the argument that cognitive deficits cannot be simply dismissed as non-specific consequences of schizophrenic symptoms, but rather are likely to be indicators of underlying genetic and neurobiological risk.

These diverse cognitive processes have been integrated under the cognitive domain of 'executive functions', which are presumed to be mediated by the prefrontal cortical system. Executive function skills are necessary to generate and execute goal-directed behaviour, especially in novel situations. Goal-orientated actions require that information in the form of plans and expectations are held 'on-line' in working memory, and flexibly changed in response to feedback. Much of social behaviour and social development would appear to depend on these capacities as they involve integration of multiple sources of informa-

tion, appreciation of others' mental states, inhibition of inappropriate prepotent responses and rapid shifting of attention.

Executive functions and onset of schizophrenia

Any cognitive theory of schizophrenia will need to explain the timing of onset during adolescence or early adulthood. Deficits in executive function and social cognition could be the developmental abnormality that predisposes to schizophrenia, as executive function deficits impinge on social skills that usually emerge in early adolescence. This period is associated with a rapid growth in abstract analytical skills, together with the development of the sophisticated social and communication abilities that underlie successful social relationships. It is during this period of development (approximately age 8–15 years) that preschizophrenic social impairments become most apparent (Done *et al.* 1994) and there is also relative decline in cognitive abilities in preschizophrenic subjects (Jones *et al.* 1994).

According to this 'risk' model of executive function deficit, the onset of psychosis would depend on the interaction between social and cognitive capacities and the demands of the environment. During adolescence, increasing academic and social demands may act as stressors on a 'high-risk' subject, pushing them over the threshold for psychosis. The greater the premorbid impairment, the earlier the age that a critical liability threshold will be passed and symptoms emerge. This model would predict that similar executive function deficits are found in non-psychotic genetically 'high-risk' relatives. However, executive functions deficits are probably not a primary cause of schizophrenia given that they also occur in other neurodevelopmental disorders including autism (Ozonoff *et al.* 1991; Hughes & Russell 1993) and attention deficit hyperactivity disorder (ADHD; Welsh *et al.* 1991; Pennington *et al.* 1993; Karatekin & Asarnow 1998).

Course of cognitive deficits

Kraepelin's term 'dementia praecox' implied a progressive cognitive decline as part of the disease process. Jones *et al.* (1994) described how academic performance becomes progressively more deviant during adolescence in those individuals destined to developed schizophrenia in adult life. There is also some tentative evidence for a possible slight decline in IQ following the onset of psychosis in childhood onset schizophrenia. In the NIMH study (Alaghband-Rad *et al.* 1995), the mean post-psychotic IQ was 83.7 (SD 17.3) compared with a mean pre-psychotic IQ of 87.7 (SD 25.4). Although a decline in IQ during the early phase of psychosis has been reported in adults with schizophrenia (Bilder *et al.* 1992), in the NIMH study the decline was in both raw and scaled IQ scores and continued for up to 24–48 months after onset (Jacobsen & Rapoport 1998). There was no evidence for a decline in post-psychotic IQ raw scores repeated after 2 years, although scaled (age-adjusted) IQ scores did still decline (Bedwell *et al.* 1999). Russell *et al.* (1997) found a small non-significant IQ decline of only 2–3 points in a 20-year longi-

tudinal follow-up study of IQ in schizophrenia (about one-third of these cases had first onset of psychosis in adolescence).

In summary, when raw scores, rather than scaled scores, are analysed, there is little evidence for an absolute loss in cognitive ability in the early post-psychotic phase of schizophrenia. If a true decline does occur it is during, or before, the transition to psychosis. The small drop in IQ after the onset of psychosis could possibly be caused by the effect of psychotic symptoms on performance. Overall, the evidence points more to a premature arrest, or slowing, of normal cognitive development in child and adolescent onset schizophrenia rather than to a dementia.

Assessment

The assessment of a child or adolescent with possible schizophrenia should include a detailed history, mental state and physical examination. In addition, a baseline psychometric assessment is desirable. A detailed understanding of specific cognitive deficits in individual cases of adolescent schizophrenia can be particularly helpful in guiding education and rehabilitation. In the physical examination, particular attention should be given to detecting dysmorphic features that may betray an underlying genetic syndrome. The neurological examination should focus on abnormal involuntary movements and other signs of extrapyramidal dysfunction. Spontaneous abnormal involuntary movements have been detected in a proportion of drug-naive first-episode schizophrenic or schizophreniform patients as well as in those receiving typical antipsychotics (Gervin *et al.* 1998).

Developmental issues

The cognitive level of the child will influence his or her ability to understand and express complex psychotic symptoms, such as passivity phenomena, thought alienation and hallucinations. In younger children careful distinctions have to be made between developmental immaturity and psychopathology; e.g. distinguishing true hallucinations from other subjective phenomena, such as dreams, may be difficult for young children. Developmental maturation can also affect the localization of hallucinations in space. Internal localization of hallucinations is more common in younger children and makes these experiences more difficult to differentiate subjectively from inner speech or thoughts (Garralda 1984). Formal thought disorder may also appear very similar to the pattern of illogical thinking and loose associations seen in children with immature language development. Negative symptoms can appear very similar to non-psychotic language and social impairments and can also be easily confused with anhedonia and depression.

Differential diagnosis

Psychotic symptoms in children and adolescence are diagnostically non-specific, occurring in a wide range of functional psy-

Table 37.2 Differential diagnosis of schizophrenia in childhood and adolescence.

Psychoses	Affective psychoses (bipolar/major depressive disorder) Schizoaffective disorder Atypical psychosis
Developmental disorders	Autism spectrum disorders (Asperger syndrome) Developmental language disorder Schizotypal personality disorder 'Multidimensionally impaired' disorder
Organic conditions	Drug-related psychosis (amfetamines, 'ecstasy', LSD, PCP) Complex partial seizures (temporal lobe epilepsy) Wilson disease Metachromatic leukodystrophy

LSD, lysergic acid diethylamide; PCP, phencyclidine.

chiatric and organic brain disorders. The differential diagnosis of schizophrenia in childhood and adolescence is summarized in Table 37.2. A summary of physical investigations in children and adolescents with suspected schizophrenia is listed in Table 37.3.

Affective, schizoaffective and 'atypical' psychoses

The high rate of positive psychotic symptoms found in adolescent onset major depression and mania can lead to diagnostic confusion (Joyce 1984). Affective psychoses are most likely to be misdiagnosed as schizophrenia if a Schneiderian concept of schizophrenia is applied with its emphasis on first-rank symptoms. Because significant affective symptoms also occur in about one-third of first-episode patients with schizophrenia, it may be impossible to make a definitive diagnosis on the basis of a single cross-sectional assessment. In DSM-IV the distinction between schizophrenia, schizoaffective disorder and affective psychoses is determined by the relative predominance and temporal overlap of psychotic symptoms (hallucinations and delusions) and affective symptoms (elevated or depressed mood). Given the difficulty in applying these rules with any precision, there is a need to identify other features to distinguish between schizophrenia and affective psychoses. Irrespective of the presence of affective symptoms, the most discriminating symptoms of schizophrenia are an insidious onset and the presence of negative symptoms (Hollis 1999). Similarly, complete remission from a first psychotic episode within 6 months of onset is the best predictor of a diagnosis of affective psychosis (Hollis 1999). Schizoaffective and atypical psychoses are unsatisfactory diagnostic categories with low predictive validity and little longitudinal stability (Hollis 2000).

Autistic spectrum and developmental language disorders

Some children on the autistic spectrum or with Asperger syn-

drome have social and cognitive impairments that overlap closely with the premorbid phenotype described in schizophrenia. Furthermore, children on the autistic spectrum can also develop psychotic symptoms in adolescence (Volkmar & Cohen 1991). Towbin *et al.* (1993) have labelled another group of children who seem to belong within the autistic spectrum as 'multiplex developmental disorder'. An increased risk for psychosis has also been noted in developmental language disorders (Rutter & Mawhood 1991). While some children on the autistic spectrum can show a clear progression into classic schizophrenia, others show a more episodic pattern of psychotic symptoms without the progressive decline in social functioning and negative symptoms characteristic of child and adolescent onset schizophrenia.

Often, it is only possible to distinguish between schizophrenia and disorders on the autistic spectrum by taking a careful developmental history that details the age of onset and pattern of autistic impairments in communication, social reciprocity and interests/behaviours. According to DSM-IV, schizophrenia cannot be diagnosed in a child with autism/pervasive developmental disorder (PDD) unless hallucinations/delusions are present for at least 1 month. DSM-IV does not rank the active phase symptoms of thought disorder, disorganization or negative symptoms as sufficient to make a diagnosis of schizophrenia in the presence of autism. In contrast, ICD-10 does not include autism/PDD as exclusion criteria for diagnosing schizophrenia.

Multidimensionally impaired syndrome and schizotypal personality disorder

Multidimensionally impaired (MDI) syndrome is a label applied to children who have brief transient psychotic symptoms, emotional lability, poor social skills and multiple deficits in information processing (Gordon *et al.* 1994). The diagnostic status of this group remains to be resolved. Short-term follow-up suggests that they do not develop full-blown schizophrenic psychosis; however, they have an increased risk of schizophrenia-spectrum disorders among first-degree relatives and the neurobiological findings (e.g. brain morphology) are similar to those in childhood onset schizophrenia (Kumra *et al.* 1998a). This group may possibly represent a genetically high-risk phenotype for schizophrenia rather than a prodromal state.

Children with schizotypal personality disorder (SPD) lie on a phenotypic continuum with schizophrenia and have similar cognitive and social impairments and are prone to magical thinking, mood disturbances and non-psychotic perceptual disturbances. Distinction from the prodromal phase of schizophrenia is particularly difficult when there is a history of social and academic decline without clear-cut or persisting psychotic symptoms. It has been reported that negative symptoms and attention in SPD improve with a low dose of risperidone (0.25–2.0 mg) (Rossi *et al.* 1997).

Table 37.3 Physical investigations in child and adolescent onset psychoses.

Investigation	Target disorder
Urine drug screen	Drug-related psychosis (amphetamines, 'ecstasy', cocaine, LSD and other psychoactive compounds)
EEG	Complex partial seizures/TLE
MRI brain scan	Ventricular enlargement, structural brain anomalies (e.g. cavum septum pellucidum) Enlarged caudate (typical antipsychotics) Demyelination (metachromatic leukodystrophy) Hypodense basal ganglia (Wilson disease)
Serum copper and caeruloplasmin Urinary copper	Wilson disease
Arylsulphatase A (white blood cell)	Metachromatic leukodystrophy
Karyotype/cytogenetics (FISH)	Sex chromosome aneuploidies, velocardiofacial syndrome (22q11 microdeletion)

EEG, electroencephalogram; FISH, fluorescent *in situ* hybridization; LSD, lysergic acid diethylamide; MRI, magnetic resonance imaging; TLE, temporal lobe epilepsy.

Epilepsy

Psychotic symptoms can occur in temporal and frontal lobe partial seizures. A careful history is usually sufficient to reveal an aura followed by clouding of consciousness and the sudden onset of brief ictal psychotic phenomena accompanied often by anxiety, fear, derealization or depersonalization. However, longer lasting psychoses associated with epilepsy can occur in clear consciousness during post-ictal or interictal periods (Sachdev 1998). In epileptic psychoses, hallucinations, disorganized behaviour and persecutory delusions predominate, while negative symptoms are rare. Children with complex partial seizures also have increased illogical thinking and use fewer linguistic-cohesive devices which can resemble formal thought disorder (Caplan *et al.* 1992). A PET study showed hypoperfusion in the frontal, temporal and basal ganglia in psychotic patients with epilepsy compared with non-psychotic epileptic patients (Gallhofer *et al.* 1985).

Epilepsy and schizophrenia may co-occur in the same individual, so that the diagnoses are not mutually exclusive. The onset of epilepsy almost always precedes psychosis unless seizures are secondary to antipsychotic medication. In a long-term follow-up of 100 children with temporal lobe epilepsy, 10% developed schizophrenia in adult life (Lindsay *et al.* 1979).

An electroencephalogram (EEG) should be performed if a seizure disorder is considered in the differential diagnosis or arises as a side-effect of antipsychotic treatment. Ambulatory EEG monitoring and telemetry with event recording may be required if the diagnosis remains in doubt.

Neurodegenerative disorders

Rare neurodegenerative disorders with onset in late childhood and adolescence can mimic schizophrenia. The most important

examples are Wilson disease (hepatolenticular degeneration) and metachromatic leukodystrophy. These disorders usually involve significant extrapyramidal symptoms (e.g. tremor, dystonia, bradykinesia) or other motor abnormalities (e.g. unsteady gait) and a progressive loss of skills (dementia) that can aid the distinction from schizophrenia. Suspicion of a neurodegenerative disorder is one of the clearest indications for brain MRI in adolescent psychoses. Adolescents with schizophrenia show relative grey matter reduction with white matter sparing. In contrast, metachromatic leukodystrophy is characterized by frontal and occipital white matter destruction and demyelination. In Wilson disease hypodense areas are seen in the basal ganglia, together with cortical atrophy and ventricular dilatation. The pathognomonic Kayser–Fleischer ring in Wilson disease begins as a greenish-brown crescent-shaped deposit in the cornea above the pupil; this is most easily seen during slit lamp examination. In Wilson disease there is increased urinary copper excretion, and reduced serum copper and serum caeruloplasmin levels. The biochemical marker for metachromatic leukodystrophy is reduced arylsulphatase-A (ASA) activity in white blood cells. This enzyme deficiency results in a deposition of excess sulphatides in many tissues including the central nervous system.

Drug psychoses

Drug use is common among young people, so the co-occurrence of drug use and psychosis is to be expected, but what is less certain is the nature of any causal connection. Psychotic symptoms can occur as a direct pharmacological effect of intoxication with stimulants (amphetamines, ecstasy, cocaine), hallucinogens (lysergic acid diethylamide 'LSD', psilocybin 'magic mushrooms', mescaline) and cannabis (Poole & Brabbins 1996). The psychotic symptoms associated with drug intoxication are usually short-lived and resolve within a few days of abstinence from the

drug. These drugs can have surprisingly long half-lives, with cannabinoids still measurable up to 6 weeks after a single dose. Psychotic symptoms in the form of ‘flashbacks’ can also occur after cessation from chronic cannabis and LSD abuse. These phenomena are similar to alcoholic hallucinosis and typically involve transient vivid auditory hallucinations occurring in clear consciousness.

It is often assumed that there is a simple causal relationship between drug use and psychosis, with any evidence of drug use excluding the diagnosis of a functional psychosis. However, drug use can also be a consequence of psychosis, with patients using drugs to ‘treat’ their symptoms in the early stages of a psychotic relapse. Overall, there is very little evidence to invoke a separate entity of ‘drug-induced’ psychosis in cases where psychotic symptoms arise during intoxication but then persist after the drug is withdrawn (Poole & Brabbins 1996). Patients whose so-called ‘drug-induced’ psychoses last for more than 6 months appear to have more clear-cut schizophrenic symptoms, a greater familial risk for psychosis and greater premorbid dysfunction (Tsuang *et al.* 1982). DSM-IV takes the sensible position that a functional psychosis should not be excluded unless there is compelling evidence that symptoms are entirely caused by drug use.

Other investigations

Whether any physical investigations should be viewed as ‘routine’ is debatable. However, it is usual to obtain a full blood count and biochemistry including liver and thyroid function and a drug screen (urine or hair analysis). The high yield of cytogenetic abnormalities reported in childhood onset schizophrenia (Kumra *et al.* 1998b; Nicholson *et al.* 1999) suggest the value of cytogenetic testing, including karyotyping for sex chromosome aneuploidies and fluorescent *in situ* hybridization (FISH) for chromosome 22q11 deletions (VCFS). The evidence of progressive structural brain changes (Rapoport *et al.* 1999) indicate the value of obtaining a baseline and annual follow-up MRI brain scans, although this is not a diagnostic test.

Assessment interviews and rating scales

Structured diagnostic investigator-based interviews that cover child and adolescent psychotic disorders include the Schedule for Affective Disorders and Schizophrenia for School-Age Children (Kiddie-SADS; Ambrosini 2000), the Child and Adolescent Psychiatric Assessment (CAPA; Angold & Costello 2000) and the Diagnostic Interview for Children and Adolescents (DICA; Reich 2000). The DSM and ICD definitions of schizophrenia do not provide symptom definitions so the detailed glossaries that accompany these interviews are particularly useful.

Rating scales give quantitative measures of psychopathology and functional impairment. Scales to assess positive and negative psychotic symptoms include the Scale for Assessment of Positive Symptoms (SAPS; Andreasen 1984), the Scale for As-

essment of Negative Symptoms (SANS; Andreasen 1983) and the Positive and Negative Syndrome Scale (PANSS; Kay *et al.* 1987). The 30-item Kiddie Positive and Negative Syndrome Scale (K-PANSS) has been developed for use in children and adolescents, and contains three subscales: positive syndrome, negative syndrome and general psychopathology (Fields *et al.* 1994). The Children’s Global Assessment Scale (C-GAS) provides a rating of functional impairment on a 0–100 scale (Shaffer *et al.* 1983; Bird *et al.* 1987). These scales can be used to record the longitudinal course of illness and treatment response. The Kiddie Formal Thought Disorder Story Game and Kiddie Formal Thought Disorder Scale (Caplan *et al.* 1989) are research instruments produced for the assessment of thought disorder in children. Assessments of extrapyramidal symptoms and involuntary movements can be made using the Abnormal Involuntary Movements Scale (AIMS; Rapoport *et al.* 1985) and the Simpson–Angus Neurological Rating Scale (Simpson & Angus 1970).

Treatment approaches

General principles

Although antipsychotic drugs remain the cornerstone of treatment in child and adolescent schizophrenia, all young patients with schizophrenia require a multimodal treatment package that includes pharmacotherapy, family and individual counselling, education about the illness and provision to meet social and educational needs (Clark & Lewis 1998).

Primary prevention and early detection

In theory at least, the onset of schizophrenia could be prevented if an intervention reduced the premorbid ‘risk’ status. However, the difficulty with the premorbid phenotype as currently conceived (subtle social and developmental impairments) is its extremely low specificity and positive predictive value for schizophrenia in the general population, assuming that these premorbid features are a causal risk factor. Future refinement of the premorbid phenotype is likely to include genetic and neurocognitive markers in order to achieve acceptable sensitivity and specificity. At present, primary prevention remains on the distant horizon.

In contrast to primary prevention, the aims of early detection are to identify the onset of deterioration in vulnerable individuals with a high predictive validity. Predictive power increases markedly in adolescence around the onset of the prodrome (Davidson *et al.* 1999). Recent work has attempted to identify ‘high-risk’ or early prodromal states with the idea of intervening to prevent the active phase of schizophrenia (McGorry & Singh 1995; Yung *et al.* 1996). However, only about one-fifth of these ‘high-risk’ cases go on to develop frank psychosis and it has proved impossible to distinguish these ‘high-risk’ cases from others that remain non-psychotic. Clearly, interventions

directed at 'high-risk' or prodromal states need to benefit the whole population at risk, the majority of whom will not develop schizophrenia. A pragmatic stance would be to monitor children and adolescents with a strong family history and/or suggestive prodromal symptoms to ensure prompt treatment of psychosis.

Strong claims have been made that early recognition and treatment of psychotic symptoms in schizophrenia improves outcome. The association between a long duration of untreated psychosis (DUP) and poor long-term outcome in schizophrenia (Loebel *et al.* 1992; Wyatt 1995; Birchwood *et al.* 1997) supports this view. A similar association has been found in child and adolescent onset psychoses (Hollis 1999). Whereas the association between DUP and poor outcome seems secure, the causal connection is far less certain. DUP is also associated with insidious onset and negative symptoms which could confound links with poor outcome. Although there are good a priori clinical reasons for the early treatment of symptoms to relieve distress and prevent secondary impairments, as yet it remains unproven whether early intervention actually alters the long-term course of schizophrenia.

Pharmacological treatments

Because of the very small number of trials of antipsychotics conducted with child and adolescent patients, it is necessary to extrapolate most evidence on drug efficacy from studies in adults. This seems a reasonable approach given that schizophrenia is essentially the same disorder whether it has onset in childhood or adult life. However, age-specific factors, such as the greater risk of extrapyramidal side-effects (EPS) and treatment resistance to traditional antipsychotics in younger patients (Kumra *et al.* 1998c), should also influence drug choice.

Antipsychotics can be broadly divided into the traditional 'typical' and newer 'atypical' drugs. The typical drugs include haloperidol, chlorpromazine and trifluoperazine which block D₂ receptors, produce catalepsy in rats, raise plasma prolactin and induce EPS. The newer atypical drugs are so-called because, while they are effective antipsychotics, they are 'atypical' in the sense that they do not produce catalepsy, do not raise prolactin levels and produce significantly fewer EPS. The atypicals have been introduced during the 1990s (clozapine was introduced in 1970 but then withdrawn following fatal blood dyscrasias) and currently include clozapine, risperidone, olanzapine, quetiapine, zotepine, amisulpiride and ziprasidone. The pharmacological profile of the atypicals is diverse, involving various combinations of 5-HT and dopamine receptor blockade. Interestingly, the therapeutic effects of clozapine (potent affinity for D₄ and 5-HT_{1,2,3} receptors) are independent of D₂ receptor occupancy, previously thought to be essential for antipsychotic action.

The typical antipsychotic haloperidol has been shown to be superior to placebo in two double-blind controlled trials of children and adolescents with schizophrenia (Pool *et al.* 1976; Spencer & Campbell 1994). It is estimated that about 70% of patients show good or partial response to antipsychotic treat-

ment although this may take 6–8 weeks to be apparent (Clark & Lewis 1998). The main drawbacks concerning the use of high-potency typicals such as haloperidol in children and adolescents are the high risk of EPS (produced by D₂ blockade of the nigrostriatal pathway), tardive dyskinesia and the lack of effect against negative symptoms and cognitive impairment. Treatment with typical antipsychotics is also associated with enlargement of the caudate nucleus, which can be reversed with clozapine (Frazier *et al.* 1996). Clozapine (the prototypic atypical) has been shown to be superior to haloperidol in a double-blind trial of 21 cases of childhood onset schizophrenia (Kumra *et al.* 1996). Larger open clinical trials of clozapine confirm its effectiveness in child and adolescent onset schizophrenia (Siefen & Remschmidt 1986; Remschmidt *et al.* 1994). Similar, although less marked, benefits of olanzapine over typical antipsychotics in childhood onset schizophrenia have been reported (Kumra *et al.* 1998d).

Drawing together this evidence, a strong case can be made for the first-line use of atypicals in child and adolescent schizophrenia (clozapine is only licensed in the UK for treatment-resistant schizophrenia). Treatment resistance in child and adolescent patients should be defined as follows:

- 1 non-response with at least two conventional antipsychotics (from different chemical classes) each used for at least 4–6 weeks; and/or
- 2 significant adverse effects with conventional antipsychotics.

Whereas atypicals reduce the risk of EPS, they can produce other troublesome side-effects (usually dose-related) including weight gain (olanzapine), sedation, hypersalivation and seizures (clozapine). The risk of blood dyscrasias on clozapine is effectively managed by mandatory routine blood monitoring. However, knowledge of potential adverse reactions with the newest atypicals is very limited in child and adolescent patients. A further consideration is the cost of newer atypicals compared with traditional antipsychotics. In the UK, a 1-month supply of haloperidol costs less than £2, compared with £100–120 for the newer atypicals, and £200 for clozapine. Although economic studies of cost-effectiveness have suggested that the costs of the atypicals are recouped in reduced inpatient stays and indirect social costs (Aitchison & Kerwin 1997), the availability of these drugs, particularly in developing countries, may well be limited because of their high cost. In the late 1990s, the use of atypical antipsychotics by child psychiatrists in the UK was still low. Over a 2-year period, only 10% of child and adolescent psychiatrists who prescribed antipsychotics in the Trent Health Region had used an atypical drug (Slaveska *et al.* 1998).

Currently, there is no clear consensus about the choice of antipsychotics in children and adolescents with schizophrenia. Some authorities suggest starting with a trial of a traditional antipsychotic (e.g. haloperidol) with substitution of an atypical if the traditional antipsychotic is either not tolerated or ineffective after 6–8 weeks (Clark & Lewis 1998). However, clinical trial evidence suggests that clozapine is the most effective antipsychotic in child and adolescent onset schizophrenia, although its use is restricted to treatment-resistant cases.

A very powerful case can be made for using atypicals such as olanzapine or risperidone as a first-line treatment given that child and adolescent onset schizophrenia is characterized by negative symptoms, cognitive impairments, sensitivity to EPS and relative resistance to traditional antipsychotics.

Psychosocial and family interventions

The rationale for psychosocial family interventions follows from the association between high EE and the risk of relapse in schizophrenia (Leff & Vaughn 1985; Dixon & Lehman 1995). The overall aim is to prevent relapse (secondary prevention) and improve the patient's level of functioning by modifying the family atmosphere. Psychosocial family interventions have a number of principles in common (Lam 1991). First, it is assumed that it is useful to regard schizophrenia as an illness, so patients are less likely to be seen as responsible for their symptoms and behaviour. Secondly, the family is not implicated in the aetiology of the illness. Instead, the burden borne by the family in caring for a disturbed or severely impaired young person is acknowledged. Thirdly, the intervention is offered as part of a broader multimodal package including drug treatment and outpatient clinical management.

Lam (1991) conducted a systematic review of published trials of psychoeducation and more intensive family interventions in schizophrenia and drew the following conclusions.

- 1 Education packages on their own increase knowledge about the illness but do not reduce the risk of relapse.
- 2 More intensive family intervention studies with high EE relatives have shown a reduction in relapse rates linked to a lowering of EE.
- 3 Family interventions tend to be costly and time-consuming, with most clinical trials employing highly skilled research teams. Whether these interventions can be transferred into routine clinical practice is uncertain.
- 4 Interventions have focused on the reduction of EE in 'high-risk' families. Whether low EE families would also benefit from these interventions is less clear. This is particularly relevant to the families of children and adolescents with schizophrenia as, on average, these parents express *lower* levels of criticism and hostility than parents of adult onset patients (Asarnow *et al.* 1994b). Hence, routine family interventions aiming to reduce high EE may be well intentioned but misguided in their focus.

Cognitive-behavioural therapy

In adult patients cognitive therapy has been used to reduce the impact of treatment-resistant positive symptoms (Tarrrier *et al.* 1993). Cognitive-behaviour therapy (CBT) has been shown to improve the short-term (6-month) outcome of adult schizophrenic patients with neuroleptic-resistant positive symptoms (Turkington & Kingdon 2000). Whether CBT is equally effective with younger patients, or those with predominant negative symptoms, remains to be established.

Cognitive remediation

Cognitive remediation is a relatively new psychological treatment that aims to arrest or reverse the cognitive impairments in attention, concentration and working memory seen in schizophrenia (Hays & McGrath 2000; Wykes *et al.* 2000). The results of an early controlled trial in adults are promising, with gains found in the areas of memory and social functioning (Wykes *et al.* 2000). The relatively greater severity of cognitive impairments in child and adolescent patients suggests that early remediation strategies may be particularly important in these younger patients. Helpful advice can also be offered to parents, teachers and professionals, such as breaking down information and tasks into small manageable parts to reduce demands on working memory and speed of processing.

Organization of treatment services

It is a paradox that patients with very early onset schizophrenia have the most severe form of the disorder yet they often receive inadequate and poorly co-ordinated services. Possibly this is because the responsibility for schizophrenia is seen to lie with adult psychiatric services. In the UK, community-based child and adolescent mental health services (CAMHS) provide the first-line assessment and care for children and young adolescents with psychoses, with only about half of these cases referred to inpatient units (Slavenska *et al.* 1998). Although inpatient admission is often inappropriate, generic CAMHS services are often not well placed to provide a comprehensive assessment and treatment service for very early onset psychoses. First, the very low population prevalence of psychosis reduces the predictive value diagnosis outside specialist centres. Second, community-based services often lack familiarity with newer therapies for psychoses including atypical antipsychotics.

One possible model for the UK would be to establish specialist regional very early onset psychosis teams serving a population of about 5 million, akin to specialist cancer centres. These expert teams would be primarily outpatient-based but with access to inpatient facilities if required. Hence, the focus would be quite different from the more traditional general purpose adolescent inpatient unit. The teams could offer early diagnostic assessments for children and younger adolescents with suspected psychotic disorders and set up treatment plans in collaboration with more local child and adult psychiatric services. Ideally, these teams would be linked to a university academic centre with an interest in psychosis research and treatment evaluation.

Conclusions

The last decade has seen a dramatic growth in our understanding of the clinical course and neurobiological correlates of schizophrenia presenting in childhood and adolescence. It is now clear that adult-based diagnostic criteria have validity in this age group and the disorder has clinical and neurobiological continu-

ity with schizophrenia in adults. Childhood onset schizophrenia is a severe variant of the adult disorder, associated with greater premorbid impairment, a higher familial risk, more severe clinical course and poorer outcome. The poor outcome of children and adolescents with schizophrenia has highlighted the need to target early and effective treatments and develop specialist services for this high-risk group. The last decade has witnessed the introduction of new atypical antipsychotics with improved side-effect profiles and efficacy, and these drugs are likely to replace the traditional antipsychotics as first-line drug therapy for schizophrenia.

However, a fundamental understanding of the underlying genetic and neurobiological bases of schizophrenia has still to be achieved. The finding of a progressive reduction in brain volume in very early onset patients and reduced synaptic density in the prefrontal cortex suggest the possibility that excessive synaptic elimination during adolescence may underlie the aetiology of schizophrenia. Although significant advances in the next decade are likely to flow from technical developments in molecular genetics and neuroimaging, advance is also limited by the defining diagnostic paradigm of schizophrenia. It is widely recognized that the clinical syndrome of schizophrenia contains considerable aetiological and clinical heterogeneity. Therefore the challenge will be to identify the genetic, neurobiological and cognitive bases of this heterogeneity. Real advance in the field will depend on a more sophisticated understanding of the interplay between genetics, neurodevelopment and environment. This will involve identifying the molecular genetic basis of neurocognitive susceptibility traits for schizophrenia. The developmental mechanisms that translate neurocognitive risks into disorder will need to be understood. Unravelling neurocognitive and clinical heterogeneity should lead to improvements in our ability to deliver individually targeted treatments, as well the ability to identify those 'at risk' in order to prevent the onset of psychosis.

Introduction

Autistic spectrum disorders are defined by the early onset of a constellation of difficulties in reciprocal social interaction and communication and restricted, repetitive behaviours or interests. They are particularly striking because of the contrast between extraordinary consistency across individuals in some behaviours, and marked differences in others. A child with autism in rural Guatemala peers out of the corner of his eye at flags made of leaves and wooden sticks in the same way that a child in suburban Chicago squints at flags made from McDonald's swizzle sticks and sweetener packets. Yet identical twins with autistic spectrum disorder may vary in IQ scores by as much as 50 points and lead very different lives, with one twin driving his own car to work and the other requiring assistance with basic hygiene.

Over the last 20 years, clinical and research emphasis has shifted from a focus on a relatively narrowly defined group of severely impaired children, to attention to a broader range of autistic disorders that share the core deficits associated with the narrower concept but in which the degree of handicap may be much less. In this chapter, we use *autism* and *autistic disorder* to refer to the narrower traditional diagnostic concept. However, when findings or implications apply more broadly, the term *autistic spectrum disorder* is used. This strategy necessarily makes for some inconsistency because, although research was often carried out only with children with autism, the implications seem likely to apply more broadly.

Clinical and epidemiological studies of autism

Early nineteenth century accounts of children described behaviours that now sound hauntingly familiar (Vaillant 1962), but it was not until nearly 150 years later that Kanner (1943) described 11 children with autism who struck him as sharing 'fascinating peculiarities'. A year later, Asperger independently described a group of children similar in many ways to Kanner's first patients (Frith 1991; Ozonoff *et al.* 1991a). At about the same time, other children who had some characteristics of the autism spectrum were described as having schizophrenia or infantile psychosis (Bender 1942; Mahler 1952). In part, confusion may have been perpetuated by the term *autism*, because of its connotations of an active withdrawal into a rich fantasy life (Bosch 1970). This is misleading, because concreteness and re-

stricted imagination constitute one of the cardinal symptoms of the autism spectrum.

In the 1960s and early 1970s, studies confirmed that children with behaviours similar to those described by Kanner could be discriminated reliably from children with mental handicaps or with other psychiatric disorders (Rutter *et al.* 1967; DeMyer *et al.* 1972). Autism differs from schizophrenia in its much earlier onset, a greater frequency of overt neurological impairment, the relatively frequent onset of seizures in late adolescence, stronger association with mental retardation and a different pattern of cognitive deficits (Rutter 1972a; Volkmar & Nelson 1990).

The first twin study of autism led Folstein & Rutter (1977) to conclude that not only was there a high concordance rate for autism in identical twins, but that identical twins discordant for classically defined autism were usually concordant for milder but related deficits. At about the same time, Wing & Gould (1979) identified a 'triad of deficits' in reciprocal social behaviour, communication and play similar to autism that occurred in a substantial number of—mostly mentally retarded—individuals. The term 'pervasive developmental disorders' (PDD) came to be adopted in both ICD-10 (World Health Organization 1992) and DSM-IV (American Psychological Association 2000) as the umbrella term used to cover a broader range of autistic-like disorders. Recently, there has been a movement from parents and professionals to replace the term PDD with the term *autistic spectrum disorders*.

Epidemiology

The epidemiology of autistic spectrum disorders has recently become quite controversial because of disputed claims that a rise in incidence was caused by use of the mumps-measles-rubella triple vaccine (for negative findings and critique of the claim see Taylor *et al.* 1999; Dales *et al.* 2001; Kay *et al.* 2001). Large systematic epidemiological studies have shown increases in prevalence from the estimated rate of autism of 2–5 in 10 000 in the 1970s, to 6–9 in 10 000 (best estimate 7.5 in 10 000) in studies conducted since 1987 (Fombonne 1999). The same studies reported an additional 12.25 in 10 000 individuals with atypical autism/PDD, producing an overall rate of about 20 cases in 10 000 individuals. Rates for Asperger disorder, when individuals who also met criteria for autism were not included, were low, at 1–2 in 10 000. Because these studies did not focus on individuals with milder variants of the autism spectrum, it is possible that the figures for atypical autism/PDD and Asperger disorder are un-

derestimates. A more recent study found even higher prevalence estimates of 16.8 per 10 000 for autism and 45.8 per 10 000 for other pervasive developmental disorders in a geographically defined population of preschool children (Chakrabarti & Fombonne, 2001). Several other recent studies also found higher rates (Arvidsson *et al.* 1997; Baird *et al.* 2000). At least part of the explanation for the apparent increase in incidence lies in more complete ascertainment and a broader definition of autistic spectrum disorders but the matter requires further study.

Diagnostic frameworks

The two most commonly used diagnostic frameworks, ICD-10 and DSM-IV, were intended to be identical in their representation of autism, although there are slight differences in wording and inclusiveness of disorders in the autism spectrum. Both conceptualize autistic spectrum disorders as comprising three areas of deficit—social reciprocity, communication, and restricted repetitive behaviours and interests—and also require recognition of some type of abnormality before 36 months of age. These features are described in more detail below (Le Couteur *et al.* 1989; Wing 1997a).

Clinical characteristics

Social deficits

The most characteristic aspects of the autism spectrum concern difficulties in reciprocal interaction and the ability to form relationships (Tanguay *et al.* 1998). Recent studies have stressed children's lack of automatic social responses, such as orienting to their names or to a parent's voice from across a room (Osterling & Dawson 1994; Lord 1995a). In the preschool years, children with autism can be differentiated from children who have mental retardation or language delay by their lack of interest in other children, a limited range of socially directed facial expressions, and unusual eye contact. Children with autism are less likely to comfort others (such as bringing a baby sister her blanket) and may not seek to share enjoyment in an event, such as the sight of a favourite animal. Some children with autism remain relatively uninterested in other children for many years, whereas others begin to want friends but have difficulty forming reciprocal relationships. Most children with autistic spectrum disorders do not show deficits in all these areas, and many gain some social behaviours as they grow older. Because it is within friendships that more complex social skills are often modelled and practised, children with autistic spectrum disorders are handicapped both by their disorder and their lack of opportunities to learn that result from their basic deficits.

Communication

The overlap between social skills and communication is great. Non-verbal communicative behaviours (e.g. facial expressions, gestures, eye contact) are considered to be social behaviours, but

conversation and social chat, which provide the context for many non-verbal behaviours, are dealt with under communication, in ICD-10 and DSM-IV. For individuals with language, the most distinctive feature is its lack of, or unusual, social quality (Tager-Flusberg & Anderson 1991; Jarrold *et al.* 1997). Children with autism have difficulty carrying on conversations, although they may ask questions about preoccupations or forthcoming events. Some children with autistic spectrum disorders are talkative, often with repetitive speech that is more of a monologue than socially directed communication. Other children speak only rarely, primarily to ask for things (Stone & Caro-Martinez 1990).

Other characteristics of the language of children with autism include reversing pronouns (e.g. referring to themselves as 'you' or 'he'), delayed echolalia or stereotypic speech borrowed from other people or videos, sometimes with meaning, and making up words (neologisms). Abnormalities of pitch, stress, rhythm and intonation have been more difficult to quantify in research, but occur more frequently in autistic spectrum disorders than in general mental retardation (Lord *et al.* 2000). Immediate echolalia, or repeating all or part of what someone has just said, often with identical intonation, is common, especially in younger children, but is also found in other populations with limited language comprehension.

Autistic spectrum disorders are associated not only with difficulties in language but also with deficits in non-verbal communication, including use of gestures, such as pointing, nodding and showing. Thus, a child with autism who wants a drink, but cannot speak, may not use eye contact, gesture or a speech-like vocalization to communicate his or her request, but may cry or attempt physical means such as putting an adult's hand on the glass to pour it. Deficits also occur in imitation, social play (such as taking both roles in peek-a-boo or hide and seek), spontaneous imaginative role play or play with dolls or action figures (Harris 1993; Lewis & Boucher 1995).

Many children with autistic spectrum disorders have severe language delays. Unlike children with other causes of language delay, children with autism have few compensatory communication skills. Earlier estimates proposed that about 50% of children with autism did not use language as their primary method of communication and so were considered non-verbal. Recent treatment studies have suggested that, at least for children in early intensive treatment, this number may be decreasing (Rogers 1998). Autism is most often associated with lower verbal than non-verbal IQ scores (Rumsey 1992). However, in those with an IQ in the normal range, many show equal or even higher levels of verbal than non-verbal skills (Venter *et al.* 1992; Green *et al.* 2000). These are the individuals for whom the category of Asperger disorder is often used (see below; also Klin & Volkmar 1997). In addition, a significant minority of children with autism, perhaps 25%, have continuing severe language impairment. In these children, receptive and expressive language are both affected; some also have general verbal apraxia that affects their articulation, sharing features with children who have specific language impairments (Kjelgaard & Tager-Flusberg 2001).

Restricted, repetitive interests and behaviours

Stereotyped behaviours and interests include unusual preoccupations and circumscribed interests, compulsions and rituals, unusual hand and finger or whole body movements, repetitive use of objects and unusual sensory reactions or interests. Typical preoccupations include street signs, vacuum cleaners and birth dates. Circumscribed interests are age-appropriate interests carried out with unusual intensity and without a social quality, such as interests in trains or books, or fascinations with letters.

Rituals and compulsive behaviours in the autism spectrum differ from those in obsessive-compulsive disorder (OCD) (Leckman *et al.* 1997). Many individuals with autistic spectrum disorders are not particularly upset by their compulsive behaviours and seemingly make no effort to prevent or stop them. The most common compulsive behaviours in OCD, such as washing, checking or counting, are not typical of autism. Often the rituals in autistic disorders are arbitrary and are not linked to the prevention of an untoward event (e.g. tapping a puzzle piece before placing it). For individuals with autistic spectrum disorders who go on to develop OCD later, however, the clinical picture may be typical.

Stereotyped movements of the hands and fingers, frequently, although not always, within peripheral vision, as well as hand-flapping, often accompanied by jumping, bouncing or rocking foot to foot, are also common. Some children with autism have strong reactions, positive or negative, to sensations such as smell, touch, sight or sound. They may smell objects that do not have any obvious odour or taste objects that most people would not put in their mouths. Peering at linear patterns or objects are also common behaviours. However, as with symptoms in other areas, no child with autism shows all of these behaviours, and many show only one or two.

Although there have been arguments for the primacy of social communicative deficits in autistic spectrum disorders (Tanguay *et al.* 1998), the addition of a criterion concerning repetition adds significantly to the specificity of the disorder (Buitelaar *et al.* 1999). Earlier hypotheses that repetitive behaviours occurred primarily as a reaction to absence of social stimulation have not been supported (Romanczyk 1986). On the other hand, children and adolescents with autism are more likely to wander or do nothing at all in unstructured situations (Lord & Magill-Evans 1995; Koegel *et al.* 1999). Because of the lack of spontaneous creative social play, repetitive behaviours may be more noticeable and take up a larger proportion of time in autistic spectrum disorders than for other children.

One of the original descriptive criteria for autism was need for sameness. Some children with autism want to sustain their own routines and are upset by changes in subtle details of the environment that have no immediate effect on them (e.g. placement of a vase on a table). These specific difficulties are more often associated with autism than other disorders, although strong reactions to changes are relatively common in children with mental retardation as well, and many children with autistic spectrum disorders do not show these behaviours at all (Volkmar *et al.* 1994). Some children with autistic spectrum disorders, particu-

larly those with mental retardation, hit themselves on the head or bite their wrists or arms. The factors eliciting these behaviours vary tremendously (Romanczyk 1986), from wanting attention to a response to overstimulation or an attempt to communicate. These behaviours are not diagnostic of autism but are of concern because of their possible consequences and social disruptiveness.

There is an important relationship between the autism spectrum and mental handicap, which is not yet well understood. Most earlier epidemiological studies estimated that about 75% of individuals with autism were mentally retarded, meaning that the children's strongest skills, usually in non-verbal problem-solving and daily living skills, were more than 2 SD below average (below 70 on a typical standardized test in which 100 is average). Yet not all individuals with autism have mental retardation. Newer epidemiological studies (Baird *et al.* 2000; Chakrabati & Fombonne 2001), and those with less narrow definitions of the autism spectrum, suggest that the proportion of non-retarded children with autistic spectrum disorders may be much higher than indicated in epidemiological studies in which subjects were recruited primarily from educational and medical services for children with severe developmental disorders.

Course of autism

Age of onset and early regression

Most children with autism are identified by their parents as showing abnormalities or delays in the second year of life, and many parents suspect problems long before this. Dates for 'onset' for children with other autistic spectrum disorders may be slightly later. Often the problems noticed are not specific autistic features, but rather concerns that the child is less 'talkative' (even before a child might normally be expected to speak) or has difficulties in settling, eating, sleeping or tantrums (Dahlgren & Gillberg 1989). Parents who have already had a child tend to recognize social deficits earlier than parents of first-borns, and social deficits are often less recognizable in very young children than when they are older (De Giacomo & Fombonne 1998). Many children under the age of 3 years who will eventually meet formal criteria for autistic spectrum disorders do not yet show clear examples of restricted or repetitive behaviours (Cox *et al.* 1999; Stone *et al.* 1999). In some cases, these behaviours may be present early on but may be difficult to differentiate from the play of normally developing toddlers.

Historically, differences in age of onset were proposed to discriminate between autism and schizophrenia at a time when both disorders were thought to represent childhood psychoses. Children with autism had developmental abnormalities in the first 3 years, whereas children with schizophrenia rarely showed abnormalities prior to later school years. Although this differentiation has been very important, in general, distinctions based on onset often confound the age of recognition with the actual onset of the disorder, a phenomenon difficult to define precisely from retrospective accounts (Volkmar *et al.* 1985). Recently,

video studies of children at 9–12 months who were later diagnosed with autistic disorder indicated that children's responses to their names, or the number of times their parents called their names, differentiated children with autism from children with other disorders (Baranek 1999; Werner *et al.* 2000). Children with autism were also more likely to have at least one non-specific unusual sensory response, although there was considerable variability and overlap in the behaviours of children with autism and children with mental retardation without autism.

About one-quarter to one-third of parents of children with autistic spectrum disorder report a loss of speech in the first years of life (Rogers & DiLalla 1990), often, although not always, accompanied by or preceded by other changes in the child's social communication. A parent may notice that a child gradually stopped saying 'baba' for blanket, and increasingly seemed to be watching the credits on television alone in a room, even when the rest of the family had moved into another area of the house. The pattern of having a few words in the first half of the second year and then not speaking at all probably occurs more often in children with autistic spectrum disorders than in children with other developmental disorders or language impairment. Although these words may have been meaningful to the child in some cases, they were usually not part of a normal developmental trajectory of vocabulary development, but 'plateaued' very early on. The relationship between regression and prognosis in the autism spectrum is not yet clear.

Predicting adult outcome from childhood characteristics

As children with autistic spectrum disorders enter school, many are described as more flexible and socially directed. In adolescence, a small minority of youngsters with autism show marked regressions in behaviour and occasionally in cognitive skills (Gillberg & Steffenburg 1987). Although individuals with Asperger syndrome or autism, particularly those with severe mental retardation, may show violent or aggressive behaviour, this is atypical (Ghaziuddin *et al.* 1991; Howlin & Goode 1998).

Predictors of outcome from early preschool to later childhood have included joint attention (Sigman *et al.* 1999), verbal imitation (Smith & Bryson 1994) and social communicative aspects of adaptive skills (Lord & Schopler 1989a). However, non-verbal IQ and language are the two most powerful predictors. A non-verbal IQ below 50 in the preschool years (or later), provided it is based on a thorough assessment (see Rutter & Yule, Chapter 7), is associated with a reduced likelihood that the child will acquire a useful level of spoken language (Lord *et al.* 1989) and a very low probability of good social functioning in adolescence/adulthood (Lockyer & Rutter 1969). Variations in non-verbal IQ between 50 and 70 have a somewhat similar effect but those within the normal range do not. In children who are not severely retarded, language skills (and verbal IQ) are the strongest predictors of social outcome. A child who does not have fluent speech by age 5 years may still make significant gains, but the later these gains come, the less likely the child's language will be flexible and complex, and the more likely language delays of some sort may re-

duce his or her level of independence (Szatmari *et al.* 2000). Non-verbal skills are important in considering methods of teaching and preparation for employment (Venter *et al.* 1992). However, even a child with very strong visuospatial skills who has significant language delays lasting into the school years is likely to have difficulty with the social and communication demands of ordinary society (Venter *et al.* 1992; Sigman *et al.* 1999). The cut-offs of IQ 50 and no language by 5 years are arbitrary (there is no specific threshold) but they provide a general guide.

Autism in adulthood

Some adults with autistic spectrum disorders experience real behavioural and social improvements in their late 20s and early 30s (Mesibov 1984). On the other hand, autism is a lifelong disorder, and the likelihood of complete independence is limited. Individuals with both autism and severe mental retardation require supervised living and working situations throughout their lives. Opportunities for such situations within communities, rather than in institutions, have increased within the last two decades. Apart from a few notable exceptions (Grandin & Scariano 1986), most adults with autistic spectrum disorders, even those with average or greater intelligence, require some help in finding and keeping jobs and coping with responsibilities and social demands (Rutter *et al.* 1992). As discussed under Medical examination and investigations, p. 643, adolescence is a time when epileptic seizures are particularly likely to develop. Comparisons of outcome studies over the last 30 years (Howlin & Goode 1998) suggest that both educational achievement and frequency of employment, with support, have increased for individuals with average, or near average, intelligence. The independence of adults with no, or mild, cognitive delays often depends on community resources and the effort of agencies and family members in seeking vocational and residential arrangements, as much as on individuals' characteristics (Venter *et al.* 1992).

Diagnosis in adult life can be difficult and depends heavily on a developmental history. Contexts for social interaction are less uniform. Adults without mental retardation and with good verbal skills may participate in superficial social interaction relatively well, but have significant difficulties in forming relationships and coping with the demands of work. However, these difficulties are not specific to autism. Comorbid disorders, particularly depression and anxiety, are common in adults with autistic spectrum disorders (Ghaziuddin & Greden 1998). Recognition of an autistic spectrum disorder is helpful in understanding the nature of social difficulties, but it is equally important to focus on social needs and to articulate useful strategies (e.g. structured goals and motivation systems).

Differential diagnoses

Receptive-expressive language disorders

Although language delay is the most common reason for initial

referral of children with autistic disorder (Siegel *et al.* 1988), autistic spectrum disorders differ from the more common varieties of developmental language disorder in the severity of receptive language impairment (Fischel *et al.* 1989; Kjelgaard & Tager-Flusberg 2001). There are non-autistic children of normal non-verbal intelligence who have a severe receptive-expressive language impairment but this is a decidedly uncommon disorder. A significant minority have undiagnosed hearing problems, so that it is important that hearing be checked routinely and expertly (Mawhood *et al.* 2000). Many have some symptoms that overlap with autistic spectrum disorders and some may fit descriptions of ‘semantic-pragmatic disorder’ (Bishop 1989; Boucher 1998), meaning problems with the social communicative aspects of conversational interchange. Children with semantic-pragmatic disorder or severe receptive-expressive language delay may have immediate echolalia, substantial social impairment and limited imaginative play, but unusual preoccupations and rituals are much less common than in autism.

Severe psychosocial deprivation

If a child’s development has been unusual from early on, effects of severe early deprivation need to be considered. There is no evidence that ‘lack of experience’, such as not attending a preschool or having a rather unstimulating babysitter, causes autistic spectrum disorders. Nevertheless, children who have experienced very severe institutional deprivation can show language delay, abnormal social behaviour and marked circumscribed interests and preoccupations (Rutter *et al.* 1999; see also O’Connor, Chapter 46). In early childhood, the clinical picture is rather like autism, although there is usually more social reciprocity than typical with autism, and the course is different, so that by middle childhood it is social disinhibition and circumscribed interests that tend to predominate.

Selective mutism

Selectively mute children may be socially withdrawn and unresponsive. It has been argued that selective mutism should be considered a symptom of social anxiety or avoidance rather than a separate disorder (Dummit *et al.* 1997; Kristensen 2000). It tends to be more common in girls than boys, with an onset before age 4 years. Specific language abnormalities associated with autism (e.g. pronoun reversal, stereotyped speech, odd intonation) are uncommon. However, selective mutism is more common in children with language impairment (Kopp & Gillberg 1997). The children often have strong attachments with parents, show reciprocal social interactions and engage in spontaneous creative play, although their behaviour may be very restricted at school (Black & Uhde 1995; see also Bishop, Chapter 39).

Schizophrenia developing in childhood

Childhood schizophrenia is very rare and should be diagnosed

only after other disorders have been carefully excluded (Rutter 1972b). Distinguishing schizophrenia from autism is not difficult, except in rare cases of older, high functioning children and adults with autism whose thought processes may sometimes appear paranoid or delusional (Klein & Slomkowski 1993; Nicolson & Rapoport 1999; Kumra *et al.* 2000). Often, a better understanding of the situation and the context to which the child or adolescent is referring may identify what initially sounded like a hallucination as repetitious behaviour coupled with social *naïveté* about how this behaviour may appear to others. There may be a relationship between significant receptive and expressive language problems and later development of schizophrenia (Howlin *et al.* 2000). However, most individuals with schizophrenia do not have the severe language delays or abnormalities (e.g. delayed echolalia, pronoun reversals) or the early history of deficits in social reciprocity that are typical in autistic spectrum disorders.

Differential diagnosis within the autism spectrum disorders

There is continuing uncertainty regarding the validity of differences among subtypes of autism spectrum disorder, apart from Rett syndrome (Wing 1997b). Once factors such as language and non-verbal cognition are controlled, there is more overlap than difference among subcategories (Green *et al.* 2000; Szatmari *et al.* 2000). DSM-IV and ICD-10 include priority rules that state that if an individual ever met diagnostic criteria for autism, the autism diagnosis takes precedence over any other diagnoses, except Rett syndrome and childhood disintegrative disorder. When this rule is followed, few individuals meet criteria for Asperger syndrome (Ozonoff *et al.* 1991b; Szatmari *et al.* 2000), although the numbers of children left in the non-specific general category of atypical autism remain quite high (Fombonne 1999).

Rett syndrome

Rett syndrome (Hagberg 1985; Naidu 1997) is an X-linked dominant progressive neurodevelopmental disorder that affects girls almost exclusively, with a population prevalence of about 1 in 10 000 to 15 000 females. Typically there is normal development until 6–18 months of age, then a developmental plateau followed by gradual loss of speech and of purposeful hand use, and the development of mid-line hand stereotypies often associated with social withdrawal. This presentation may be confused with autism. Subsequently, mobility becomes limited, and seizures and irregular respiration may develop. However, the range of clinical presentations is wider than at first appreciated, with both milder atypical varieties and profound mental retardation, as well as occasional cases in males (Shahbazian & Zoghbi 2001). An important clinical sign differentiating Rett syndrome from idiopathic autism is the deceleration in head growth leading to acquired microcephaly. Mutations in the *MECP2* gene (Amir *et al.* 1999), of which some 78 types have

been described, have been found in 75–90% of sporadic cases and 50% of familial cases (Shahbazian & Zoghbi 2001). An animal model has now been developed (Guy *et al.* 2001) and this should facilitate elucidation of the mechanisms by which the mutations lead to the clinical syndrome.

Childhood disintegrative disorder

Childhood disintegrative disorder (CDD) refers to a syndrome in which apparently normal development over the first 2 years is followed by marked behavioural change and developmental regression. Receptive and expressive language are lost, often with loss of co-ordination and bowel or bladder function (Volkmar & Rutter 1995). Other behavioural changes include social withdrawal and the development of simple rituals, unusual sensory behaviours and hand and finger stereotypies, much like those of autism. The regression in CDD differs from that in autism in extending well beyond language; the loss of skills is usually more severe, and normal development of language and pretend play was usually clear before the regression began. Most commonly, the regression in CDD extends over several months and then plateaus, resulting in a developmental and behavioural pattern that is not distinguishable from autism with profound mental retardation (Hill & Rosenbloom 1986; Mouridsen *et al.* 1999). In some cases, deterioration continues, with increased motor dysfunction, development of seizures and localized neurological signs (Corbett *et al.* 1977). Cases have been caused by cerebral lipidoses or leukodystrophy but, in most instances, no clear cause is ever identified. Because, initial medical tests may be negative, even when neurological disorder is eventually identified, medical investigations should be repeated if there is progressive deterioration.

Landau–Kleffner syndrome

Landau–Kleffner syndrome or acquired aphasia with epilepsy (Miller *et al.* 1984; Mouridsen 1995; Deonna 2000) may also occasionally mimic autism, although the differentiation is usually straightforward. Children with this disorder have normal development and then lose receptive and then expressive language, typically in conjunction with the development of seizures or transient electroencephalogram (EEG) abnormalities (see Bishop, Chapter 39). The regression may be associated with some social withdrawal and behavioural change but family relationships are usually maintained. Non-verbal cognitive and motor functioning and adaptive skills not related to language remain intact. The outlook is better than for CDD, and sometimes language is regained.

Asperger syndrome

In the last 10 years, the concept of Asperger syndrome, as used by researchers (Gillberg 1989; Frith 1991; Klin *et al.* 2000) and clinicians (Wing 1981; Attwood 1997), has served to highlight the occurrence of autistic spectrum disorders in individuals who

are intellectually able and verbally fluent (Grandin & Scariano 1986). It has become clear that these disorders can and do occur in people who did not experience the language delay that is typical of autism. However, it has not proved easy to produce satisfactory diagnostic criteria, and differences in both definition and sampling have led to conflicting findings (Green *et al.* 2000; Klin *et al.* 2000; Szatmari *et al.* 2000). In keeping with the lack of language delay, Asperger syndrome tends to be associated with a higher verbal than non-verbal IQ (Klin *et al.* 1995). This aside, it remains uncertain whether Asperger syndrome and autism differ in pattern of neuropsychological deficit (Ozonoff *et al.* 1991b). Whether diagnosed as having Asperger syndrome or autism, individuals who are verbally fluent tend to be less impaired. However, the question arises as to whether having a history of delay in early language acquisition has a specific effect, independent of current verbal fluency (Green *et al.* 2000). Szatmari *et al.* (2000) found that, after equating for non-verbal IQ, children with autistic spectrum disorder who did not have early language delay had milder social deficits than those with language delay who had equal non-verbal intelligence. Other studies have not found an effect of language delay when current language level is controlled (Eisenmajer *et al.* 1996).

Atypical autism/PDDNOS

The terms ‘atypical autism’ and ‘pervasive developmental disorder not otherwise specified’ (PDDNOS) refer to non-specific patterns that seem to involve the same deficits as those associated with autism, although they do not fulfil all the accepted diagnostic criteria (Towbin 1997; Buitelaar *et al.* 1999). The atypicality may lie in the symptom pattern, its severity, or age of first manifestation. Epidemiological analyses (Wing & Gould 1979), clinical investigations (Fein *et al.* 1999) and family studies (Bolton *et al.* 1994) all indicate the frequency of these atypical patterns but they have been subject to little systematic research. It is likely that they reflect variations in the ways in which autistic spectrum disorders may present, rather than a separate category (Rapin 1997; Wing 1997a). The service needs are similar to those for autism, and it remains unknown whether the apparent atypicality has any implications for aetiology.

Another frequently used term in research is the broader ‘autism phenotype’ (see section on genetics). It refers to mild autistic-like features that are evident in some relatives but it does not necessarily imply a need for services, as discussed below.

Assessment and intervention

Screening for possible autism spectrum disorder

Screening is best considered in terms of two different questions (Filipek *et al.* 2000). The first is whether autistic spectrum disorders can be reliably identified in very young children who have not been referred for assessment and whose parents have not raised concerns about their development. One theoretically

based instrument, the Checklist for Autism in Toddlers (CHAT) showed initial promise (Baron-Cohen *et al.* 1992) but its poor sensitivity at 18 months (indicating that it misses many cases) means that it cannot be relied on for screening at that age (Baird *et al.* 2000). Whether other questionnaires would do any better in children who are at a point in development when key skills are often only just emerging remains uncertain and screening at 2 years might be more practicable.

A second question concerns a different kind of ‘screening’ to decide which children referred to primary care clinicians, who are not experts, should be expertly evaluated for a possible autistic spectrum disorder. Several promising instruments intended for this purpose are under development (Siegel *et al.* 1996; Stone *et al.* 2000). Assessment may be indicated for children whose parents spontaneously say they seem to be ‘in a world of their own’ or lack social responsiveness, or have stopped speaking for more than a few weeks after having developed some language. A history of not orienting to parents’ voices or not consistently understanding any words out of context by age 2 years (when motor development was unremarkable) also identified children with autistic spectrum disorders at age 2 years in one study (Lord 1995b).

Assessment and diagnostic methods

Diagnosis is based on the identification of a particular pattern of deficits, together with consideration of whether this might be fully attributable to cognitive impairment or deafness or severe neglect. Multiaxial frameworks, such as ICD-10 and DSM-IV, are well-suited to the purpose of step-by-step diagnoses, with their explicit recognition of the need to consider intellectual level, specific developmental delays, other psychiatric disorders and psychosocial factors in each decision (see Taylor & Rutter, Chapter 1).

A comprehensive psychological assessment is an important component of this diagnostic process. Several tests are available but they differ in their suitability for very young or non-verbal children, as well as in their standardization and the range of abilities they tap (Klin *et al.* 1997). The selection of appropriate tests depends on the goals of the assessment, the individual child’s specific strengths and difficulties, and the psychometric properties of the test. Generally, a single test will not be sufficient. The psychologist must be knowledgeable about test selection and about ways to make the testing process more comprehensible to the child (Koegel *et al.* 1997; see also Rutter & Yule, Chapter 7). Although the use of mental ages is problematic psychometrically, the concept of approximate developmental level can be very helpful for parents and professionals, if put in perspective.

As part of an initial diagnosis, children with autistic spectrum disorders should always have a detailed skilled communication and language assessment. Articulation, language comprehension—both of single words and more complex language—and expressive language, including vocabulary, sentence structure and pragmatics, should be assessed. Aspects of non-verbal communication, including both conventional (e.g. signs) and less

formal systems (e.g. use of gaze, non-standard gestures), should also be evaluated (Wetherby & Prizant 1999). For older, higher functioning children and adolescents, individualized achievement testing that differentiates decoding (which is often an area of strength) from reading comprehension, and practical problems in arithmetic from computations, may also be important in educational and vocational planning.

Diagnostic instruments

Interview of parents or caregivers

Standardized diagnostic instruments have become a routine part of practice in the assessment of autistic spectrum disorders. The Autism Diagnostic Interview–Revised (Le Couteur *et al.* 1989, in press; Lord *et al.* 1994) is a standardized 90-min interview that provides a diagnostic algorithm for ICD-10 and DSM-IV diagnoses of autism, although not yet for other disorders within the spectrum. Separate scores are generated for socialization, communication (non-verbal and verbal) and restricted repetitive behaviours, focusing particularly on the period between 4 and 5 years of age, and on the current pattern. The Diagnostic Interview for Social and Communicative Disorders (DISCO) Handicaps Behaviour Schedule by Lorna Wing (1999) is also available. The DISCO provides a broad base of information concerning developmental and behavioural functioning. Even when standardized instruments are not used, clinicians should have a framework to gather information from the interview to ensure comprehensive coverage of important aspects of development.

The Vineland Adaptive Behaviour Scales (Sparrow *et al.* 1984) can also be helpful, not just in structuring information about everyday skills such as dressing and independent travel, but also in producing data that compare to established norms in these areas (Carter *et al.* 1998). Autism tends to be associated with very low scores on socialization, together with low scores on receptive and expressive language in the early years, and relatively higher scores in daily living skills and motor skills.

Observation/interview of the child

The goal of a clinical observation is for the clinician to be able to witness behaviours in the domains described in the interview. There are several protocols for semistructured observations of children and adults with autistic spectrum disorders including the Psychoeducational Profile (PEP-R; Schopler *et al.* 1990), for children with developmental levels between about 2 and 5 years, and the Adult–Adolescent Psychoeducational Profile (AAPEP; Mesibov *et al.* 1989). Checklists are also available that provide a framework for characterizing behaviours associated with autistic spectrum disorders. These include the Childhood Autism Rating Scale (CARS; Schopler *et al.* 1986), probably the best known and well-validated scale; the Gilliam Autism Rating Scale (GARS; Gilliam 1995); the Aberrant Behaviour Checklist (ABC; Aman & Singh 1986); and the Autism Behaviour

Checklist (ABC; Krug *et al.* 1980). These scales may be used for screening in clinical trials to evaluate behaviour but are less appropriate for diagnoses.

The Autism Diagnostic Observation Schedule (ADOS, formerly called the ADOS-G; Lord *et al.* 2000) both structures the clinician's behaviour, by providing a range of communicative demands and social 'presses' during which to observe children, adolescents and adults, and structures the observations by specifying features to rate within the context of a 30-min observation/interview. The current version of the ADOS includes four modules, each intended for children or adults with different levels of expressive language. Most children with autistic spectrum disorders appear most normal in conditions of high structure. It is not possible to evaluate a child's spontaneous social behaviour if the clinician structures the situation so well that all the child has to do is respond. Equally, in an unstructured environment (such as wandering around an office while their parents are interviewed), children with autistic spectrum disorders may show little social behaviour at all (Bartak & Rutter 1973). With younger children, an experienced clinician may observe characteristically autistic behaviours before parents recognize them as such, but with older children and adults it may be difficult to elicit these behaviours during a brief observation in an unfamiliar setting. Thus, a comprehensive diagnostic evaluation should include information from both parent interview and direct observation.

Medical examination and investigations

A comprehensive physical examination should always be undertaken to detect recognizable syndromes, particularly tuberous sclerosis, and any localizing neurological impairments (see Bailey, Chapter 10). Visual and hearing acuity should also be assessed. Even in the absence of a history or signs of identifiable syndromes, high-resolution karyotyping and molecular genetic testing for fragile X should be routine. Further investigation may be warranted when there are symptoms or signs suggestive of metabolic abnormalities. Although autism is associated with macrocephaly in a minority of cases, this sign by itself is not an indication for neuroimaging studies (Filipek *et al.* 2000). Seizures occur in perhaps one-quarter to one-third of individuals with autism, but often do not develop until adolescence (Rutter 1970; Volkmar & Nelson 1990), and clinicians need to be alert to the possibility of absence or complex partial seizures when there are sudden unexplained changes in behaviour that are not typically autistic in character. EEG abnormalities in autism are very common and are not an indication for anti-convulsant medication in the absence of symptomatology.

Aetiology

Since Kanner's original description, there have been several significant shifts in thinking about the aetiology of autistic spectrum disorders that affect our understanding of the boundaries

of the disorder and the features that require explanation. Kanner (1943) initially described autism as an inborn disorder but then reconceptualized the disorder as a reaction to abnormal child-rearing (Eisenberg & Kanner 1956). In the late 1960s, the biological basis of autistic disorder became generally accepted, and autism was assumed to be a consequence of brain damage, caused by either recognized medical disorders or obstetric hazards. However, over the last 20 years or so, there has been an increasing recognition of the role of specific genetic factors in the aetiology of most cases of autistic spectrum disorders, with an appreciation of the complexity of the underlying biological and psychological processes.

Approximately 10–15% of cases of autism are associated with identifiable medical disorders (Rutter *et al.* 1994; Barton & Volkmar 1998). Although cerebral palsy and trisomy 21 are both occasionally associated with autistic spectrum disorders, these common causes of mental handicap are infrequent causes of autism. Similarly, although a wide range of chromosomal abnormalities are associated with autistic spectrum disorder (Gillberg 1998), these are only found in approximately 5% of individual, a rate substantially lower than that found in unselected mental handicap populations (Curry *et al.* 1997). The rate of fragile X anomaly is probably no higher than 4% (Dykens & Volkmar 1997), whereas the rate of tuberous sclerosis (see below) in individuals with autism is approximately 100 times higher than expected (Fombonne 1999).

A number of studies in the 1970s and 1980s reported a relationship between mild prenatal, perinatal and neonatal factors and autism (Piven *et al.* 1993). However, no association has been found between autism and the severe obstetric complications that are typically associated with a significant risk of brain damage. Twin (Bailey *et al.* 1995) and family (Bolton *et al.* 1997) genetic studies suggested that the mild obstetric difficulties sometimes associated with autistic disorders are usually a consequence of either abnormal fetal development or the genetic risk for autism rather than a cause.

Genetic influences

Interest in the genetics of the autism spectrum has recently intensified. Asperger (1944) first hypothesized that autistic psychopathy had a genetic basis which was passed from father to son. Twin studies were necessary, however, to determine whether the elevated familial recurrence risk for autism had an environmental or genetic basis. Across several twin studies, concordance rates in monozygotic (MZ) pairs have been much higher (36–91%) than in dizygotic (DZ) pairs ($\approx 5\%$) (Steffenburg *et al.* 1989; Bailey *et al.* 1995). In none of these studies was concordance for autism attributable to severe obstetric hazards. The substantial difference in concordance rates between MZ and DZ twins is incompatible with a Mendelian mode of inheritance. Thus, these findings point to the likely involvement of multiple interacting genes (Bailey *et al.* 1995), with a heritability of liability to autism of $>90\%$. The first UK twin study and several other family genetic studies of autism

(reviewed by Bailey *et al.* 1998; Szatmari *et al.* 1998) have found an elevated risk for autism and other autistic spectrum disorders amongst siblings, ranging between 2 and 6%. Overall, the relative risk (the risk to relatives compared with the general population risk) is higher for autistic spectrum disorders than for just about any other genetically influenced multifactorial disorder. In practical terms, the current literature suggests a recurrence risk for a pervasive developmental disorder of about 5%, but it is not yet possible to give more precise estimates if more than one person in the family is affected.

Milder phenotypes

Folstein & Rutter's (1977) twin study was remarkable for indicating that the phenotype associated with a genetic predisposition to autistic disorder included cognitive and social difficulties extending beyond autism as traditionally diagnosed. In a follow-up into adulthood of this original sample, the majority of non-autistic MZ cotwins showed substantial social difficulties that were autistic-like but of less severity (Le Couteur *et al.* 1996). Most of the non-autistic MZ cotwins, even individuals of normal intelligence, showed social and/or cognitive abnormalities, with the most severely affected individuals having more well-defined autistic spectrum disorders (Bailey *et al.* 1995). A parallel family history study found that similar social and/or cognitive abnormalities also occurred at an increased rate amongst the relatives of probands with autism compared with the relatives of probands with trisomy 21 (Bolton *et al.* 1994). In fact, individuals with autism represented only a small proportion of all the individuals showing some phenotypic expression.

Most investigators have assumed that mild autism-related behavioural phenotypes are likely to manifest themselves as social, communicative and repetitive impairments, either alone or in combination. Some relatives of individuals with autism show a lack of interest in others or, less frequently, a lack of socioemotional responsiveness, whereas others may show socially odd behaviour (Piven *et al.* 1997a; Starr *et al.* 2001). This broad range of difficulties map onto three of the four domains of social impairment in autism in ICD-10 and DSM-IV. Amongst adult relatives, related personality traits, particularly aloofness and shyness, are also more common than in controls (Piven *et al.* 1997b). There is little evidence from these and other studies (reviewed by Bailey *et al.* 1998; Szatmari *et al.* 1998) of a sharply defined social deficit that is identical in all affected individuals. Rather, the findings point to a range of related social difficulties and personality traits that co-occur.

Most studies have found a history of language delay in a small proportion of relatives (Bailey *et al.* 1998). These individuals have lower verbal IQs than unaffected relatives (Fombonne *et al.* 1997; Folstein *et al.* 1999), indicating that language delay reflects a cognitive impairment rather than a transitory developmental lag. Some relatives show difficulties in communication planning, pragmatic and conversational ability, speech abnormalities and reading and spelling difficulties, although these have a tendency to co-occur with other language difficulties

and so their significance in isolation is at present uncertain (Fombonne *et al.* 1997; Piven *et al.* 1997b; Folstein *et al.* 1999).

Repetitive behaviours have received much less attention than social and communication impairments and are more difficult to define and measure. Bolton *et al.* (1994) identified increased rates of circumscribed interests, rigidity, obsession/compulsions and repetitive behaviours in relatives compared to controls, and Piven *et al.* (1997b) have argued that a lack of interest in seeking change may also be more common amongst relatives of individuals with autism. Abnormalities in the repetitive domain seem to be more specific to autism than social or communication impairments (Pickles *et al.* 2000). Clear-cut generational and sex differences have been found in some but not all studies (Folstein *et al.* 1999; Pickles *et al.* 2000). In contrast to the relationship between autism and milder variants of the behavioural deficits that define it, recent studies have found neither an increased rate of mental handicap amongst relatives nor a consistent pattern of cognitive discrepancies (see Fombonne *et al.* 1997 and Folstein *et al.* 1999 for contrasting findings).

Whether genetic susceptibility to autistic spectrum disorders also predisposes to the development of other psychiatric disorders is presently unclear. DeLong & Nohria (1994) suggested that autistic spectrum disorders represent the early onset of a severe, particularly bipolar, affective disease, but studies using standardized diagnostic instruments have not found an increased rate of bipolar disorder amongst relatives. Nevertheless, relatives do seem to be at increased risk for affective disease, particularly major and recurrent depressive illness, with the first depressive episode tending to occur before the birth of the child with autism (Smalley *et al.* 1995; Piven & Palmer 1999). These depressive disorders do not seem to overlap with autism-related social or language deficits, either at the individual (Piven & Palmer 1999) or familial level (Bolton *et al.* 1998), suggesting that if they are consequences of the genetic liability to the autism spectrum, some different intervening mechanisms are involved. Two studies have reported elevated rates of anxiety-related personality traits amongst adult relatives (Murphy *et al.* 2000) but there is currently no consensus about whether relatives are also at increased risk for generalized anxiety disorders or social phobia (Smalley *et al.* 1995; Bolton *et al.* 1998).

Although it is possible that Mendelian inheritance is implicated in a minority of cases of autism, the evidence suggests that most idiopathic cases arise on the basis of multiple susceptibility genes. Each susceptibility gene probably has only a weak or moderate effect and may not be sufficient to cause the full clinical phenotype. Several susceptibility genes acting together, however, confer a marked risk. Genetic heterogeneity may be assumed. Applying Risch's (1990) approach to family and twin data for autism and related phenotypes, Pickles *et al.* (1995) calculated that between two and 10 loci may be implicated in autism; models with three or four interacting loci provided the best fit.

A further question concerns the relationship between individ-

ual genetic loci and specific components of the behavioural phenotype. On the one hand, Folstein *et al.* (1999) suggested that susceptibility loci must be contributed by both parents, and that individual components of the phenotype are inherited separately and manifested independently in non-autistic family members. In contrast, Pickles *et al.* (1995) found that their data on autism and milder phenotypes was best fitted by a model in which interactions between loci contributed to a single latent trait or measure of autism, rather than individual loci predisposing to one component of the phenotype. Even when further families were added to this data set (Pickles *et al.* 2000), there was little evidence of phenotypic expression on both sides of a family, or of bilineal inheritance patterns (e.g. one parent showing social difficulties, the other language problems). Volkmar *et al.* (1998) found that relatives of individuals with Asperger syndrome showed an increased rate of autism as well as Asperger syndrome and milder phenotypes, supporting the transmission of susceptibility for a range of autistic spectrum disorders, rather than of specific disorders.

As yet, there are no clear indications that familial transmission is different for social deficits, language abnormalities or repetitive behaviours. Le Couteur *et al.* (1996) found that there was almost as much variation in IQ and in autistic symptoms within MZ twin pairs concordant for autism as there was between pairs. Starr *et al.* (2001) also found that the rates of milder phenotypes amongst relatives of probands with severe/profound mental retardation were broadly similar to those reported by Bolton *et al.* (1994) in relatives of more able probands. On the other hand, Bolton *et al.* (1994) found there was a relationship between familial loading, for milder phenotypes, and the severity of disorder in the proband, only in the families of probands with useful speech. The preponderance of males with autism (and probably also milder phenotypes) has led to the suggestion that at least some autism susceptibility loci are X-linked. However, in the UK family studies (Pickles *et al.* 2000) there was no evidence for X-linkage, sex-specific patterns of expression, imprinting effects (Skuse 2000) or higher familial loading amongst the relatives of female probands—as predicted under a multifactorial threshold model—suggesting that the sex differences are most probably a consequence of biological sex rather than X-linked genes (Pickles *et al.* 2000).

Identifying susceptibility genes

The identification of susceptibility genes should provide clues to the pathophysiology underlying autism (through identification of the functions of the encoded proteins), and should enable genetic counselling to be based on knowledge of the individual's genotype, rather than group-based risk. Several approaches are currently being used to identify susceptibility loci for autism; these include association studies of 'functional' and 'positional' candidate genes and, most promisingly, linkage studies across the whole genome (Maestrini *et al.* 2000).

Association strategies are based on identifying alleles (versions) of a gene or marker (naturally occurring variations in

DNA sequence) that occur at significantly different frequencies in samples of affected and control individuals. Family-based association designs, such as the transmission disequilibrium test, use the frequencies of parental alleles that are not transmitted to affected offspring as internal controls. An association strategy can be used to examine variations in 'functional' candidate genes, genes hypothesized to be implicated in the aetiology of a disease on the basis of what is known about the underlying pathophysiology. Because of limited knowledge about the neurobiological mechanisms and the lack of specific drug effects, there are very few true functional candidate genes for autism. Most attention has focused on the serotonergic system, both because of reports of elevated platelet serotonin levels in patients and their relatives compared with controls (see below), and because of the efficacy of selective serotonin reuptake inhibitors (SSRIs) in reducing repetitive behaviour (McDougle *et al.* 1997). Several groups have examined allelic variation in the promoter of the serotonin (5-HT) transporter gene but the data are contradictory (Cook *et al.* 1997a; IMGSA 1998), and studies of various serotonin receptor genes and other potential candidates are also equivocal (reviewed by Lamb *et al.* 2000).

Another strategy is to examine 'positional' candidate genes, brain-expressed genes that are potentially implicated because of their proximity to chromosomal abnormalities associated with autistic spectrum disorders (Maestrini *et al.* 2000). These have been reported for nearly all chromosomes (reviewed by Gillberg 1998), but most interest has focused on the reports of a rare association between an autistic-like phenotype and cytogenetic abnormalities of an unstable region of chromosome 15 (reviewed by Lamb *et al.* 2000). This region contains several imprinted genes and includes the Prader-Willi/Angelman critical region.

The most commonly observed abnormalities are interstitial duplications or a supernumerary pseudodicentric chromosome 15 (inv-dup[15]) in patients with autism spectrum disorders—often associated with severe mental retardation and seizures. When parental origin has been investigated, all of the 15q duplications associated with autism have been derived from the mother (Cook *et al.* 1997b), raising the possibility of imprinting effects. The GABA_A receptor gene cluster—containing several genes of interest—lies in this region and was the initial focus of interest, although so far the evidence for association is contradictory (Cook *et al.* 1998; IMGSA 1998). It remains to be seen whether specific genes in this region are implicated in idiopathic autism, or whether it is the increased dosage of mutant genes associated with chromosomal abnormalities that occasionally gives rise to an autistic-like picture.

Although many research groups are engaged in functional and positional candidate gene analysis, most effort is currently being expended on linkage approaches that make no prior assumptions about gene position or function. Linkage analysis is based on identifying markers that cosegregate with disease within families (Maestrini *et al.* 2000). Because the mode of inheritance of autism is not known and extended pedigrees of

affected individuals are not available, most research groups use linkage methods that rely on allele sharing between two or more affected individuals within multiple nuclear families, otherwise known as multiplex families. The goal is to identify markers for which affected pairs share alleles more often than expected by chance, indicating that they may be linked to a susceptibility gene. At the time of writing, four whole genome scans have been reported in full and one in abstract form (reviewed by Lamb *et al.* 2000), with sample sizes ranging between 51 and 139 multiplex families containing two or more individuals within the autism spectrum.

So far, several chromosomal regions appear particularly promising. The strongest initial evidence for linkage was to a region on chromosome 7q (IMGSAC 1998). Subsequently, five weaker, but still positive, linkages spanning a 50-cM region including the original region of interest have been reported in other samples (reviewed by Lamb *et al.* 2000). Because none of the six groups has reported findings that meet the accepted threshold for proven linkage (Turner *et al.* 2000), it remains possible that the results simply represent the chance co-occurrence of a number of false-positives. Nevertheless, if idiopathic autism is aetiologically heterogeneous—as seems likely to be the case—and susceptibility loci are of modest effect, then overlaps in the location of linkages across multiple studies are likely to index a susceptibility locus, even if random variations in gene sharing between samples lead to modest statistical significance. In fact, the linkage in the IMGSAC sample has held up with the addition of further families (IMGSAC 2001), and a combined analysis of three other independent samples provides confirmatory evidence for linkage of autism to 7q (Santangelo *et al.* 2000), with the peak of linkage falling close to that in the IMGSAC sample.

A second region of interest lies on chromosome 2q, initially identified independently by IMGSAC (1998) and Philippe *et al.* (1999). The preliminary results were modest, but appear stronger with the addition of further families and replication by Buxbaum's group (see Lamb *et al.* 2000). Other regions currently identified by two independent groups (reviewed by Lamb *et al.* 2000) lie on 13q, 16p and 19p. Given the generally poor replicability of linkage findings in psychiatric genetics, the findings from these preliminary studies are encouraging, presumably reflecting both the strength of the genetic liability and the acceptance across research groups of well-validated diagnostic instruments (Rutter 2000). The next task is to move beyond preliminary linkage findings to cloning (identification) of genes (see McGuffin & Rutter, Chapter 12). Once a putative susceptibility gene has been identified, the next task is to establish its biochemical function, if that is not already known. Animal models may be helpful in understanding gene function; the goal is not to reproduce complex behaviours, which may occur, but to study the physiological and neuropathological consequences of particular genetic constitutions. Once a susceptibility locus is cloned, the relationship between phenotype and genotype can be re-examined, but now in the reverse direction (Turner *et al.* 2000).

Psychological studies

Although the neurobiological basis of autism is undisputed, understanding the cognitive or emotional processes that mediate abnormal behaviours is relevant for several reasons. First, these psychological mechanisms are important for clarifying the underlying brain abnormalities and their role in mental functioning. Secondly, direct psychological testing may be necessary for recognizing milder phenotypes, for elucidating the differences between behavioural traits and overt disorder, and for understanding why susceptibility alleles have persisted in the population. Thirdly, understanding the psychological mechanisms underpinning developmental psychopathology may improve early diagnosis and lead to new intervention strategies.

Over the last 15 years or so, there have been significant advances in identifying some of the cognitive abnormalities associated with autism (Happé & Frith 1996). However, there has been less progress in achieving an overall conceptualization of the relationships among different deficits, either within or across behavioural domains. Deciding which features of autism spectrum disorders require explanation is a prerequisite for judging the adequacy of theoretical accounts. For example, the co-occurrence of autism with mental retardation was frequently assumed to be caused by brain damage that impaired both specific and general cognitive processes. However, the strong genetic basis to autistic spectrum disorders suggests that any associated mental retardation is a manifestation of the underlying disease process. On a more concrete level, for older preschool and school-age children, IQ scores are as consistent across time and measures within autism as they are for language disorders or for other developmental delays (Lord & Schopler 1989b), with correlations generally above 0.65 for periods in childhood of 5–8 years. Yet this does not mean that IQ scores do not change. Several follow-up and treatment studies have shown substantial increases in IQ scores (some 15–25 points) occurring in a significant proportion of children with autism for preschool to school years and decreases in IQ scores particularly in older children who do not acquire language (Lord & Schopler 1989a; Sigman *et al.* 1999). IQ scores for children with autistic spectrum disorders should be interpreted within broad ranges and should never be used as the sole basis for placement. Whether any cognitive deficit is truly primary, with other abnormalities simply representing developmental sequelae, has been a contentious issue since psychological studies began. Wing & Wing (1971) proposed that autism might arise on the basis of more than one cognitive deficit, and Goodman (1989) has highlighted that autism and Asperger syndrome are characterized by similar social impairments but differ in the extent to which language is affected. The implication is that neither social nor language abnormalities can be construed as secondary phenomena. Although some theorists still adhere to the notion of a single primary deficit, most researchers now accept that autism arises on the basis of multiple primary cognitive deficits.

Autism has been reported in several, although not all, studies

(Starr *et al.* 2001) to be more often associated with mental retardation in females than in males (Lord *et al.* 1982), with the greatest male preponderance reported for individuals of average or greater intelligence (Volkmar *et al.* 1993). Autistic symptoms increase with more severe mental retardation for both sexes. In an epidemiological study, Wing & Gould (1979) found that about 2% of individuals with IQs of 50–69 had a triad of impairments similar to those seen in autism, in contrast to 82% of individuals with IQ scores below 20.

Effects of cognitive level on diagnosis

Diagnosis of autistic spectrum disorders can be particularly problematic at either end of the intellectual spectrum: profound mental retardation, or average and greater intelligence. The need to consider absent or limited social communicative behaviours, such as initiating joint attention, means that most standardized diagnostic instruments for autism yield high scores for many mentally retarded individuals with mental ages of less than about 12–18 months (DiLavore *et al.* 1995; Berument *et al.* 1999), despite the fact that profoundly retarded individuals with and without autism show different patterns of behaviour (De Giacomo & Fombonne 1998). Conversely, children with autistic spectrum disorders with strong intellectual and verbal skills can develop ways of engaging in social interaction that may work around some of their deficits. Two studies following children from preschool to school age found that the higher the IQ score, the greater the proportion of children who were reclassified as having PDDNOS or Asperger syndrome several years later (Eisenmajer *et al.* 1996).

Any explanatory model must account for psychological deficits at all levels of functioning. A corollary is that autism is not reducible to only those deficits found in the most able individuals, who are sometimes considered to have ‘pure’ autism (Minshew *et al.* 1997). Indeed, fundamental cognitive deficits may be masked in very able individuals by the availability of alternative cognitive strategies. It seems likely that what is specific about the psychological processes underlying autistic spectrum disorders is not the presence of one critical deficit, but rather the particular *combination* of abnormalities.

Several different mechanisms may be relevant for the co-occurrence of cognitive and emotional abnormalities. Abnormal development of one psychological function can affect other developmental processes. Thus, in the modular system of development of ‘theory of mind’ proposed by Baron-Cohen (1995), dysfunction of the shared attention mechanism is hypothesized to impair input to the theory of mind mechanism. Adequate language skills are also necessary to understand the beliefs of others. A second possibility is that deficits co-occur because they arise from abnormal functioning of a particular brain region; models of autism as a frontal lobe disorder typify this type of explanation (Pennington & Ozonoff 1996). A third possibility is that impaired cognitive and emotional processes arise on the basis of a shared, but not anatomically localized, neurobiological abnormality. Finally, behaviours that result in the selection

and restriction of individuals’ environments and activities may lead to correlated psychological abnormalities and their persistence over time.

Theories emphasizing social cognitive deficits

Early psychological studies of autism focused on attention, memory and meta-cognitive processes. Studies of ‘theory of mind’, beginning in the mid-1980s, concern children’s ability to understand that others have beliefs and desires, and to use this knowledge to predict the behaviour of others (Flavell 1999). Observations of these deficits in understanding the mental states of others in children with autism (Baron-Cohen *et al.* 1985) initially led to the conclusion that autism was a specific cognitive disorder of ‘mind-blindness’ (Baron-Cohen 1990). ‘Theory of mind’ (ToM), or mentalizing ability, was examined using tests of false belief: the ability to recognize that an individual or agent will act on the basis of his or her beliefs, not on the basis of how things really are.

Deficits in mentalizing ability have been found in individuals with autism using many experimental protocols. In a meta-analysis, Happé (1994) found that some 50% of tested individuals with autism failed a first-order ToM test. Although it is not a universal or specific deficit, ToM has been accepted as important to the understanding of autism. The social difficulties associated with ToM that characterize autism (e.g. not understanding what another person is thinking) have been attributed to impairments in general cognitive processes (e.g. attention, memory, executive functioning). Attempts to disprove the ToM hypothesis have illustrated how ToM skills are influenced by other psychological processes. Thus, Tager-Flusberg & Sullivan (1994) showed that when second-order false belief tasks are presented to individuals with autism in a way that minimizes working memory requirements, individuals who passed simpler ToM tasks could pass the more difficult tasks as well and justify their answers appropriately. Russell *et al.* (1999) demonstrated how executive factors can contribute to failure on false belief tasks. Language abilities also seem to play a critical part in ToM skills in autism. In her meta-analysis, Happé (1994) found that, for children with autism and children with mental retardation, ToM skills were related to language level but the language level necessary for success was significantly higher in the individuals with autism than those with mental retardation. Similarly, Kazak *et al.* (1997) found that ToM performance was correlated with language skills in children with autism, but not in normally developing children. One implication of these findings is that individuals with autism who pass ToM tasks may be using language-based strategies. Indeed, overall language competence is a critical factor in early social development. Thus, Lord & Pickles (1996) found that many, although not all, social and non-verbal communication impairments reported in young children with autism were also evident in individuals without autism but with severe language impairment.

Because the appearance of social abnormalities in autism typically occurs before ToM skills would even be expected to occur,

and because impairments do not account for many social abnormalities in autism, such as impaired expressions of emotion (Rutter & Bailey 1993), attention has shifted to possible precursors of ToM and other social behaviours in infancy (Dawson *et al.* 1998). Modularists, such as Baron-Cohen (1995), postulate early developing modules specialized to deal with social stimuli, such as an 'eye direction detector' (EDD). Deficits in shared attentional behaviours, e.g. following another's gaze, pointing and showing, have been even more consistently documented than ToM deficits (Leekam *et al.* 1998; Sigman 1998).

Other theorists have focused on the infant's interest in facial expressions. Hobson (1993) proposed that mentalizing skills derive from children's inborn ability to perceive the affective states or attitudes of others. For Meltzoff & Gopnik (1993), the apprehension that others are like the self arises from a cross-modal mapping between the observed facial expressions and actions of others and the infant's own body movements. Although impairments have been reported in the recognition and naming of emotional expressions (Hobson *et al.* 1988), identity (Klin *et al.* 1999), holistic processing (Langdell 1978) and determination of eye gaze direction (Howard *et al.* 2000) by individuals with autism, the extent and specificity of face processing impairments and the primacy of particular cognitive processes is currently unclear and the subject of considerable scrutiny. Although facial expressions of emotion are often impaired in individuals with autistic spectrum disorders (Sigman *et al.* 1995), the relative contribution of neurological and cognitive/affective processing is not known.

Aspects of other accounts of the development of ToM may also be relevant to autistic difficulties. Russell *et al.* (1996) argued that the infant's experience of willed action is necessary for understanding the mind. Impairments in self-monitoring, as seen in impaired executive functions, were seen as critical. Moore (1996) emphasized the importance of situations in which the infant and adults were in matched psychological activity. Such opportunities may arise less frequently in autism because of other cognitive impairments. Others (Bartsch & Wellman 1995) have emphasized the role of subsequent social experience in the ongoing development of the child's ToM: opportunities that may be diminished in the lives of autistic children, who show an impaired capacity to generate social scripts (Trillingsgaard 1999).

On the other hand, able individuals with autism may eventually simulate the mental states of others based on introspection (Harris 1992). Theorizing about the acquisition of normal social behaviour has placed considerable emphasis on the role of visual input in early infant development. Nevertheless, individuals with autism are also impaired in familiar voice recognition (Boucher *et al.* 1998). Although some useful comparisons have been made with blind or deaf children (Peterson & Siegal 1997; Hobson *et al.* 1999), there is further scope for investigating the alternative cognitive strategies used to achieve social competence in the presence of sensory impairment, and examining why these are not effective in autistic individuals.

Accounting for communication deficits

One consequence of the recent focus on abnormal social development in autistic spectrum disorders has been a relative lack of interest in the mechanisms underlying abnormal language comprehension and production. Attention has mainly focused on the need to control for language level when investigating other aspects of autism (Lord & Paul 1997). This focus represents a significant shift from the earlier conceptualization of language difficulties as a core deficit (Rutter 1968). The field's focus on behaviours and cognitive processes that show diagnostic specificity may have been the major factor leading to the relative neglect of language abnormalities (and mental handicap), with the possibility raised that communication impairments were secondary consequences of impaired mentalizing abilities (Tager-Flusberg & Sullivan 1994). Nevertheless, pragmatic and conversational impairments are characteristic features of the language of individuals with both mild and severe autistic spectrum disorders.

A principal theoretical focus has been on the role of joint attentional impairments and the possibility that children who cannot achieve shared reference and understanding with others may not be motivated to learn to communicate (Mundy & Sigman 1989). Joint attention and representational play skills are strongly correlated with language skills in autistic children (Sigman 1998) but do not completely account for these language impairments. In Asperger syndrome, many aspects of language acquisition are not significantly delayed but affected individuals show some impaired joint attentional skills, albeit less than in high-functioning autism (Gilchrist *et al.* 2001). Conversely, language delay and related difficulties are found in relatives with milder phenotypes (reviewed by Bailey *et al.* 1998), although there is no suggestion that these individuals show joint attentional impairments. Even in individuals with language, although words appear to be stored with reference to their semantic properties (Tager-Flusberg 1985), retrieval in context is impaired (Happé 1997), suggesting that there are persisting abnormalities in the overall organization of the language system.

Accounting for repetitive and stereotyped behaviours

Although autistic spectrum disorders are characterized by limited imaginative play and creative activities and a tendency to stereotyped and repetitive behaviours, the relationship between limits in creativity, imagination and social communication skills and repetitive behaviours is unlikely to be simple. The intensity of interests and routines in some individuals tends to suggest that they represent a primary abnormality rather than an attempt to fill a 'creative vacuum'. An alternative explanation may be that both deficits and abnormalities are linked to a broader abnormality, such as executive functioning. Executive function refers to a set of higher cognitive abilities involved in maintaining an appropriate problem-solving network (Pennington & Ozonoff 1996). A suggestion that deficits in this area were the

most likely explanation for repetitive and stereotyped behaviours first arose on the basis of comparisons with patients with acquired frontal lobe damage (Damasio & Maurer 1978). Impairments have been found in executive processes that can potentially contribute to rigid and repetitive behaviours: switching set and preservation, planning and organization, working memory, and generativity (Ozonoff 1995). Nevertheless, not all executive impairments are evident early in development (Griffith *et al.* 1999), suggesting that other cognitive or neurological processes are likely to be implicated.

Occasionally, intense interests and activities are associated with savant skills (Hermelin 2001). How these skills relate to other aspects of repetitive behaviours is unclear. Young & Nettlebeck (1994) found that calendrical calculators showed extreme concentration and motivation, had particularly reliable delayed recall of information, and practised regularly but applied strategies in a rigid form. Other researchers have also noted unusual perceptual processing (Plaisted *et al.* 1998) and increased discrimination of false memories (Beverdorf *et al.* 2000) in individuals with autism. One attempt to explain the coexistence of superior skills and deficits has been the suggestion that individuals with autistic spectrum disorders show weak central coherence: they have a tendency to process incoming information in context with an emphasis on detail rather than high-level meaning (Frith 1989). With the exception of studies of verbal-semantic coherence (Frith & Snowling 1983; Happé 1997), most attention has focused on studying the balance of global/local processing in visuospatial-constructional tasks, such as block design or the identification of embedded figures—an area in which individuals with autism usually show preserved abilities (reviewed by Happé 1999). Whether the same cognitive processes are relevant in language and complex social situations is not clear.

Attentional abnormalities

Information processing researchers have also investigated the role of other fundamental psychological mechanisms in autistic spectrum disorders. In the past, these were pitted against impairments in specific socioemotional processes, but lately there has been an increasing acceptance of the potential coexistence of specific and non-specific abnormalities. Attentional impairments have been the subject of theoretical accounts of autism since the late 1960s (Rimland 1964). These were motivated by the apparent highly focused attention of children with autistic disorders on minor environmental stimuli. Difficulties in visual orientating and attentional shifting have been a source of interest (Wainwright-Sharp & Bryson 1993; Townsend *et al.* 1999), and have been linked with putative cerebellar abnormalities (Harris *et al.* 1999) but not consistently (Pascualvaca *et al.* 1998). Sustained attention appears intact except, possibly, for individuals with autism and severe mental retardation (Burack *et al.* 1997). In a comprehensive study of information processing abilities in able individuals, Minshew *et al.* (1997) found normal or superior performance on simple attentional tasks but impair-

ments in skilled motor, complex memory, complex language and reasoning tasks. A recent study of infants with autistic spectrum disorders (Swettenham *et al.* 1998) found decreased looking at people compared with objects and reduced attentional shifting between objects and people, suggesting complex influences on the allocation of attentional resources.

Neurobiology

The findings from a large number of neurobiological studies have been summarized in two comprehensive books (Bauman & Kemper 1994; Gillberg & Coleman 2000). Many of the data are contradictory (Bailey *et al.* 1996). This area of study is problematic, partly because we know relatively little about the functioning of the normal brain and even less about the acquisition of skills during normal development. In addition, many of the features of autistic spectrum disorders that require a biological explanation, including early onset, sex ratio, association with mental handicap, and the onset of seizures in late adolescence and early adult life, have not been addressed. Also, there has been little or no study of the milder and partial phenotypes seen in some relatives.

Neuropathology

Kemper & Bauman (1998) undertook the first major neuropathological study, reporting abnormally small, densely packed neurones in the hippocampus, subiculum, mammillary body, septal nuclei and some amygdala subnuclei of nine brains. No abnormalities were noted in the cerebral cortex. In the same brains, there was evidence of decreased Purkinje cell density in the cerebellum. Findings from other comprehensive published post-mortem studies are somewhat different. Bailey *et al.* (1998) reported that four of seven brains were megalencephalic. Limited sampling revealed other cortical dysgenetic lesions in most of the cases. There were also obvious developmental abnormalities of the brainstem, particularly of the inferior olive. There was no apparent increase in neuronal density in the hippocampus, although decreased Purkinje cell density was identified, sometimes accompanied by gliosis. Significantly increased brain weight was also noted in the majority of individuals in the series of Kemper & Bauman (1998).

These findings have been open to various interpretations. Thus, Kemper and Bauman suggested that forebrain abnormalities underlie autistic symptomatology, whereas the decreased number of Purkinje cells together with the reported hypoplasia of cerebellar vermal lobules VI–VII (Courchesne *et al.* 1988) led to the suggestion of a cerebellar pathogenesis (Courchesne *et al.* 1994). Bailey *et al.* (1998) noted that autism was associated with widespread neurodevelopmental abnormalities and speculated that areas of focal cortical dysgenesis indexed a more pervasive abnormality in cortical organization. The true significance of the various post-mortem findings will have to be judged in relation to convergent evidence concerning structural and functional abnormalities.

Structural imaging studies

The many neuroimaging studies of autism have been recently reviewed (Filipek 1999; Chugani 2000; Santosh 2000). In terms of replication of post-mortem findings, increased brain volume has been reported in four studies (Howard *et al.* 2000), with some suggestion that frontal lobe volumes are not increased. Whether the underlying cause is an increase in cell number (Bailey *et al.* 1998) has yet to be confirmed. The evidence of increased head circumference (Woodhouse *et al.* 1996; Lainhart *et al.* 1997) is in keeping with the post-mortem and magnetic resonance imaging (MRI) findings, with some indications that increased head size may be a familial trait (Stevenson *et al.* 1997). With regard to the hippocampus and amygdala, these structures have been reported in different studies as unchanged, decreased and increased in size (Piven *et al.* 1998; Howard *et al.* 2000). Autism is not associated with hippocampal sclerosis.

There has been disagreement about the claims of specific hypoplasia of cerebellar vermal lobules VI and VII (Courchesne *et al.* 1988). Interpretation of the medial temporal lobe findings is problematic, both because of the relatively small size of the amygdala and hippocampus and because of the need to control for cerebral volume. Bolton & Griffiths (1997) noted an association with tubers located in the temporal lobes in individuals with tuberous sclerosis and autism, although whether these tubers primarily disrupted function of medial temporal structures or the neocortex is unclear. In terms of other structural imaging findings, there are occasional reports of localized cortical developmental abnormalities but no consistency in their site. Several studies have reported a disproportionately small corpus callosum (Piven *et al.* 1997c), raising the possibility of disturbed axonal path formation.

Studies of brain function

Along with epilepsy (Rutter 1970), one of the first indications of abnormal brain function in autism came from EEG studies. With repeated and/or extensive testing, EEG abnormalities are found in about 50% of individuals with autism (Minshew 1991). There is no evidence of regional localization of abnormalities, although regional differences in EEG power have been reported (Dawson *et al.* 1995). It has recently been suggested that autistic regression is a consequence of epileptiform activity (Lewine *et al.* 1999) but this has not been found consistently (Tuchman & Rapin 1997). Resting single photon emission computed tomography (SPECT) and positron emission tomography (PET) studies have not found consistent evidence of globally decreased or increased blood flow. There is one report (Zilbovicius *et al.* 1995) of reduced frontal perfusion in young autistic children, but it was unremarkable 3 years later, and Horwitz *et al.* (1988) reported decreased interregional correlations in metabolic rates, raising the possibility of impaired functional connectivity.

For many years, event-related potentials (ERPs) were the only means available to investigate brain function during specific cognitive tasks (Burack *et al.* 1997). The data from many of

these studies are particularly contradictory, probably in part because of the low spatial resolution of EEG. The utility of studies of brain function in autistic spectrum disorders will be significantly increased with the development of functional MRI (fMRI) and magneto-encephalographic techniques. Several studies illustrate the potential of these fMRI approaches. Baron-Cohen *et al.* (1999) found that able individuals with autism or Asperger syndrome failed to activate the amygdala in an fMRI study of judging thinking or feeling from photographs of eyes. Schultz *et al.* (2000), using similar methodology, found that adults with autism or Asperger syndrome showed less activation of the right fusiform gyrus in a face recognition task. Magneto-encephalographic studies have found lack of face specificity in right fusiform gyrus (Swithenby *et al.* 2000) and impaired contextual effects in reading, possibly related to differences in the time course of representations (Bailey *et al.* in press). Other approaches to identifying neurological abnormalities are also available; Minshew *et al.* (1999) demonstrated normal cerebellar control of eye movements but impairments in cortically controlled saccades.

Neurochemical studies

Over the years, all the major neurotransmitter systems have been implicated in autistic spectrum disorders at some time but, despite the research effort in this field, many findings have not replicated (see reviews by Cook 1990; Anderson & Hoshino 1997). The most consistent findings relate to the serotonergic system. Elevated levels of whole blood serotonin have been observed in 25–33% of autistic subjects (Anderson *et al.* 1987), although more recent studies suggest that the elevation may be more prevalent in prepubertal individuals (McBride *et al.* 1998). Breakdown products are not elevated in cerebrospinal fluid, and elevated peripheral serotonin levels are also found in severe mental retardation. Hyperserotonemia may arise on the basis of multiple mechanisms, as non-retarded relatives of hyperserotonemic probands are also reported to show increased levels of whole blood serotonin (Cook 1996).

SSRIs have beneficial effects in the treatment of some individuals with autism, particularly reducing anxiety and obsessive-compulsive behaviours. In contrast, tryptophan depletion techniques were reported to result in a significant increase in autistic behaviours (McDougle *et al.* 1996). One PET scan study revealed decreased 5-HT synthesis in frontal cortex and thalamus, but elevated 5-HT synthesis in the contralateral dentate nucleus (Chugani *et al.* 1997). A preliminary study also found that the normal developmental process, whereby humans undergo a period of high brain 5-HT synthesis capacity until the age of 5 years, appears disrupted in children with autism (Chugani *et al.* 1999). The extent to which the observed abnormalities are primary causes of autism or simply one of the many consequences of abnormal brain development that also contribute to symptomatology is presently unclear.

The post-mortem and neuroimaging data together raise the possibility that autistic spectrum disorders affect the develop-

Table 38.1 Overall treatment programme.

<i>Feedback to family</i>
Diagnosis, prognosis and treatment
Genetic counselling

ment and function of both the cerebral cortex and subcortical structures with considerable interindividual variation. The outstanding question is whether any one of these abnormalities is truly primary, or whether the fundamental problem lies in connectivity within and between different structures.

Treatment and intervention

The specifics of treatment will necessarily vary across children and families but it is helpful to have an overall plan of areas that will always need coverage (see Table 38.1; Rutter 1985). Necessarily, this begins with feedback to the family and ensuring that medical care needs are met. An individualized plan is necessary with specific, immediate and long-term objectives appropriate to the chronological age and developmental level of the child. This should incorporate special educational provision, treatment of the child's deficits and problems, and help for the family. Working with a family is an important part of any evaluation. Clinicians must familiarize themselves with sources of information about services in their communities and work with professionals from many other disciplines in order to be effective in the treatment of autistic spectrum disorders.

Education

Education has been the most powerful source of improvement for children and adolescents with autistic spectrum disorders in the last 50 years (National Research Council 2001). With access to appropriate educational services, far fewer children are placed in long-stay institutions (Schopler & Olley 1982; Howlin & Goode 1998), rates of functional language may be higher, and there are more direct relationships between ability levels and eventual academic functioning of individuals with autistic spectrum disorders (Venter *et al.* 1992).

There is good evidence that specific behaviours and skills can be directly taught to children and adults with autism, although there are limitations to the generalization and spontaneous usage of skills learned (Lord 2000). Children with autism can be taught ToM skills, but the social benefits have been minimal (Ozonoff & Miller 1995; Hadwin *et al.* 1996). Although most studies of the effects of different methods of instruction were carried out on small samples, many have been replicated. Increasingly, the emphasis has been on teaching children proactive behaviours (e.g. learning to communicate using objects and pictures, being able to respond to a teacher's direction within a group), rather than on eliminating negative behaviours, with the assumption that many problem behaviours decrease with the child's understanding and acquisition of skills (Carr *et al.* 1999).

There have been few direct comparisons of different teaching strategies. This lack is partly caused by the heterogeneity of needs of individuals with autistic spectrum disorders, so that a programme appropriate for one child may not be relevant for another, and in part because carrying out well-controlled randomized comparisons with independent evaluations is extremely difficult in educational settings.

Gains in education have come from diverse areas (see Howlin, Chapter 68), but it is the role of early intervention that has caused the most controversy. Applied behaviour analysis (ABA) is a technique that involves one-on-one repeated presentations by an adult of materials and behaviours intended to elicit specific responses. The adult says, for example, 'Get ready. Look at me!' and the child is expected to put his or her feet on the floor, hands in his or her lap and look at the adult. Behavioural approaches include reinforcement schedules and hierarchies, methods of 'shaping' behaviours and techniques in teaching associations (Leaf & McEachin 1999). Lovaas (1987) carried out a group design study of ABA with very young preschool-age children with autism. The study included quasi-random assignment to treatment conditions and produced extraordinary results, both in the breadth of improvement of some children who were described as 'indistinguishable from normal' by school age, and in the proportion of children with autism who showed such great improvements (nearly half). In the 1990s, numerous studies, using the original ABA techniques and modified versions, replicated findings of significant but smaller improvements in intellectual skills (gains of about 20 points; Smith *et al.* 2000) but did not find the restoration of 'normal' functioning

that was first reported (Leaf & McEachin 1999; Smith 1999). Overall, these findings resulted in a general increase in intensity and organization of services for preschool-age children.

There are many different ‘packages’ of model programmes, mostly for preschool and early school-age children with autism (Handleman & Harris 2000). Although these programmes have different emphases, they share many common features. Most of these features apply to programmes for school-age children as well (Rutter 1985). These features include entry into programmes at an early age (usually at 2 or 3 years); full-day programming (at least 25 h a week); repeated planned activities organized in small units of time (e.g. 15–20 min) with a low student:teacher ratio; inclusion of family goals and parent training; and mechanisms for ongoing assessment and changes in strategy if measurable progress does not occur within several months (Dawson & Osterling 1997; Howlin 1998; Rogers 1998; Hurth *et al.* 1999). Other features include the idea of *structure* (clearly discernible expectations and physical representations of planned activities, e.g. visual schedules; Marcus *et al.* 2000), *developmental appropriateness* (building new behaviours on behaviours the child already has), and *using strengths to support gains in weaker areas*.

More variability across programmes exists as to whether even more intensive programming (up to 40–50 h a week) should occur; where it should occur (home vs. school); the proportion of time in incidental teaching vs. highly structured, teacher-directed programming; when and how interactions with peers should be addressed; and whether a purely speech-based approach, with no use of alternative language systems, is ever appropriate. Because there are such great differences in families of children within the autism spectrum and in the resources available across school systems, decisions must be based on what is best for an individual child and family (Howlin & Rutter 1987). How best to integrate the ‘active ingredients’ from ABA and other well-known programmes, such as Treatment and Education of Children, Adolescents and Adults with Autism (TEACCH; Mesibov 1997; Marcus *et al.* 2000) which involves a multilevel family and community-orientated approach; more peer-orientated programmes, such as Walden School (McGee *et al.* 2000) or LEAP (Strain & Hoyson 2000); and more ‘natural teaching’ approaches (Greenspan & Wieder 1997; Wetherby & Prizant 1999) merits further study. In general, good evidence that specific strategies are effective (such as using schedules and visual systems and home-based parent training) is available (Howlin & Rutter 1987; Ozonoff & Cathcart 1998), but research comparing various treatments or programmes is not (Rogers 1998). Information about many different programmes is currently available on the Internet, often with extraordinary claims for outcome. This can be quite confusing for parents.

Research has suggested that when children with autism have opportunities to play with typically developing children in situations where there is skilled adult guidance, they have fewer behaviour problems and more social interaction than with peers with autism (McGee *et al.* 2000). On the other hand, in less well-supervised settings with typical children, children with autistic

spectrum disorders may have minimal interactions, little directed behaviour and significant behavioural difficulties (Guralnick 1976). The principle of seeking the least restrictive environment that is appropriate for each child offers opportunities to children who might have been excluded out of hand, but the level of structure, support and knowledge of the teaching staff is crucial. Often, plans where children with autism spend some time in highly structured individualized or small group teaching and other time where there are opportunities for positive interactions with other children are most effective. However, individualization is most important.

Help for family

Families have multiple roles in their children’s lives, particularly when their child has an autistic spectrum disorder (Harris 1994). They provide emotional support and act as teachers, models of behaviour and social interaction and advocates for services. Concerns vary even within a family across time, as do the roles that parents need and want to serve for their children. The degree to which spouses are able to support each other (Bristol *et al.* 1988) and have time to spend with other children in the family are critical factors (Celiberti & Harris 1993).

Parents experience a range of emotions in response to having a child with autism, and for some families this results in considerable stress. Helping parents to accept the disappointment and fear that they feel, know that ambivalent feelings are acceptable, and that they are not alone in these feelings is part of treatment. Practical help, such as in finding respite care or dealing with social services or educational systems, may be as important as emotional support and teaching management techniques.

Parents not only need information about what they should do but how they might do this (Runco & Schreibman 1987). It is much more useful to work with parents to devise ways in which they will respond to their child’s tantrums or get him or her to bed than simply to direct them to solve the problem. There is a substantial literature on working with parents in the home and in clinics (Howlin & Rutter 1987; Schopler *et al.* 1990). In order to make useful suggestions, familiarity with the child, the family and community resources is essential. Support for families is available from a wide range of agencies concerned with both autism and learning disorders. In addition, many parents take on an advocacy role for their children, which may require other new skills. Parent-based groups have made significant differences in the dissemination of knowledge, development of specific programmes (such as summer camps, social groups and residential services) and the stimulation of research funding in the UK and USA.

Specific therapies

Many different therapies are available: speech and language therapy, occupational therapy, physical therapy, cognitive-behaviour or individual psychotherapy for older high-functioning adolescents and adults, and social groups (Cohen &

Volkmar 1997), but there is little evidence on their relative efficacy (National Research Council 2001). It seems likely that it is not the profession of the therapists but what they teach, and their knowledge and abilities to teach this skill well, that make a difference. Different treatment paradigms such as auditory training (Bettison 1996), facilitated communication (Mirenda *et al.* 1983) and holding therapy (Richer & Zappella 1989) have tended to come and go over the years. However, working with an expert experienced with children with autism spectrum disorders to develop strategies for an individual child and family can be helpful. This is particularly true for communication and language, which are not only pivotal features of social and cognitive learning, but also are often extraordinarily limited in autism. The more the actual treatment can take place in the contexts in which the behaviours occur in real life, the more likely changes are to generalize and to be maintained over time. Thus, family involvement and active school or work consultation are critical to effective treatment.

Brief psychotherapy or cognitive-behaviour treatment may be helpful with adolescents and adults with sufficient verbal skills to be able to discuss their social difficulties and/or who may have cooccurring anxiety or depression. These techniques may be particularly effective when combined with social groups or consultation with a school or a job coach so that new skills can be practised in a supportive environment (Mesibov 1984; Lord 1996).

Positive behaviour support (PBS) systems address what used to be called behaviour management, by developing a comprehensive set of procedures that include changing the environment to make the problem behaviours less relevant, teaching appropriate behaviours that are more efficient than the problem behaviours in attaining the child's goals, and manipulating the consequences so that appropriate behaviours are more consistently and powerfully rewarded than are problem behaviours (for a review see Carr *et al.* 1999). Most severe behaviour problems do not go away on their own and so it is important to begin treatment early and carefully. A functional analysis that identifies the contingencies in the environment that sustain a child's problem behaviours is a crucial part of this approach (Table 38.2). The emphasis is on avoiding the use of 'aversives' or punishments and focusing on positive aspects of both the child's behaviour and the environment. *Structure* (making the environment more predictable and meaningful) often reduces the need for intense behaviour management programmes. If a non-verbal child can see from a picture schedule what his or her day's activities are, and have some choice in how he or she spends his or her free time, then he or she will be less likely to throw a tantrum when asked to do another activity.

Vocational training and support

Most individuals with autistic spectrum disorders have abilities that can be used in some type of employment although, as with other aspects of autism, there is tremendous variability across individuals. Most need help finding a place of work and support to be able to deal with social and other expectations of a job. Sys-

Table 38.2 Behavioural treatment goals.

Promotion of cognitive development and learning including academic and work skills
Promotion of language/communication development including social use of communication
Promotion of social development including self-help, social problem-solving and social relationships
Reduction of maladaptive behaviour including use of diversion, avoidance of precipitants and provision of coping skills

tems for providing training and ongoing support have become increasingly sophisticated (Van Bourgondien & Schopler 1990; Mawhood & Howlin 1999) but long-term support varies greatly in availability. School programmes that emphasize both general work behaviours (e.g. dealing with delays) and practice in job environments have improved the outlook for individuals with autism (Mesibov 1984; Howlin & Goode 1998).

Even for intellectually able individuals, learning appropriate work behaviours, such as respect for privacy, can be very difficult. However, great strides have been made in specific programmes to provide job coaches, 'enclaves' (where there is a core of support within a large business, such as a hotel chain, and individuals with autism work with varying degrees of support in a range of jobs) and job placement programmes (Smith *et al.* 1994). The key element for success appears to be flexibility, such as modified working hours and job requirements for individuals with autism and for their employers. With gradual training, continued support and long-term planning, it should be possible for almost every person with autism to have work in some setting. This generally requires more than simply help finding a job, but continued support on various levels from ongoing consultation to full-time staff and specialized job settings.

Many individuals with autism cannot live independently as adults. Systematic training for staff in residential programmes, from supervised apartments to group living arrangements, are available (Van Bourgondien & Schopler 1990). Many of the same features that occur in successful education characterize residential living programmes. Residential opportunities have also become much more individualized, with services ranging from supervised individual apartments to clusters of apartments and farm communities, to small-group homes. In addition, the development of leisure skills may be a long, but worthwhile, process. In many regions, there is a tremendous need for support and respite for adults with autistic spectrum disorders who are still living at home and for their families. Ongoing social groups can provide support, contact with peers with and without autism, and specific skill training beyond traditional psychiatric follow-up (Mesibov 1984; Williams 1989).

Psychopharmacology

Currently, there is no drug that has a specific ameliorative effect on autism but there is an occasional important contributory role

for pharmacotherapy as an adjunct to psychological and educational interventions. Experience suggests that there are substantial variations among countries in the rate of medication use and that, outside of specialist centres, medication may quite often be the main intervention used (Aman *et al.* 1995). Injudicious medication may simply sedate a child, which, although reducing intrusive behaviours, may also diminish social interaction and the opportunity to learn. On the other hand, medication combined with behavioural analysis and appropriate psychoeducational interventions may enable a child to modify his or her behaviour in a way that would not have been possible in a drug-free state. There are several recent helpful reviews (McDougle 1997; Tsai 1999; Volkmar *et al.* 1999; see also Heyman & Santosh, Chapter 59).

Although there has been much research into the neurochemical basis of autism, pharmacotherapy is still largely based upon clinical trials rather than extrapolated from basic neurochemical findings. The majority of studies are open trials and most have been conducted in adult populations. However, clinicians may consider that a trial of medication is warranted in an individual child, even though there is no licence for use in children, and long-term safety is not yet established. In these circumstances, clinicians are advised to use medication with caution, to discuss individual cases with colleagues and to aim for as short a period of medication as is practical.

Over the years, there have been numerous claims for unusually dramatic responses to various drugs but these claims have not generally been replicated by other investigators. Probably the best-documented response has been to haloperidol (Campbell *et al.* 1990), particularly with respect to reduction in stereotypies and behavioural improvement. However, haloperidol has been associated with a high incidence of extrapyramidal side-effects, particularly when the drug is withdrawn (Campbell *et al.* 1990). Consequently, there has been much recent interest in the efficacy of the newer neuroleptics, such as risperidone and olanzapine. A double-blind placebo-controlled study of risperidone in adults with autism and other pervasive developmental disorders (McDougle *et al.* 1998) reported significant reductions in repetitive behaviour, aggression, anxiety or nervousness, and depression, although measurable changes in social behaviour and language did not occur. Open trial studies of risperidone in children have produced encouraging results (Nicolson *et al.* 1998) leading to ongoing multisite controlled studies (McDougle *et al.* 2000). Similar improvements have been reported in open trial studies of olanzapine (Potenza *et al.* 1999); nevertheless, weight gain remains a significant problem with these new drugs.

The other significant advance in the pharmacotherapy of autism and related disorders is the extent to which disabling anxiety, obsessional and repetitive behaviour and self-injury can sometimes be ameliorated by SSRIs (McDougle *et al.* 1996; Fatemi *et al.* 1998). These drugs are also an effective treatment for depression, which may be a particular problem for able individuals in adolescence. It is possible that these drugs are most ef-

fective in individuals with a family history of anxiety/depressive disorders.

Control of overactivity can often be problematic and may necessitate a trial of several different types of medication (Nicolson & Castellanos 2000). A major difficulty can be the worsening of stereotypies with stimulant use. Aman *et al.* (1995) concluded that there was little role for these medications, although others have reported beneficial effects (Quintana *et al.* 1995).

There has been some interest in the use of opiate antagonists, particularly to promote social engagement and decrease self-injurious behaviour (for a review see Tsai 1999). Naltrexone may be effective in reducing overactivity (Campbell *et al.* 1993; Willemsen-Swinkels *et al.* 1995), but other researchers have concluded that there are no positive effects (Gillberg 1995). With respect to other agents, at present there is a paucity of properly controlled clinical trials reporting consistent beneficial effects. Claims have been made for the benefits of secretin but the findings have been negative (Dunn-Geier *et al.* 2000). Similarly, although vitamin B₆ and magnesium may sometimes provide modest benefits, the results of studies do not support its regular use (Pfeiffer *et al.* 1995). Epilepsy should be managed by clinicians experienced in the use of anticonvulsant medication; the newer drugs offer significant advantages in terms of decreased cognitive impairment and long-term side-effects.

Looking to the future

Advances in understanding autistic spectrum disorders seem likely to provide important scientific and practical insights in the next few years. Standardized diagnostic measures and more appropriate measures of language and non-verbal intelligence should make replication of research across sites more straightforward and allow more systematic assessment of developmental factors. Greater collaborative efforts will allow larger samples and clearer stratification of subsets of individuals within the spectrum.

The considerable resources being expended on molecular genetic studies of autism seem likely to ensure that susceptibility loci start to be cloned in the next few years. Our understanding should accelerate rapidly once the first loci are identified, because they will point to complex pathways whose constituents will become candidates for subsequent genetic analysis. There will be much interest in whether genetic susceptibility is conferred by variation in protein-coding regions or in promoter regions or in the mechanisms that control alternative splicing of proteins. Of equal interest will be the degree of genetic heterogeneity. Identifying and understanding the mechanisms underlying genetic heterogeneity will be crucial for using genotype findings to provide improved genetic counselling.

Identification of susceptibility genes will lead directly to studies of protein function in single cell systems, if these are not already known. It might also be possible to develop an animal

model of gene function. They may provide an opportunity to study the neuropathological and neurophysiological consequences of gene activity in the developing organism and to develop novel psychopharmacological strategies. There is likely to be an impact on post-mortem studies, both in terms of orientating researchers to potentially relevant pathology as well as enabling identification of more homogeneous groups of cases.

Functional imaging approaches provide a means to move beyond localization of abnormal brain activity to an understanding of the underlying mechanisms. Equally importantly, neuroimaging approaches offer one of the few opportunities to identify when normal task performance (in both affected individuals and their relatives) is mediated by abnormal mechanisms. At present, the potential of PET radioligand approaches, especially in the study of psychopharmacological mechanisms, is unclear.

There have been significant advances in our understanding of some central aspects of developmental psychopathology in autistic spectrum disorders. Nevertheless, there is still a need to identify more accurately those abnormalities that are potentially specific as well as understanding the possible interactions among different processes early in development. That task represents a considerable intellectual and practical challenge that will require a combining of many different types of approaches. The ability to identify more homogeneous groups of individuals will be advantageous, particularly in terms of understanding the mechanisms underlying effective early intervention. Increasingly, attention may shift to milder manifestations of autism spectrum disorders. Variability in phenotypic expression offers an opportunity to examine the role of specific cognitive deficits and their relationship to behavioural traits as well as establishing the extent to which these are consequences of single or multiple genes, as well as determining whether such genes are responsible for variations in similar behavioural traits in non-autistic groups.

There is a clear need for more efficient and broader mechanisms to evaluate interventions. The merging of various techniques in intervention, such as those described in ABA, developmental and TEACCH models, provides more comprehensive strategies but also makes the evaluation of critical components more difficult (National Research Council 2001). Attempts to integrate knowledge from outcomes of intervention, neurobiological research and descriptive studies are much needed. The development of statistical methods that allow quantification of individual differences within models of change or continuity may be particularly helpful.

In clinical work, difficulties in dissemination and availability of services are often even more limiting than the absence of knowledge. The strong upsurge in interest from parents' organizations in neurobiological research has had remarkable effects but should not take away from continued parent and professional advocacy for clinical and educational services. Service models should be modified to address the needs of individuals, from younger children to older adults and their families. The im-

portance of multiple faceted individual treatment plans, specific to a particular child and family and supported by knowledgeable clinicians and educators, must continue to be recognized, as models for evidence-based and manualized interventions are disseminated. How to extend the responsibility from family and clinician to community bases is also a major challenge. Overall, there is much hope for improved understanding and the identification of neurobiological factors in the next decade. However, as these investigations proceed, the roles of clinicians and educators continue to be most likely to affect the lives of families and children with autistic spectrum disorders.
