Contents

- Contributors, vii
Preface to the Fourth Edition, xii
Preface to the First Edition, xiv
- Part 1: Clinical Assessment**
- 1 Classification: Conceptual Issues and Substantive Findings, 3
Eric Taylor & Michael Rutter
 - 2 Clinical Assessment and Diagnostic Formulation, 18
Michael Rutter & Eric Taylor
 - 3 Diagnostic Interviews with Parents and Children, 32
Adrian Angold
 - 4 Case Identification in an Epidemiological Context, 52
Eric Fombonne
 - 5 Rating Scales, 70
Frank C. Verhulst & Jan Van der Ende
 - 6 Psychological Testing and Observation, 87
Joseph Sergeant & Eric Taylor
 - 7 Applied Scientific Thinking in Clinical Assessment, 103
Michael Rutter & William Yule
 - 8 Children's Testimony, 117
Stephen J. Ceci, Livia Gilstrap & Stanka A. Fitneva
 - 9 Family Interviewing: Issues of Theory and Practice, 128
Ivan Eisler
 - 10 Physical Examination and Medical Investigations, 141
Anthony Bailey
 - 11 Clinical Neurophysiology, 161
Colin D. Binnie, Steward C. Boyd, Renzo Guerrini & Ronit Pressler
- Part 2: Influences on Psychopathology**
- 12 Genetics of Normal and Abnormal Development, 185
Peter McGuffin & Michael Rutter
 - 13 Molecular Genetic and Chromosomal Anomalies: Cognitive and Behavioural Consequences, 205
David H. Skuse & Jonna Kuntsi
 - 14 Brain Disorders, 241
Robert Goodman
 - 15 Chronic Adversities, 261
Ruth J. Friedman & P. Lindsay Chase-Lansdale
 - 16 Culture, Ethnicity, Society and Psychopathology, 277

Preface to the Fourth Edition

The rate of change in child and adolescent mental health has accelerated in the years between the third and fourth editions of this book. Nearly every chapter has had to be completely rewritten and reconceptualized to take account of substantial research and clinical advances; the preparation of this volume has correspondingly been an exciting and encouraging (albeit challenging) task. In this preface, we pick out some of the main factors that are driving this development.

This edition differs from its predecessors in seven main respects. First, it reflects real gains in empirical knowledge and conceptual understanding. These are evident in all chapters throughout the book. Second, there is an extended range of chapters on measurement issues, a field in which considerable progress has been made. Third, we have sought to balance 'academic' advances with an equally detailed attention to clinical skills and clinical application. That is evident through the book but is also indexed by new chapters on diagnostic formulations and on the applied science aspects of clinical assessment. Fourth, we have endeavoured to introduce a greater developmental orientation; again, this is reflected both in many individual chapters and in a new chapter on this consideration. Fifth, we have sought to pay greater attention to sociocultural and ethnic issues and have added two chapters dealing specifically with these features. Sixth, there is greater attention to genetic findings and their implications, with a detailed discussion of misunderstandings about supposed genetic determinism and the possible misuse of genetics, as well as the huge clinical potential that is likely to follow genetic advances. Finally, the trend for an increasing international, and interdisciplinary, authorship that has applied over the first three editions has been further extended. This reflects not only the wide distribution of centres of excellence in the field of mental health but also the increasing cooperation and collaboration among such centres.

The gains in knowledge over the last few years have been driven both by the accumulation of scientific research and by changes in the wider society. One research development with high impact has been the advance of the methodology of assessment. Reliable instruments for data capture, and agreed criteria for disorders, have made knowledge more public. This in turn is driving both an increase in replicable findings about disorders and an increase in the practical application of quantitative measures to clinical assessment. Many clinics, for example, now apply schemes of assessment that were originally worked out for research purposes.

Advances in basic scientific knowledge have also provided some influential changes in the field. The pervasiveness and im-

pact of genetic contributions to disorder have been increasingly recognized: twin and adoptive studies have clarified both the genetic and the environmental influences on the common problems of mental health, and an increasing range of uncommon single-gene influences have been identified. The mapping of the human genome and the use of molecular chemistry to clarify the modes of expression of genetic variations have added an immediate relevance to genetic investigations and it seems certain that these will continue. Of course, the application of this knowledge to the clinic is for the most part confined to the advice and explanations that clinicians provide. Indeed, it is necessary to caution against a narrowly deterministic notion of how genes influence psychopathology. Even for the simplest genetic influences, their expression is strongly influenced by the actions of other genes and by interactions with the environment. The relationships between genotype and phenotype will need a great deal more understanding, and for the multifactorial disorders with which psychiatry usually deals their complexity may baffle our understanding for some time to come.

The rapid development of neuroimaging techniques is also full of promise for the future, and the chapter on physical investigations has correspondingly been expanded substantially. The availability of techniques (such as magnetic resonance) that do not depend upon ionizing radiation has allowed their application to young people, and the psychiatry of childhood has therefore started to be changed by the understanding of the brain that has informed adult psychiatry for decades. For this, as for genetic advances, the major immediate impact has been intangible: it has created a climate of opinion in which the disorders of mental health are seen in the context of neurobiology. The use of psychotropic drugs for young people has increased considerably in most countries over the last ten years. This increase is not primarily because new and more satisfactory drugs have been introduced but, rather, it has arisen as a result of an increased professional readiness to prescribe, and this in turn may follow as much from beliefs about causality as from improved knowledge of indications. Indeed, there may be a risk of a professional and practical division between a biologically oriented psychiatry and a group of disciplines focusing on psychosocial influences. Any such split would weaken understanding and practice. The authors in this volume come from a wide range of professional disciplines, but all have been at pains to bring together different perspectives and indicate how different approaches can fit together.

Developmental psychopathology, still a young science, is making it possible for clinicians to make more informed judgements

about the future course of disorder and the influences upon it that need to be assessed. The impact of deprivation and adversity is better understood, and advice to social work agencies and law courts has changed accordingly. The psychological understanding of what is altered in the neurodevelopmental disorders has pressed on, and has been one of the agents of change in the ascertainment and treatment of pervasive developmental disorders. The increased recognition of depressive disorders in young people owes a good deal to the clarification of their longitudinal course. The developmental issues involved in psychopathology have received increased attention in this edition, both in disorder-oriented chapters and in a new chapter bringing them together.

The increase in randomized controlled clinical trials is making the foundations of treatment ever more explicit. For the most part, it is still the case that evidence for any one disorder comes from a number of small trials with varying methodology. Indeed, the differences are so substantial that it has not yet been possible to base all treatment recommendations on systematic and quantitative meta-analytic reviews. Rather, authors have made critical narrative reviews about the evidence base and their recommendations are based on clinical expertise as well as the published literature. Nevertheless, it is plain from the chapters on treatments and services that evaluative research is increasingly the basis of guidelines.

Many of the factors driving change have been social and economic rather than scientific. Health care purchasers have become more organized, better informed, and increasingly concerned to contain the costs of health care. The results, whether in managed care or publicly funded services, includes pressure on providers to follow agreed guidelines and even detailed protocols in management regimes. This can have advantages: treatment recommendations should of course be explicit and challengeable, and there are too many areas noted in this volume where common clinical practices still fall well short of good practice guidelines. But there are dangers if protocols are applied mechanically and without sufficient consideration of individual variability. It remains the case that treatment should be focused on the individual, not the disorder. Our authors have correspondingly emphasized the principles underlying assessment and treatment rather than a set of rules, and they have borne in mind the great variety of ways in which health care is organized. Furthermore, protocols that are not based on sound evidence are very likely to be counterproductive, and the chapters of this book have striven to indicate the extent to which recommendations are based on public and reliable evidence and therefore the confidence that can be placed in them.

The information revolution has combined with other forms of social change to make a different relationship between the consumers and the providers of health care. In principle, there is everything to welcome in the increasingly active and well-informed participation of families in treatment decisions. But the heterogeneity and volume of health information available, for instance on television and the Internet, brings its own problems. Myths spread as quickly as truths. Our authors have often found it hard to recommend sources of health information for the pub-

lic that are clear, accessible and authoritative. The problem of improving the quality as well as the quantity of public information about mental health remains unsolved. The need for authoritative and integrative texts for professionals remains strong.

The changing face of child and adolescent psychiatry is reflected in changes of authors for a good number of the chapters, and we should like to take this opportunity of expressing our deep gratitude, not only to the contributors to this edition but to those who created the previous three editions. Most especially, we are personally as well as editorially indebted to Lionel Herscov for his wise and supportive editorship over the whole of the earlier history of this work and for his contribution to its success.

Acknowledgements

We are most appreciative of the authors' expertise and effort, and of their constructive responsiveness in dealing with the many editorial suggestions on possible new material that needed adding, topics that required strengthening, extended international coverage that was desirable, clarifications that would help readability and integrations across chapters. We note with great sadness the premature deaths of Channi Kumar and Donald Cohen during the course of producing the book. Both were at a peak in their careers. The world is much indebted to Channi Kumar for his pioneering work in developing and championing the field of perinatal psychiatry, and to Donald Cohen for his bridging of psychoanalysis and biological research, as well as for his international leadership in child and adolescent psychiatry as a whole.

The production of the book has been very much a team effort, and we have been fortunate in having such a good team to work with. Special thanks are due to Rachel Mawhood who exercised overall administrative responsibility for the complex enterprise of checking chapters prior to submission to the publishers, and to Gill Rangel who had the comparable responsibility for the task of checking and collating proofs (as well as much detailed work on individual chapters prior to submission). Both stages needed to run smoothly to a tight timetable and it was crucial to keep an eagle eye for inconsistencies or inaccuracies. We are also most grateful to Alice Emmott for her efficiency in translating the manuscripts into the printed page. Authors will be well aware of the care with which these multiple tasks were undertaken. Thanks also go to Angela Cottingham for her professionalism in preparing the index. Expert referees who commented on individual chapters were very helpful, but must remain anonymous. The editorial team also owes much to Jenny Wickham who had the main responsibility for dealing with several individual chapters but who also played a full role as a member of a cohesive, effective administrative team. We would also like to express particular thanks to David Shaffer for most helpful guidance and suggestions on authors during the planning stage of the book.

Preface to the First Edition

These are exciting times for anyone working in the field of child psychiatry. A wider understanding of child development now throws a clearer light on deviations from the normal pattern; knowledge of the nature and causes of psychiatric disorders in childhood is steadily increasing; new and effective methods of treatment are evolving; and clinical and education services for children with mental disorders are growing in scope and sophistication. The first academic departments of child psychiatry in the United Kingdom are now established to meet the needs for teaching and research and to add to the existing body of knowledge. A serious concern to raise training standards in the specialty has led to recommendations on the range of content of training and a national exercise to visit and appraise all training schemes is under way.

For these reasons the time seemed ripe for a new and different textbook of child psychiatry. Our aim has been to provide an accurate and comprehensive account of the current state of knowledge through the integration of research approaches and findings with the understanding that comes from clinical experience and practice. Each chapter scrutinizes existing information and emphasizes areas of growth and fresh ideas on a particular topic in a rigorous and critical fashion, but also in practical vein to help clinicians meet the needs of individual children and their families.

In planning the book we had to decide how to choose authors of individual chapters. Obviously we wanted colleagues who had made important contributions in their fields of interest and who could write with authority and knowledge. We were fortunate in our choice and we are deeply indebted to all of them. We also decided that it would be appropriate to invite contributions from those who had worked at The Bethlem Royal and The Maudsley Hospital or its closely associated postgraduate medical school, The Institute of Psychiatry. Over the years 'The Maudsley' has played a major role in training psychiatrists from all parts of the world and members of its staff have been among the leaders in both research and clinical practice. The fact that we have all worked at the same institution has produced some similarities: a firm acceptance of the value of interdisciplinary collaboration; an intense interest in new ideas and creative thinking; a commitment to the integration of academic and clinical approaches; a concern for empirical findings; and a belief in the benefits that follow from open discussion between people who hold differing views. As all of us work with children we have a common concern with developmental theories and with the process of development. However, as will also be

apparent, we do not share any single theoretical viewpoint. A variety of theoretical approaches are represented in the chapters which also reflect a differing emphasis on biological, sociocultural, behavioural and psychodynamic aetiologies and formulations.

It is also fitting that this book should be based on The Joint Hospital as it has played such an important part in the development of child psychiatry. Children with psychiatric disorders were first seen at The Bethlehem Royal Hospital as long ago as 1800 and Henry Maudsley was unusual among the psychiatrists of his day in appreciating the importance of psychiatric disorders arising in childhood. In his *Physiology and Pathology of Mind*, published in 1867, he included a 34-page chapter on 'Insanity of early life'. The Maudsley Hospital first opened its doors just over half a century ago, children have always been included among its patients and the Children's Department became firmly established during those early years. Since then, and especially with the first British academic appointment in child psychiatry at the Institute of Psychiatry in the 1950s, it has trained many child psychiatrists who now practise in all parts of the globe.

The book is organized into five sections. The first eight chapters review different influences on psychological development in childhood and are followed by three that discuss the foremost developmental theories. A third section describes some of the crucial issues in clinical assessment and the fourth deals systematically with the various clinical syndromes and their treatment. The final section comprises six chapters that bring together knowledge on some of the main therapeutic approaches. We have sought to include most of the topics and issues that are central to modern child psychiatry, but there has been no attempt to cover all known syndromes and symptoms. Instead, the focus has been on concepts and methods with special emphasis on those areas where development of new ideas or knowledge has been greatest.

We hope that the book's contents will be of interest and use to all those professionally concerned with the care, study and treatment of children with psychiatric disorders. We will be satisfied if, in the words of Sir Aubrey Lewis, it also helps the psychiatrist in training to acquire 'reasoning and understanding' and fits him 'to combine the scientific and humane temper in his studies as the psychiatrist needs to'.

Clinical Assessment

1

Classification: Conceptual Issues and Substantive Findings

Eric Taylor and Michael Rutter

Uses and abuses of classification

A classification is more like a language than a collection of objects. It supports communication and provides an aid to thinking about complex problems. The virtues of a good scientific classification are clarity, comprehensiveness, acceptability to users and fidelity to nature; a scheme should change as understanding alters. Each class in the scheme is a concept, not a thing. Its value is in relating individual cases to others, and a scientifically powerful class will do so in ways that are important to the user and include a good deal of meaning. When a case is assigned to a powerful class, many predictions follow.

Students of mental health face a remarkably broad collection of phenomena, the sort of classification they need will vary for different purposes, and therefore any one scheme is bound to be a compromise. Early attempts at classifying children's disorders were strongly based on psychoanalytic theory (Freud 1965; Group for the Advancement of Psychiatry 1966). However, this was theory without strong empirical foundations and it soon became evident that different practitioners used the concepts in rather different ways. The reliability among raters was found to be very low for diagnoses based on theoretical concepts (Rutter *et al.* 1969); by contrast, reasonable agreement could be reached on the description of what mental problems were actually being presented. The overriding need for clarity in communication therefore gave rise to a change of approach. Modern schemes, which can be taken to date from DSM-III (American Psychiatric Association 1980) and ICD-9 (World Health Organization 1977, 1978) are founded mostly, though not exclusively, on descriptions of patterns of symptomatology. However, they are not intended to end there. The classic instance of psychiatric classification is Kraepelin's distinction between schizophrenia and manic-depressive psychosis; it was justified by the prediction from symptom pattern to developmental course. The justification of child psychiatric classes is their ability to predict significant aspects of course, causes and response to intervention (Rutter 1965, 1978). As understanding develops, these aspects are likely to play a stronger part in the definition of concepts of disorder.

Research purposes

Researchers into the psychopathology of young people need good diagnostic schemes for several purposes. They often need

groups of children that are reasonably homogeneous with respect to what is being investigated. The replicability of their group definitions will affect the use that others can make of their results. They are also likely to be interested in the testable predictions that derive from a classification. In mature sciences, a classification can itself be a scientific tool, as in cladistics where the relations of bodily structure among animals are a means for studying evolutionary descent. This is occasionally the case in psychopathology, when similarities between obsessions and stereotypies led to trials of a treatment for one condition in the other, or similarities between the symptoms of mania and attention deficit hyperactivity disorder (ADHD) led to cross-disorder neurochemical studies. For all these purposes, precision and replicability are the key requirements. Often it will not matter very much if many cases are left unclassified, so long as those that are classified are done so accurately but researchers also want their conclusions to guide practice, and therefore they wish to choose classes that practitioners will recognize and use.

Clinical purposes

Practitioners need to know how to apply research findings to an individual case, so a widely accepted classification scheme is indispensable. For them, a scheme leaving many cases unclassified has serious drawbacks because it cuts the bridge between their practice and the research that should inform it. Indeed, if research definitions have drifted too far from clinical ones, it may be quite misleading to generalize lessons from strictly defined research groups to broader and vaguer clinical ones. They have other needs for classification: for example, in communication between clinicians, statistical record-keeping and audit, for which homogeneity of groups in severity and responsiveness to intervention may be more important than homogeneity with respect to cause. In communication with users and carers, they may use an implicit system of classification that is based upon lay as well as scientific concepts; as when the idea of a minimal brain dysfunction, although discredited scientifically, supposedly is still found useful in explanation.

Abuses

Classifications, like other useful tools, can be abused. Critics have attacked the abuses of psychiatric categorization from various points of view. The critiques are important to heed because they carry lessons for practice. They caution, for example,

that it is possible to reify a diagnosis and exaggerate the power of the concept. Psychiatric categories may come to be regarded by long familiarity as things rather than as concepts. This would occur if, for example, a teacher protests that an inattentive and impulsive child does not ‘really’ have ADHD because the cause lies in the social situation; or if children with a disproportionate difficulty in learning to read were to be denied specific educational help on the grounds that they did not ‘really’ have a specific learning disability because there was no evidence of neurological abnormality. It needs to be kept in mind that psychiatric diagnoses are usually descriptive, not explanatory. ‘ADHD’ is a description of the behaviour of a child who is inattentive and impulsive, not a disease that explains why the child behaves in that way.

A diagnostic label may also be misleading by lumping unlike things together. For example, it has been noted several times that tricyclic antidepressants are very frequently prescribed for children with major depressive disorders in spite of the evidence base that indicates that they are usually ineffective in depressed children. The practice seems to be maintained by the use of the diagnostic concept derived from adult psychopathology without sufficient recognition of a crucial age difference with respect to tricyclic medications.

Another adverse effect of diagnosis is the obscuring of assumptions that are involved. Sonuga-Barke (1998) has re-emphasized the psychopathologist’s fallacy—that because a child has been brought as a patient there must be something wrong with him or her. Impulsiveness, for example, is not necessarily an organismic dysfunction; it may, under some conditions of reward, represent an adaptive adjustment to the environment. Therefore one needs to keep in mind the full range of problems that present; for example, to classify social stressors as well as behavioural patterns.

Similarly, a diagnosis may hide heterogeneity. Children with a disorder are not all the same. To take just one example of this truism, the intelligence of children with Down syndrome (which is not usually inherited) still shows strong genetic influences, because the differences of intelligence within children who have Down syndrome are marked and are partly determined by the same factors that determine intelligence in the general population. The corresponding caution is that disorders are the subject of classification, not people. Descriptors, such as ‘the autistic’ or ‘the brain damaged’, seem to imply that all affected people are similar and that the disorder represents all that is important about the individual. This serves to reinforce false overgeneralization and stereotyping; phrases such as ‘people with autism’ are to be preferred.

Other problems in developing classifications, such as cultural dependence, will be considered throughout this chapter. The recognition of abuses is not a reason to abandon classification. It would be impossible to do so if we are to maintain the possibility of learning and teaching about disorder. However, it does underline the need to appreciate the strengths and the weaknesses of particular classificatory schemes. This chapter describes scientific issues in identifying and arranging the taxons (which

are the units of a scheme of classification and may be categories or dimensions), and in assigning individual cases to the taxons, and some practical issues in the application of their results.

Types of classification

Categories and dimensions

The choice of a categorical or a dimensional system of ordering has generated much debate (Sonuga-Barke 1998). A thoroughgoing categorical arrangement is often described, although only by its detractors, as a medical model. This is a highly misleading view of medicine, which incorporates dimensional as well as categorical approaches. One example would be that of blood pressure, which is a dimension distributed continuously in the population; elevated blood pressure (hypertension) is a diagnostic category, but it is based on the quantitative idea of the degree of elevation that entails significant risk and at which treatment is justified. Another example is that of anaemia; not only are levels of haemoglobin continuously distributed, but the level that is judged to be a problem to treat will depend upon other factors, such as the cause and the society in which it is encountered.

Nevertheless, it is plain that there are many constraints on clinicians’ thinking that favour a set of categories. The output from many clinical encounters is a set of categorical decisions: a child either is, or is not, prescribed a drug; or admitted into a treatment programme; or taken into care. It is therefore convenient, though obviously not essential, for diagnostic thinking to fall into the same mode. The convenience may be more apparent than real. It invites an immediate abuse, in which the treatment is determined directly and exclusively by the diagnosis. This possibility becomes all too real in some types of practice. The need of busy clinicians for simple rules of thumb, and the wish of some purchasers of health care to restrict treatment to mechanically defined groups and protocols, can lead to a lack of careful planning of care for the individual case.

It is sometimes said that categorical thinking is inherent in the human mind. It arises in the first months of life (Blewitt 1994); in adults it is deeply rooted, to the extent that formless sets of stimuli are often perceived as consisting of component categories, and categorical thinking characterizes the lay theories through which non-experts perceive psychological abnormality (Schoeman *et al.* 1993). Even if this is the natural tendency of the mind, especially when coping with complex information under pressure to make decisions, it is not necessarily the best approach. Artificial intelligence can increasingly be used to assist in handling complex information sets, and need not be constrained by human infirmity.

Categories have other practical advantages (Klein & Riso 1996); a single term, if carefully chosen, carries a great deal of meaning very conveniently and will be much more tractable in communication with parents and teachers than a large set of dimensional scores. These advantages have ensured that diagnostic schemes are mostly categorical; and dimensional ordering is

for the most part either secondary or rather tentative and speculative (e.g. Appendix B of DSM-IV: American Psychiatric Association 1994).

Dimensional thinking has been more attractive to contemplative researchers, especially those dealing with graded environmental stressors, be they physical or psychosocial. However, dimensional liability is also a key feature in genetic thinking, despite the fact that individual alleles are either present or absent (see McGuffin & Rutter, Chapter 12). Which type of thinking maps most helpfully on to the causes of disorder is not obvious, and may well differ for different kinds of psychopathology. Nevertheless, throughout medicine, even when dealing with categorical disease states, dimensional risk factors are the rule rather than the exception.

The distinctions between categories and dimensions should not be exaggerated. Generally, each can be translated into the other. A category can be expressed as a set of dimensional scores, and a profile of dimensional scores is a category. Indeed, the degree to which an individual case fits a category can itself be a dimensional construct, and should perhaps be considered as such more often. Sometimes it is preferable to use both ways of thinking about a single domain. IQ is better conceived as a dimension when the purpose is to predict educational achievement; but low IQ (e.g. below 50) is better thought of categorically when the purpose is to consider whether structural disorder of the brain is likely to be present (see below). Hypertension is conveniently regarded as a diagnostic category when the purpose is to select cases for treatment; as a dimension when analysing the physiological reasons for changes in blood pressure; and as a category again when considering the different factors determining variations in the most severely affected cases at the top of the range.

Another conceptual problem arises because an undoubtedly discrete cause may give rise to a continuum of problems at the level of behavioural expression. For example, the two genes known to give rise to tuberous sclerosis can both be associated with a very wide range in the severity and type of the resulting psychological disorder. This is not strange; their effects in giving rise to physical changes, such as the characteristic malformations in the brain, vary greatly between individuals. It would have been quite wrong to conclude from the continuously distributed range of severity of psychological disorder associated with tuberous sclerosis that the underlying cause would also be graded in severity.

In spite of the difficulties involved, the testing of assumptions about the nature of the underlying problems is important. For example, it is likely to guide research strategy in investigating a genetic contribution to disorder (see McGuffin & Rutter, Chapter 12). One classic research strategy has been to examine distributions of cases along a continuum of severity to see if there is a discontinuity between normality and pathology, such as a bimodal distribution. Most rating scales, for example, have indicated that hyperactive behaviour is distributed continuously, with progressively fewer cases at successively higher levels of definition and no sign of a 'hump on the graph' (Taylor *et al.* 1991). This is technically and conceptually problematic. The power of

tests for mixed distributions is low (Meehl 1995) and even very large numbers of cases can fail to give unequivocal answers. Random error in the measurement of properties will blur the sharpness of any distinctions based upon them. Severity in itself may not be the grounds for definition of a separate category. For example, the identification of a poor-outcome subgroup in early onset schizophrenia is based upon a qualitative difference—the presence of neurocognitive changes—rather than on the severity of 'schizophrenic symptoms' (see Hollis, Chapter 37).

Some investigators have compared the effect size of a continuous measure with a categorical one in predicting an external association such as outcome. For example, Fergusson & Horwood (1995) argued on this basis that a dimensional measure of disruptive behaviour in childhood gave a better prediction of adolescent outcome than a discrete category of childhood disorder. This may say more about the power of alternative statistical methods than about taxonomy; and it ignores the possibility that a strongly predictive category of antisocial behaviour may be present, but one that is based upon the type of problems rather than the severity of disruptiveness. This was, for example, the conclusion of Bergman & Magnusson (1997) in another longitudinal study, predicting antisocial outcome, that included a wider range of possible predictors, physiological as well as behavioural. Moffitt (1993) also concluded, from analysis of the longitudinal course of a population cohort of boys, that an antisocial outcome in adult life was characteristic, not so much of the boys who had been the most disruptive adolescents, but those who had had the combination of early onset and neurodevelopmental impairments.

Another research strategy has been to examine the distribution of cases against a measure of presumed aetiology and to seek a point of discontinuity; for example, in comparing successive levels of definition of hyperactivity against measures of neurodevelopmental delay and reporting that the putative risk factor was more common only in the most severe subgroup of 'hyperkinetic disorder' (Taylor *et al.* 1991). This strategy shares the limitations of the first, and entails the further doubt of whether the risk factor chosen is truly causative. It may become more feasible as more specific causes are discovered—such as molecular genetic abnormalities. Other genetic strategies have already been elegantly employed in twin designs. Eaves *et al.* (1993) went beyond the definition on the basis of single cut-off scores, and applied a latent class analysis to ADHD symptoms in a comparison of monozygotic and dizygotic twins. They successively fitted models assuming different numbers of classes, and found the best fit with a model of three separate classes. Gjone *et al.* (1996) addressed a similar question by comparing group heritability with individual heritability of ADHD symptoms in a twin study using multiple regression techniques (De Fries & Fulker 1988). Their conclusion was different. The extent to which cotwins show a regression to the mean in their scores did not function differently at the extremes of the distribution. This was in keeping either with a more dimensional view—with heritability similar across the whole continuum—or with a single, very common category. The issues are not resolved, even for this

rather well-studied condition; and indeed the method can require troublesomely large numbers. But genetic strategies such as these, especially when they can be applied to test hypothesized qualitative distinctions of severity, seem to offer encouraging future advances.

In short, the choice of dimensions against categories is complex, hard to resolve, and likely to be different for different conditions. Mixed classification systems are likely to develop, in which some types of problems are subclassified by severity and others by type. For the moment, there are so many uncertainties about whether dimensional or categorical arrangements better represent nature that a deeper pathogenetic understanding will be needed before the question is resolved.

Multiaxial classification systems

Categorical classifications can be based on allotting cases to the single category they best fit, or on multiple categorization—a case may be simultaneously classified in several ways. Powerful classifications, such as those of botany, aim for a set of mutually exclusive categories that are collectively exhaustive. Every case then falls into one, and only one, class. This would be an idealized view of medicine, because in practice multiple diseases are often present in the same person—sometimes because one kind of adversity tends to entail others. It can be a good discipline to try to fit multiple problems into a single pattern, but it is also important to detect a secondary disease even when it is masked by a more obvious one.

One kind of multiplicity is obviously necessary; different domains of problems need different classifications. It makes no sense to ask whether a child has asthma or intellectual retardation. They constitute problems of different types, and are best considered on separate axes. Field trials of early versions of the International Classifications of Disease (ICD) (Rutter *et al.* 1969; Tarjan *et al.* 1972) indicated that many disagreements between clinicians were of this type and, correspondingly, that reliability among diagnostic raters could be increased if they were not asked to choose between, say, autism and severe intellectual retardation, but were allowed to choose both, one on an axis of psychiatric disorder and the other on one of intellectual ability. This not only increases agreement, but provides a richer conceptualization and an opportunity to code and examine the extent to which, in this example, intellectual ability modifies the course and treatment response of autism.

A multiaxial system embodies this conceptual refinement; it differs from a multicategory system in that every axis needs a coding (even if the coding is of ‘no abnormality’). Axes of psychiatric syndromes, somatic diseases, psychosocial stressors and severity of impairment have been incorporated in the multiaxial version of ICD-10 (WHO 1992, 1993). Specific learning disabilities and intellectual impairments are dealt with in rather different ways by DSM-IV and ICD-10 (in which they are independent axes); the important feature is that both, in different ways, allow the clinician to record, systematically and separate-

ly, the extent to which both general and specific learning impairments are present.

Multiaxial systems of classification have become the norm in child/adolescent psychiatry for five main reasons. First, they avoid false dichotomies resulting from having to decide between two diagnoses that do not, in any meaningful sense, constitute alternatives. The example given of autism or mental retardation illustrates the point. The first gives information on the clinical syndrome whereas the second describes the level of intellectual impairment. Secondly, because there has to be a coding on each and every axis, the classification provides information that is both more complete and less ambiguous. Thus, in a multicategory system the absence of a coding of mental retardation could mean that the child had normal intelligence, or that the child was mentally retarded but the clinician did not consider that it was relevant to the referral problem, or that the diagnosis was omitted by error. Such an ambiguity could not arise with a multiaxial system. Thirdly, it avoids artefactual unreliability resulting from differing theoretical assumptions. Thus, psychosocial adversity would be coded as present by both the clinician who viewed it as the main cause and by the clinician who saw it as only a minor contributor. The same would apply to somatic conditions such as cerebral palsy or diabetes. Fourthly, it provides a means by which to note systematically, not only the presenting clinical picture, but also possible causal factors (or factors likely to influence prognosis or response to treatment) and degree of overall psychosocial impairment. Finally, because of these features it represents a style of thinking that is much closer to most clinician’s preferred style of conceptualization than is the case with a system that forces everything into the Procrustean bed of a diagnosis based only on symptom pattern.

Handling of comorbidity: single vs. multiple category systems

Another kind of multiplicity is provided by the co-occurrence of two different types of symptom pattern, such as major depression and conduct disorder. The key issue is whether, in reality, these represent varied manifestations of the same disorder, the simultaneous presence of two conditions that happen to have arisen in the same individual quite independently, the fact that the two disorders share some of their risk factors, or some mechanism by which one disorder creates a risk for the other (Caron & Rutter 1991; Rutter 1997). Such comorbidity (meaning the situation in which two or more separate and independent disorders are present in the same person) is almost the rule in the field of psychopathology (Angold *et al.* 1999). It complicates the diagnostic process throughout medicine. On the other hand, the reasons for the associations among disorders can also provide valuable clues to the understanding of pathogenesis.

The presentation of several patterns of disturbance by the same person may not be caused only by comorbid disorders; and in practice the term ‘comorbidity’ is often applied more broadly, to all the possible reasons for apparent associations between disorders. Comorbidity is less common in epidemiological studies

than in clinic surveys, because referral and other biases play a part in generating—or obscuring—associations in clinic attenders. It has long been known that comorbid disorders will always be misleadingly frequent in clinic groups, if either condition can lead to referral (Berkson 1946). However, it is plain that overlap is very common in epidemiological series, even if less dramatically so than at clinics, so these kinds of bias cannot be the whole story. Sometimes the overlap stems from imperfections in the definitions of disorder, so that the same criteria are common to more than one condition, as when symptoms of overactivity are included in the definitions both of mania and of ADHD. Sometimes an apparent association arises because of a lack of clarity about the boundaries of disorders. Obsessive-compulsive symptomatology may, for example, sometimes arise only in the course of a depressive disorder and remit with it. Similarly, the complications of a disorder may sometimes, and misleadingly, appear as a separate problem; people with long-standing obsessive-compulsive disorder may become depressed as a reaction to their predicament. Sometimes an association between disorders arises because they are both consequences of an underlying, and more fundamental psychopathological liability. For example, autistic and hyperactive features are quite commonly found together in children with diffuse disease or disorder of the brain. Evidence can be quite conflicting about the reasons for associations, and they may vary from one centre to another. For example, there is an undoubted link between Tourette disorder and ADHD, but some investigators find that this reflects genetic cosegregation, others that it does not (see Leckman & Cohen, Chapter 36).

However, comorbidity can also arise because one disorder represents an early manifestation of the other; this seems to be the case with generalized anxiety and depressive disorder (Silberg *et al.*, 2001), and with oppositional/defiant disorder and conduct disorder (Lahey *et al.* 1999; Eaves *et al.*, 2000). In this circumstance, at the point of transition, both ‘disorders’—actually both manifestations of the same disorder—may co-occur. Alternatively, the presence of one disorder may, through its effects, provide a risk mechanism for another condition. Possibly, this is one reason why antisocial behaviour predisposes to depressive symptomatology. Antisocial individuals act in ways that create interpersonal and social stress situations (Robins 1966; Champion *et al.* 1995).

Fuller consideration of the reasons for comorbidity and investigational strategies are provided by Caron & Rutter (1991) and Rutter (1997). Classification schemes need to be able to change to reflect advancing knowledge, and to be flexible enough to accommodate the differing reasons for the coexistence of mental disorders.

In the meanwhile, classification systems have to have rules on how to deal with comorbidity. Both ICD-10 and DSM-IV accept the need to be able to make multiple diagnoses if it is clear that the individual truly does have two or more separate conditions. After all, in most circumstances, it cannot be supposed that the presence of one disorder protects against others, although that can happen. Accordingly, someone with, say, autism or schizo-

phrenia, will sometimes develop some other mental disorder if they experience the risk factors for it. It is necessary to be able to record that that is the case. A strict single category system would be unworkable and neither of the main systems have such a requirement.

Nevertheless, there is a dilemma on how to classify when there is uncertainty on whether or not the two conditions are truly separate and independent. ICD-10 and DSM-IV differ somewhat in their approach (see Rutter & Taylor, Chapter 2). Both provide for a hierarchical approach in a few instances (see below) and both provide a few mixed categories when there is good evidence that they both represent a single disorder (e.g. mixed episode of mania and depression). However, ICD-10 has rather more mixed categories (e.g. mixed anxiety and depressive disorder and depressive conduct disorder). The rationale is that the weight of evidence suggests either that there is something distinctive about the admixture, as compared with the situation when either condition occurs on its own, or that the same disorder commonly gives rise to this admixture of symptoms. It provides an economical way of communicating and it is a practice that is common in medicine. However, it has two possible disadvantages. First, the overall placement of the combination category in the classification system carries messages that may be misleading. Thus, in ICD-10, mixed anxiety and depression is classified as a variety of anxiety disorder, although the evidence suggests that it is more likely to represent a mood disorder (see Harrington, Chapter 29). Depressive conduct disorder is classified as a variety of conduct disorder which does seem to be better justified in that research findings suggest that conduct disorder has much the same set of correlates and much the same outcome, irrespective of the co-occurrence of depression (Rutter *et al.* 1970), although there are some differences (Simic & Fombonne, 2001). On the other hand, the evidence is inconsistent on whether the presence of conduct disorder alters the meaning of the depression (Fombonne *et al.*, 2001a,b). Secondly, it limits finer distinctions, such as between the subvarieties of anxiety disorder that may be associated with either conduct disorder or major depression.

The availability of mixed categories in ICD-10 is quite limited, however, and the bigger difference from DSM-IV lies in the approach to mixed symptom patterns that are not covered by a combination category. ICD-10 is not entirely explicit in how they should be dealt with but the implicit expectation is a profile recognition or prototypic approach. Thus, if the main picture is one of severe depression, but there are marked obsessional features that ebb and flow with fluctuations in the depression, the mood disorder only would be the expected diagnosis. By contrast, DSM-IV would code obsessional disorder in addition (if the criteria were met) unless the *content* was mood-specific (as, for example, with a guilty rumination). The ICD-10 prototypic approach probably closely approximates ordinary clinical practice. The main problem is that it has proved difficult to make prototypes sufficiently explicit that they will always be used in the same way. For example, Asperger syndrome has been conceptualized on the basis of clinical case descriptions (see

Lord & Bailey, Chapter 38) but this has led to rather varied diagnostic sources on both the history of the concept and the experience of the clinicians using it.

With DSM-IV the mixture of two or more symptom patterns leads to the coding of as many diagnoses as there are patterns. This has the advantage of not requiring hierarchical judgements about which pattern is primary when in reality it may be very hard to tell, and it also succeeds in retaining a good deal of information when many patterns are present and no single category would convey them all. On the other hand, there are practical drawbacks to such a scheme. It encourages an unchallenged assumption that they are indeed independent patterns and that each can be dealt with in the same way as if there were no other problems. Alternatively, after multiple diagnoses are made, the clinician may then after all resort to a superordinate single-category way of thinking in which every possible profile has its own place. The coexistence of many diagnoses can be confusing and work against the key purposes of clarity and understanding how the research literature may apply to a particular child. It does not allow for the possibility of artefactual associations (see below). Furthermore, it is cumbersome, and perhaps impossible, for a clinician to review the presence or absence of every possible category and clinicians vary a good deal in their willingness to record symptom patterns that are not the main presentation (Rutter *et al.* 1975).

Hierarchical classification systems

Most classification schemes make some use of hierarchies based on a view that some conditions are fundamental and that, if others are present, they are likely to derive from the fundamental condition. The implication is that the former includes and accounts for the latter. Foulds (1976), for example, presented rating scale data from adult psychiatric inpatients to argue that the symptoms of people with schizophrenia usually included depression and anxiety; that those of people with depression did not usually include those of schizophrenia but did include anxiety; whereas people with anxiety did not usually show either depression or schizophrenia and were therefore at the bottom of a hierarchy of schizophrenia–depression–anxiety. There are evident dangers of circular reasoning, but with care the predictions can be tested. Clearly, this type of prediction would be unlikely to give a complete account of child psychopathology; but could be practical within groups of children sharing risk factors, such as diffuse brain damage, or with problems in a particular domain, such as hyperactivity (Taylor 1986).

Thus, DSM-IV excludes the diagnosis of generalized anxiety disorder if it occurs exclusively during a mood disorder, or a psychotic disorder (such as schizophrenia) or a pervasive developmental disorder (such as autism), and ICD-10 does so if the criteria for a panic disorder or an obsessive-compulsive disorder are met. Both DSM-IV and ICD-10 exclude the diagnosis of autism if Rett disorder is present, and exclude the diagnosis of

reactive attachment disorder if a pervasive developmental disorder is present. The general assumption that severe and pervasive mental disorders may often give rise to secondary symptom patterns is well based. The problem is that the evidence to justify hierarchies is generally rather thin and neither DSM-IV nor ICD-10 is consistent in its approach.

Polythetic/monothetic classes

Almost all medical classifications are polythetic. That is, cases are defined on the basis of having many, but not all, of a list of specified attributes in common. That is because variability in manifestation is a general biological feature, even with diseases solely caused by one major gene. In the neuropsychiatric arena, such variability is evident in marked degree with conditions such as tuberous sclerosis or the fragile X anomaly (see Skuse & Kuntsi, Chapter 13). There is similarly great variability in the manifestations of autism, as shown by the genetic findings (see Lord & Bailey, Chapter 38). The phenotype extends from severe handicap to quite subtle disturbances of social function. It would not therefore be reasonable to require that the disorder in any particular individual had to have *all* the diagnostic features. The trouble is that, in the absence of a diagnostic test of some kind, there are real difficulties in deciding both how varied the manifestations could be and where and how the boundaries should be drawn. Latent class analyses may help but what are really required are external validators (see below).

Lumping, splitting and empirical justification

There can be no one answer to the question of whether it is better to have a relatively small number of well-validated diagnoses or, rather, a large number that provides finer clinically useful distinctions that lack adequate empirical justification. Much depends on the purpose to which the classification is to be put. The most crucial distinction is between classifications to facilitate communication, and those designed to test out the meaningfulness of new ways of grouping and splitting disorders (Stengel 1959). The latter have been crucial in the identification of new syndromes (see Rutter & Taylor, Chapter 2, for examples). It would make no sense to confine researchers to the prevailing classifications. On the other hand, researchers have to communicate their findings to others and it would be equally unhelpful to have a proliferation of ‘private’ classifications.

Subclassification using dimensions

There are many examples in medicine of dimensional approaches being used as a supplement to a categorical classification. For example, respiratory physicians make more use of dimensional measures of lung function in considering clinical management and prognosis than they do of whether or not the criteria for chronic bronchitis or emphysema are met. Similarly, oncologists regularly grade the degree of malignancy of tumours and

cardiologists measure the degree of occlusion of coronary arteries and the degree of exercise tolerance. The multiaxial system in child psychiatry (World Health Organization 1996) provides a similar facility with respect to degree of social impairment and intellectual level and DSM-IV provides a means of coding the severity of disorders, as well as the extent to which a disorder is in remission. Similarly, in dealing with schizophrenia it is helpful to differentiate between positive and negative symptoms (see Hollis, Chapter 37). Some of these further differentiations, both categorical and dimensional, have become standardized and quantified in ways that are used routinely, but others are still in the course of development. However, what is clear is that there is an important place for functional subclassification that falls somewhere between overall diagnostic classifications and individual diagnostic formulations (see Rutter & Taylor, Chapter 2).

ICD-10 and DSM-IV

ICD-10 (World Health Organization 1992, 1993) and DSM-IV (American Psychiatric Association 1994) constitute the two major psychiatric classifications used throughout the world. Their predecessors (ICD-9 and DSM-III) were very different from one another and strenuous efforts were made to bring ICD-10 and DSM-IV much closer together. Those efforts were successful in all sorts of important ways that constituted a major step forward in achieving better international understanding and communication. Nevertheless, there are some differences. Mention has already been made of the difference in approach to comorbidity and an equally important difference is that DSM-IV has one scheme that is designed for both research and routine clinical usage, whereas ICD-10 has two separate but interlinked schemes for these two rather different purposes, the research version being closer to DSM-IV.

There is something to be said in support of deliberate differences when evidence is lacking to decide which of two alternatives is to be preferred. Further research comparing the two systems should provide for an empirically based choice in the future. For example, the two schemes differ in the rules to be followed in the diagnosis of ADHD. The symptom lists are almost identical but the two systems have different requirements for pervasiveness across situations, whether all problems or only some need to be present, and on the use of exclusion criteria in relation to comorbidity. The consequence is that hyperkinetic disorder in ICD-10 is a subcategory of ADHD in DSM-IV, the grounds for translating one into the other are reasonably clear, and the research findings to compare the two should be informative. The two schemes also differ in how they deal with emotional disorders with an onset in childhood. ICD-10 makes a distinction between separation anxiety that represents an exaggeration or prolongation of a normal stage of emotional development (operationally defined as requiring an onset before age 6 years and absence of a generalized anxiety disorder) whereas DSM-IV makes the diagnosis solely on the basis of symptom

pattern without regard to either age of onset or generalized anxiety. Whether or not the developmental approach of ICD-10 is helpful remains uncertain. Research could resolve the issue but, unfortunately, researchers tend to have an allegiance to one scheme over the other rather than a commitment to test the validity of different diagnostic approaches.

In addition to these deliberate differences, there are other minor differences which, although trivial in themselves and seemingly inadvertent in their origins, have been found to have major implications (Kendell 1991) as shown, for example, by the findings with respect to post-traumatic stress disorder (PTSD). A difference between the two schemes in relation to just one item (numbing of general responsiveness) had a dramatic effect on concordance between the two schemes (Andrews & Slade 1998).

Culture-specific categories

There are many syndromes that have been particularly, or exclusively, associated with particular cultures or populations. 'Brain fog' in West African students and both 'koro' and 'latah' in Indonesia constitute well-known examples. Such syndromes continue to have a controversial status. Both ICD-10 and DSM-IV have appendices dealing with them but neither provides a satisfactory solution for their handling. Clearly, some represent culturally influenced variations in the manifestations of well-validated disorders (see Rutter & Nikapota, Chapter 16). Thus, there are variations in the terms people use to describe depressive feelings (Kleinman & Good 1985) and in the significance attached to anxiety and to oppositional behaviour in childhood (Weisz *et al.* 1993). It is important that clinicians are aware of these variations if they are to avoid mistaken references (Bhugra & Bhui 2000; Canino & Bravo 2000; Cohen & Kasen 2000). However, it is also possible that there could be disorders that are truly different and found only in certain populations if they derive from risk factors that are confined to those populations. Empirical findings that could test that possibility are largely lacking.

Validation of diagnostic categories

Basis for diagnosis

The first systematic attempt to bring some sort of order into the classification of child psychopathology was provided by Hewitt & Jenkins's (1946) factor analysis of symptoms and linking of factors with differences in psychosocial circumstances. Their differentiation of emotional disturbance and disruptive behaviour, both on the grounds of intercorrelations among symptoms (that is, they 'hung together' in ways that separated the two), and different correlations with family features, has been amply confirmed in numerous subsequent studies. In the last few decades, more sophisticated multivariate analyses have led to

the derivation of a much larger number of syndromes based on symptom profiles (Achenbach & Edelbrock 1978; Achenbach 1988, 1995). They bear some resemblance to the diagnostic categories in modern psychiatric classifications but it is not evident that the multivariate dimensions have any strong advantages over the latter and they have not led to much research testing diagnostic validation. Nevertheless, what the two have in common is the use of groupings based on patterns of symptomatology. The Washington University group were pioneers in the development of systematic rules for psychiatric diagnosis in the adult field (Feighner *et al.* 1972) and Cantwell (1975) extended the model to child psychiatry.

Both DSM-IV and ICD-10 have adopted this phenomenological approach. Without doubt it has aided comparability across centres in diagnostic usage. However, real comparability requires both the use of standard diagnostic instruments and application of diagnostic criteria (see Angold, Chapter 3; Cantwell 1988). A greater problem has come from the assumption that diagnoses should be based only on cross-sectional patterns of symptomatology, as if this was an end in itself. It is not enough that diagnoses differ in symptomatology; if those differentiations are to have any meaning they must be validated by criteria that are *external* to the symptomatology and which have clinical meaning and utility (Rutter 1965, 1978; Rutter & Gould 1985; Cantwell & Rutter 1994).

Clinicians sometimes assume that an ideal classification should be based on aetiology; however, that is not so. Most successful medical diagnoses are based instead on the underlying pathophysiology that gives rise to the clinical syndrome. Thus, diabetes is defined in terms of the metabolic abnormality and not which pattern of susceptibility genes is present. Similarly, ischaemic heart disease is based on the process of occlusive atheroma and not on the presence of key risk factors, such as high cholesterol levels, smoking or genetic liability. The key consideration is that most disorders are multifactorial and cannot therefore be classified on the basis of a single main cause. Elucidation of causal factors is important because it is likely to lead to an understanding of the basic pathophysiology (Rutter & Plomin 1997). However, it needs to be recognized that there may be more than one causal route to the same syndromic endpoint (Rutter 1997). The consequence of these considerations is that the goal must be the identification of the underlying pathophysiology of mental disorders, rather than finding the single main cause. We are a long way from reaching that goal at the moment. For the same reason, there cannot be any one validating test against some hypothetical gold standard. Instead, there has to be recourse to multiple validating approaches with the hope, and expectation, that when they all point in the same direction, it is likely that the diagnosis has some meaningful discriminative validity. Accordingly, we summarize such evidence briefly before seeking to draw conclusions on the current state of play on diagnostic validity. When the research findings were reviewed in previous editions (Rutter & Gould 1985; Cantwell & Rutter 1994), or elsewhere, we simply refer to these reviews but we note the main new findings.

Biological findings

In many respects, the clearest biological distinction is between severe mental retardation (IQ below 50), mild mental retardation (IQ 50–69) and the range of normal intelligence (Rutter & Gould 1985; Cantwell & Rutter 1994; Simonoff *et al.* 1996). Individuals who are severely retarded have a much reduced fecundity and life expectancy, the great majority show gross neuropathological abnormalities of the brain, and most have either clinical brain disorders (such as cerebral palsy or epilepsy) or marked congenital abnormalities. Their social class background is generally similar to that of the general population. By contrast, most people with mild retardation show a normal fertility pattern and a normal life expectancy, but to a marked extent they are disproportionately likely to come from a socially disadvantaged background. The genetic influences are more likely than in the case of severe retardation to reflect many genes operating as part of a multifactorial liability, and thus constitute the end of a continuum on the dimension reflecting normal variations in intelligence. Nevertheless, a substantial minority (the precise proportion is not known) have the same major genetic mutations as those found with severe retardation. That would be so, for example, with Down syndrome, tuberous sclerosis, fragile X and Williams syndrome. Accordingly, the validation is more accurately expressed in terms of a two-group differentiation that is roughly indexed by IQ level, rather than in terms of a severe vs. mild retardation split (see Volkmar & Dykens, Chapter 41).

Autism is differentiated from the broad run of other psychiatric disorders by its reduced life expectancy, mainly as a result of deaths associated with epilepsy (Isager *et al.* 1999), and by the high rate of epilepsy (about 25%). It does not differ from mental retardation in either respect but it does differ with respect to the age of onset of epilepsy (Rutter 1970; Gillberg & Steffenburg 1987; Volkmar & Nelson 1990). In autism, the peak is in late adolescence/early adult life, whereas in mentally retarded individuals it is in early childhood (Richardson & Koller 1992), as it is also in individuals of normal intelligence (Cooper 1965). Neuropathological studies are few, but the findings do not reflect the gross pathology that is typical of severe retardation (see Lord & Bailey, Chapter 38). Also, whereas small head size is associated with mental retardation, a larger than normal head size is more characteristic of autism (Woodhouse *et al.* 1996; Fombonne *et al.* 1999).

Biological findings are distinctly less helpful in differentiating among other disorders. Abnormalities on both structural and functional imaging are found in many cases of autism (see Lord & Bailey, Chapter 38), schizophrenia (see Hollis, Chapter 37), hyperkinetic disorder (see Schachar & Tannock, Chapter 25) and obsessive-compulsive disorder (see Rapoport & Swedo, Chapter 35), for example, and the findings provide a substantial case for a neural basis for the disorders, at least as a contributory factor in aetiology. Much the same applies to the positive findings with respect to neurodevelopmental impairment. Three main problems arise with any use of these findings for valida-

tion. First, the specifics of the abnormalities found are rather inconsistent within diagnoses (Bailey *et al.* 1996, with respect to autism; Eliez & Reiss 2000, with respect to magnetic resonance imaging findings across a range of disorders). Secondly, the associations have only limited diagnostic specificity. Thirdly, there have been rather limited direct comparisons across diagnostic groups. We do not know, for example, whether the findings in relation to autism might not apply also to, say, anxiety disorders or tics. Accordingly, the most that can be said is that the biological findings suggest that neural abnormalities are particularly likely to be found in some of the most severe psychiatric disorders, and there are a few pointers to possible diagnostic specificity, but the findings provide at best only weak evidence of diagnostic validation.

To some extent, similar problems apply to the associations between neurodevelopmental impairment—as indexed by motor delay and language impairment—and schizophrenia (McDonald *et al.* 2000). Thus, although the associations are weaker, those seem to apply also to bipolar psychoses (although probably not to other forms of emotional or behavioural disturbance; Cannon *et al.*, in press). The associations between schizophrenia and obstetric complications or congenital anomalies are weaker (Byrne *et al.* 2000; Kendell *et al.* 2000) and even less ‘diagnosis-specific. Life-course-persistent antisocial behaviour differs from that which is adolescence-limited in its association with neurodevelopmental impairment (Moffitt *et al.* 1996; Rutter *et al.* 1998; Moffitt *et al.*, 2001).

Drug response

It might be expected that drug responses would help greatly in diagnostic validation but, regretfully, they do not. The generally marked beneficial response to neuroleptics in the case of schizophrenia constitutes a partial exception (see Hollis, Chapter 37). Although these classes of drugs carry some benefits in other disorders (see Heyman & Santosh, Chapter 59), their efficacy in schizophrenia is substantially greater. Several problems arise with respect to the use of drug response as a diagnostic validator. First, and most importantly, most drugs have several distinct therapeutic actions. For example, tricyclics have independent effects on disorders as diverse as depression, ADHD and nocturnal enuresis (see Heyman & Santosh, Chapter 59). Secondly, in many cases the therapeutic effects fall far short of the dramatic. There are substantial benefits at the group level but these are not sufficiently great at the individual level to help much in diagnosis. Most especially, the fact that someone who is depressed does not return to a normal mood following administration of antidepressants by no means rules out the diagnosis of depression. Marked individual variations in drug response are common throughout medicine. Thirdly, many drugs appear to affect behaviours rather than diagnosis-specific pathophysiologies. Thus, the effects of stimulants on inattention/overactivity are qualitatively much the same, albeit quantitatively less marked, in individuals who do not have ADHD as in those who do (see Schachar & Tannock, Chapter 25; Heyman & Santosh, Chap-

ter 59). There had been a hope that the response might nevertheless help in differentiating ADHD from restlessness/inattention caused by high anxiety. Early studies indicated a lesser effect of stimulants in the presence of high anxiety (see Schachar & Tannock, Chapter 25) but this was not found in the recent US multicentre trial (March *et al.* 2000).

Genetic/family study findings

Findings from twin, adoptee and family studies have been crucial in establishing some very important differences among diagnostic groups. Schizophrenia tends to breed relatively true, with associations that extend to schizotypal and paranoid disorders but not much wider than that (see Hollis, Chapter 37; Kendler *et al.* 1995). The same applies to autism and its broader phenotype (Bolton *et al.* 1994, 1998; Bailey *et al.* 1995; see also Lord & Bailey, Chapter 38). There is no evidence of any genetic association between schizophrenia and autism. Affective disorders similarly show a substantial familial loading for depression, but also for generalized anxiety disorders, with twin data suggesting a substantial shared genetic liability (Kendler 1996). Twin data also raise queries about whether prepubertal depression is the same disorder as major depression starting in adolescence or adult life (see Harrington, Chapter 29; Thapar & McGuffin 1994; Silberg *et al.* 1999, 2001). The findings are not clear-cut on whether bipolar disorders and unipolar depression are genetically distinct (see Harrington, Chapter 29; Silberg & Rutter, in press), but they may be. Some overlap is, of course, to be expected because some cases of unipolar depression are bound to represent bipolar disorders that have not yet included a manic episode. The heritability of bipolar disorder is clearly much greater than that of the ordinary run of unipolar disorder, but whether this reflects a different condition or a more severe variant of the same disorder is the unresolved query.

Attention deficit disorders with hyperactivity clearly stand out as having a substantively higher heritability than that for other disorders involving disruptive behaviour (Thapar *et al.* 1999). On the other hand, to an important extent, they share the same genetic liability (Eaves *et al.*, 2000; Nadder *et al.*, in press), but the findings also raise queries about the validity of a qualitatively distinct diagnosis of ADHD, because the heritability of hyperactivity seems much the same throughout its range (Levy *et al.* 1997) and because of the shared genetic liability with other disorders of behaviour. However, from a genetic perspective there is no justification for differentiating between oppositional/defiant disorder and conduct disorder (Eaves *et al.*, 2000).

The genetic findings on Tourette syndrome are mainly of interest in relation to validity because they suggest some overlap with both multiple chronic tics and obsessive-compulsive disorder. Genetic findings on other disorders (see chapters throughout the book) all indicate a significant genetic component but they are less informative on discriminative diagnostic validity, apart from the findings in adults (Kendler *et al.* 1992) suggesting that the specific phobias may be relatively distinct from general-

ized anxiety and from panic disorder. Rett syndrome is probably distinctive through its association in some cases with a specific genetic mutation (Amir *et al.* 1999) but to date there have been no studies testing for its association with other psychiatric conditions.

Psychosocial risk factors

On the whole, there is relatively little diagnostic specificity with respect to the psychopathological risks associated with psychosocial stress and adversity (see Friedman & Chase-Lansdale, Chapter 15; Sandberg & Rutter, Chapter 17). However, there are two important exceptions. First, severe institutional deprivation in the early years of life has a relatively specific association with syndromes involving disinhibited attachment (see O'Connor, Chapter 46; Rutter *et al.*, 2001). Secondly, severe and acute stress experiences of an exceptional kind are particularly likely to lead to post-traumatic stress disorder phenomena (see Yule, Chapter 32). There is also some tendency for psychological loss stresses to lead to depression and danger-type stresses to lead to anxiety (see Sandberg & Rutter, Chapter 17). Family conflict, discord and hostility are also more likely to lead to antisocial behaviour than to emotional disturbance; the same applies to social disadvantage (Rutter *et al.* 1970). Within antisocial disorders, life-course-persistent varieties show a stronger association in serious family adversities than that found with adolescence-limited varieties (Rutter *et al.* 1998).

Cognitive correlates

Autism stands out from other psychiatric disorders both because of its particularly strong association with general cognitive impairment and its relatively specific association with theory of mind deficits (see Lord & Bailey, Chapter 38). ADHD is also relatively distinctive, but to a much lesser degree, through its association with mild cognitive impairment (Fergusson *et al.* 1993; see also Schachar & Tannock, Chapter 25). To a lesser extent, schizophrenia is also associated with a slightly below average IQ before the onset of the psychosis (Tarrant & Jones 2000).

Epidemiology

The two epidemiological features that are of greatest value with respect to diagnostic validity are age of onset and sex ratio. Interestingly, they go together to a considerable extent. Thus, disorders involving neurodevelopmental delay, such as developmental disorders of language, autism, ADHD, and life-course-persistent antisocial behaviour, characteristically begin early in life and are much more common in males. Emotional disorders beginning in adolescence, such as depression and eating disorders, by contrast, tend to be much more common in females (see Rutter & Taylor, Chapter 2). Antisocial behaviour beginning in adolescence also differs from earlier onset varieties

in having a much weaker male preponderance (Moffitt *et al.*, 2001). Rett syndrome is unique in being confined—or almost confined—to females (see Lord & Bailey, Chapter 38).

Course of disorder

The long-term course of disorders also helps sort out diagnostic distinctions. The plateau of developmental progress and loss of purposive motor skills associated with Rett syndrome (see Lord & Bailey, Chapter 38) makes it quite distinct. Adult outcome findings (Rutter 1995) are relevant in showing the major continuities between depression in childhood/adolescence and recurrent depression in adult life (Harrington *et al.* 1990; Weissman *et al.* 1999a,b; Fombonne *et al.*, 2001a,b); similarly, strong continuities between antisocial behaviour, including conduct and oppositional/defiant disorders, and personality disorders in adult life (Rutter *et al.* 1998); the strong persistence of autism (see Lord & Bailey, Chapter 38); the relatively strong persistence of schizophrenia (see Hollis, Chapter 37), of obsessive-compulsive disorders (see Rapoport & Swedo, Chapter 35), and of tics/Tourette syndrome (see Leckman & Cohen, Chapter 36). There are fewer data on anxiety disorders but, although there is some overlap with depression, specific phobias seem somewhat distinct (see Klein & Pine, Chapter 30).

Summary of validity inferences

Putting together the evidence discussed above, it is possible to arrive at a threefold division of disorders into those that are reasonably well-validated; those with pointers suggesting possible validity; and those where the evidence indicates that the categorical subdivisions are probably invalid.

The first group clearly contains autism and autism spectrum disorders (considered together), schizophrenia and schizophrenic spectrum disorders (again as a grouping), depressive disorders, hyperkinetic behaviour as a feature that differentiates it from other disorders of disruptive behaviour, oppositional and conduct disorders (considered together) and Rett syndrome. A range of contrasting approaches all provide good evidence of discriminative validity. The same applies to the distinction between the usually severe mental retardation that is associated with gross neuropathology and the usually mild retardation that is not.

The second cluster of possibly valid syndromes includes obsessive-compulsive disorder, eating disorders (pooling anorexia and bulimia nervosa), tics and Tourette syndrome, specific phobias, post-traumatic stress disorder, disinhibited attachment disorder, bipolar affective disorders, and the distinction between life-course-persistent and adolescent-linked antisocial behaviour. As briefly noted above, in each instance there is some evidence of discriminative validity but it is either less consistent or it spans fewer research approaches. From a practical point of view, these provide sufficient grounds for retaining the di-

agnostic category, even though there are important questions to be tackled.

The third cluster of probably invalid categories is less easy to deal with, if only because of the usual problem of knowing how much weight to attach to a lack of evidence of a meaningful difference, when new research could change that situation completely. Nevertheless, it is important to be aware that our usage of prevailing classifications means that we are making distinctions that, at least currently, lack substance. That applies to most of the detailed subclassifications, such as those among anxiety disorders or those among pervasive developmental disorders (PDD), Rett syndrome apart. It definitely does not mean that we should necessarily switch to some broader category. Thus, although there is no good evidence that the distinction between, say, autism and Asperger syndrome or atypical autism means much, the evidence on discriminative validity applies to the more narrow category of autism and not to the broader category of PDD. Also, up to now it has proved quite difficult to provide either a clear conceptualization or precise application of the criteria for the broader category. The issue is the one that pervades psychiatry: namely, uncertainty on the boundaries of a syndrome when the defining pathophysiology is unknown. It should be added that this uncertainty applies in some (often major) degree to most of the conditions for which there is no evidence of validity.

A second group of probably invalid categories includes syndromes that are clinically striking but for which the external correlates provide little support for basic differences from other diagnostic categories. Selective mutism and conversion reactions fall into that group. In both cases, the distinctiveness of the clinical picture and the particular therapeutic challenges it presents probably warrant the retention of the category. However, the same might have been said of school refusal (Hersov 1977) and that no longer has a place in most classification schemes (Elliott 1999). Then there are categories that derive from theoretical concepts but which lack satisfactory diagnostic criteria that would allow the testing of validity. Inhibited attachment disorder (see O'Connor, Chapter 46) is a diagnosis of that type and many would argue that borderline personality disorder is too (see J. Hill, Chapter 43). Certainly, subdivisions among personality disorders remain rather unsatisfactory. It should be added that epidemiological findings indicate that there are quite a few children with psychosocial impairment but whose mental health problem does not fulfil any particular diagnostic category. Moreover, they have a mental health outcome, at least in the short term, that is as poor as those with a diagnosis (Angold *et al.* 1999). Evidently, there is a need for some sort of residual psychopathological category.

Finally, it is necessary to return to the uncertainties when deciding between categorical and dimensional approaches. ADHD disorders well illustrate this dilemma (see Schachar & Tannock, Chapter 25). Most of the biological validity evidence, such as the neuroimaging findings and associations with motor and language problems, applies to a relatively narrow diagnos-

tic category, but most of the genetic findings point to a dimensional liability (Levy *et al.* 1997). Of course, it may well be that there is both a qualitatively distinct disorder and a risk dimension, which look similar but which differ in their pathophysiology.

Agreement on clinical psychiatric diagnoses

Diagnostic ratings by experienced clinicians show at least a modest concordance. Limited agreement within panels of independent clinicians has been found over the years: for DSM-III (Mattison *et al.* 1979; Mezzich *et al.* 1985; Prendergast *et al.* 1988) and for ICD-9 (Gould *et al.* 1988; Prendergast *et al.* 1988; Remschmidt 1988). Field trials for DSM-IV reported better agreement, but on the basis of self-selected pairs of psychiatrists who made diagnoses on selected patients. The shortcomings of this strategy were pointed out by Rutter & Shaffer (1980), who noted that one would expect clinicians working together to have similar diagnostic practices. Further work needs to be carried out before the language of child psychiatry becomes sufficiently explicit to sustain scientific progress.

On the other hand, good diagnostic agreement can be achieved by independent research teams that have agreed supplementary criteria in advance (Prendergast *et al.* 1988). This satisfactory agreement is comparable with that obtained by studies in which two clinicians from the same centre rated cases with fuller information (Stroeber *et al.* 1981; Werry *et al.* 1983). The conclusion seems to be that training can improve diagnostic reliability to a satisfactory level, so the goal of an adequate system is not impossibly distant. The increased clarity of diagnostic rules in ICD-10 has been reported to increase interrater reliability, though the overall accuracy still leaves much to be desired (Steinhausen & Erdin 1991). Other procedures that have been reported to enhance reliability are the use of a standard coding form after interview (Beitchman *et al.* 1989) and the use of a multiaxial system (Skovgaard *et al.* 1988).

Clinical diagnosis and formulation

The clinical diagnosis is made for purposes of convenient and economical communication, for statistical recording and purposes of audit. Diagnosis is seldom the automatic generator of a plan for management. A child with autism and repetitive self-injury should not be treated in the same way as a person with autism who does not show challenging behaviour; a child with ADHD who is socially competent and valued should not receive the same management as one who is severely impaired in social role performance. Pervasive variables, such as IQ and peer relationships, are important predictively, even if their lack of discriminative validity means that they do not enter into current definitions. The diagnosis is just one of several aspects of the case

that guide decision-making. It functions like a map for navigators, to help them know what they are likely to encounter. Ignoring it is like going to sea without a map; relying upon it to dictate treatment is more like the action of a navigator who never looks at the ocean to spot approaching vessels or the danger of icebergs. There is a potential danger in the development of treatment protocols or payment plans that are based solely upon diagnosis: they may inhibit the process of tailoring services to individual needs.

The product of assessment should therefore be not only a categorization, but a full clinical formulation. The point is so important that a separate chapter (see Rutter & Taylor, Chapter 2) considers the development of clinical formulations that bring out what is individual and special about the problems faced by a child. The clinical formulation encompasses more information than the diagnosis. It is a convenient way of combining dimensional with categorical information, and it allows for the inclusion of information that may determine clinical decision-making even if it does not enter into the diagnosis. It should include a problem list, a description of the child's profile of disturbance on the major types of behavioural change, cognitive abilities and impairment, strengths and weaknesses in the family and school environment, and any relevant risk factors.

A formulation can also indicate uncertainties or missing information, and the possible needs for review. It allows, for instance, judgements to be recorded about the confidence with which different aspects of the case have been assessed. This in turn directs the clinician's attention towards re-evaluations that may need to be made in the management of a case, and avoid perseveration on an initially erroneous judgement. It allows for plans to be made for the management of a case falling short of diagnostic criteria. Rather similarly, it allows a case to be detected as having a definite problem even if the exact nature of the problem does not fit current diagnosis.

Another function of the clinical formulation is to record judgements about the developmental significance of clinical findings. The 'psychosocial' axis of the ICD refers to stressors that may affect the child. Reliability for research purposes is enhanced if one codes only their presence or absence rather than their role in aetiology. The formulation of the case can and should include judgements concerning the impact of those stressors upon the child's development (see Sandberg & Rutter, Chapter 17).

The clinical formulation also permits the clinician to record judgements about the weight to be given to different aspects of the case. For example, within a multicategory scheme such as DSM-IV, it will be commonplace for a referred child to receive several diagnoses. Serious errors of judgement could be made if it were assumed that each diagnosis had the same significance as it would have in a non-comorbid case and that each diagnosis could be treated independently. A child with autism who is afraid of going out of doors may have come to that state through a very different route from one with simple social phobia and may need a different approach in treatment.

Conclusions

The development of agreed and reasonably reliable diagnostic schemes has been essential for beginning a scientific understanding of child mental health problems. Cross-sectional symptom patterns have been the foundation for this advance. Succeeding chapters describe the considerable progress that has been made in the accuracy and reliability with which symptoms are elicited. Several sources of developing knowledge can now be expected to have a great impact on the details and the principles of classifications. Advancing knowledge of patterns of inheritance is likely to lead to some redefining of the boundaries of disorder. The long-term process of mapping genotypes to phenotypes will probably produce new diagnostic entities and lead to some re-grouping of old ones. Advances in neuropsychological understanding about the bases of a disorder may lead to altered views about what constitute its key features. New treatments will call for new categorizations of the groups of patients to whom they are relevant. The nosological study of comorbid groups will clarify how the overlap of different symptom patterns should be handled. Developmental psychopathology will produce knowledge about the interaction of risk and protective factors that allow a richer classification of the factors operating on a child and the developmental tracks that children may take. These foreseeable advances have in common the increasing integration of other sources of information with current symptomatology as the basis of classification. It seems certain that sound classification will remain a necessary condition for progress.

Clinical Assessment and Diagnostic Formulation

Michael Rutter and Eric Taylor

Initial questions regarding referral

Any clinical appointment will have been initiated by someone making a referral and usually that will involve some form of focused question, although the extent to which this is made explicit is likely to vary among referrals. In the case of children and younger adolescents, it will be rather unusual for the young people themselves to have initiated referral, but that may sometimes be the case. Although the clinician is likely to wish to organize the initial assessment around the question as to whether the child has a clinically significant disorder and, if there is such a disorder, what its nature is, that may or may not be the question that is uppermost in the mind of the person making the referral. The main concern may be what the family or school should do about a particular behaviour that is causing concern in that setting. Alternatively, there may be questions over particular administrative decisions, such as whether the school the child is attending is most appropriate, whether there is a need for exclusion from school, or whether the child should be removed from the family. In other cases, the referral may be to request an opinion that is relevant to a court case involving either child care or the child's responsibility for some criminal act or possible need to respond to such an act with some form of therapeutic intervention. In yet other cases, there may be an implicit query as to the meaning of the child's behaviour—perhaps as to whether or not it represents an early manifestation of some serious mental disorder (such as schizophrenia or autism) that is thought to run in the family. Another possibility is that the main problem concerns disturbed family function that happens to have involved the child in some way (Shepherd *et al.* 1971). If so, there is the need to understand why this child has been referred at this time in this way. It is quite common, too, for different people to have quite discrepant views as to what is the problem and what needs to be done about it. Thus, the father and mother may be at loggerheads over this, their views may be different from those of the child, and all of these may differ from the perspectives of the school, the social services or the family doctor.

Because of all of these uncertainties, and the wide range of possibilities, it is crucial for any assessment to begin with some procedures designed to clarify questions about the referral (Kanner 1957; Rutter 1975). Who initiated the referral? Why was the referral made? Why was the referral made now? Whose problem is it? What are the key concerns or questions to which people want a response? Are there administrative decisions that hang on the assessment and, if so, what are they?

To some extent, these questions can be clarified through obtaining relevant reports in advance of the interview for diagnostic assessment. This needs to be done through discussion with the family and with their approval. However, it is desirable to have available at the time of the first interview relevant reports from the school, from any social agencies that have been involved, from previous medical assessments, and from psychological and educational evaluations.

As well as clarifying the reasons for referral, the initial assessment needs to be planned in such a way as to provide information on how the members of family interact with one another and how they deal with each others' concerns. The aim is to identify possible strengths and limitations in the family and to understand their ways of functioning in order that this may be taken into account in planning therapeutic interventions.

Observations of the family

Observations need to begin with the ways in which the communications—either by letter or telephone call—were dealt with prior to the first interview (Cox & Rutter 1985). Who took the lead? What was the style used? What implications might there be for either the parents' attitudes towards their children or towards professionals. Similar questions need to be considered in relation to observations in the waiting room. If the availability of chairs provided open choice, how did the family choose to sit? What was the style of interactions among family members while waiting to be seen and how did they respond to meeting the clinicians? How did they spend their time in waiting and what were they doing when the clinician went to collect them for interview?

Regardless of how later stages of the assessment are to be undertaken, it is usually informative to have a brief meeting with the family all together in order to clarify these sort of issues and also to explain how the assessment will be organized and who will be seeing who for what purpose. Similar queries to those posed in relation to the waiting room arise with respect to the seating in the interview room. If the aim is to assess family interaction, it is crucial that the interview questions be addressed to the family as a whole, rather than singling out individual family members for their views. Often it may be better to put the query in the form of a questioning statement of a general kind, rather than a specific enquiry. Thus, the clinician may say something like: 'I wonder how much you talked together about coming to

see me today?’ or there could be a general question such as ‘Have you had a family discussion about the reasons for coming here today?’ Many parents are likely to have the cultural expectation that they, rather than the child, should answer the clinician’s questions and, in interpreting how they respond, it is important to take that into account. Nevertheless, direct questions to the child in this initial family session may make him or her feel put on the spot and, thereby, uncomfortable. Again, a more general style of bringing the whole family into the interview may be preferable (see Eisler, Chapter 9, for a fuller discussion of family interviewing). For example, if someone has responded with a firm answer on expectations or the reasons for coming, the interviewer might say something like: ‘I wonder whether everyone in the family sees things in this way?’ It is helpful to note how much the parents provide the child with ‘space’ to express his or her own views. How do the parents react if the child puts things in oppositional or confrontational ways? How do members of the family react when someone is expressing feelings of distress, anger or resentment? What are the patterns of eye to eye gaze among family members? What are their facial expressions and body gestures? Although it is usually a mistake to move quickly into interpretations, it may be helpful to make observations or express reactions as a means of getting the family to talk about the situation. Thus, the clinician may say things such as, ‘That appears to be a very difficult situation’ or ‘It feels as if that was awkward for you to talk about’ or ‘It sounds as if that came as a bit of a surprise to you’.

Depending on how the interview progresses, it may be appropriate to move on to direct questions about some aspect of the referral. For example, if the school or social services initiated the referral, the family may be asked how they felt about whatever it was that precipitated the referral. Was that something that they, too, were concerned about or did they see it rather differently? Similarly, if the parents have initiated referral because they were worried about some aspect of the child’s behaviour or emotional state, it may be important to ask the child directly whether this was something he or she was concerned about.

Younger children should not be expected to sit still during the interview and the interviewer needs to decide in advance what toys or play materials will be made available for the children. The interview provides the opportunity of seeing what the children decide to do and also whom they talk to or whom they turn to during the interview. How do the parents respond if the child seems distressed or is behaving in a disruptive way? Again, it is necessary to recognize that there may be culturally influenced expectations as to how the parents should behave. If the clinician wants the parents to be able to respond to the child it may be appropriate to say that directly by indicating ‘It’s okay if you want to respond to (*child’s name*) while we’re talking’ or ‘By all means go to (*child’s name*) if you’d feel more comfortable doing that’.

Interview with the child

Angold (Chapter 3) describes the approaches to be used in inter-

viewing children. As he notes, interviews with older children and adolescents can follow rather similar approaches to those used with adults, but various adaptations are needed with young children. Several points warrant emphasis in that connection. First, it is usually helpful to be able to assess children’s behaviour, styles of social interaction and ways of talking, in several contrasting situations. Thus, it is usually desirable to have an opportunity of seeing the child with the rest of the family. Psychological testing will provide the quite different stimulus of a series of structured tasks requiring the child’s engagement and attention. Psychological testing should always include a careful description of the child’s behaviour and social interactions, as well as test performance (see Sergeant & Taylor, Chapter 6). The interview with the child will be different yet again in providing a dyadic interaction opportunity but of a much less structured kind. Particularly at the beginning of the interview, the style needs to be such as to encourage the child to express his or her own concerns and this needs to proceed to a more systematic approach to specific behaviours and feelings.

Ceci *et al.* (Chapter 8) describe some of the considerations that apply particularly to the interviewing of young children. On the whole, free descriptions in answer to open questions provide accounts of behaviour that are most accurate and least prone to distortion. On the other hand, these tend to be very lacking in detail and, almost always, it will be necessary to follow with more specific questions. As Angold (Chapter 3) points out, however, it is important that this be done in a way that does not provide a lead to specific answers. People of all ages are open to the influence of suggestion but this is particularly the case with younger children (see Ceci *et al.*, Chapter 8).

Variations in the style of child interview and observation are needed when the child has some handicap in their communication and social skills and when the clinical issues require a focus on particular forms of behaviour that may not be tapped adequately in an ordinary interview. The Autism Diagnostic Observation Schedule (ADOS) provides an example of the former (DiLavore *et al.* 1995; Lord *et al.* 1989, 2000). This was developed as a set of social/communicative situations that provide a ‘press’ or expectation for either social/communicative responses or overtures. A generic version of the test with four modules adapted to children of different communicative levels is now available (Lord *et al.* 2000). It was initially developed primarily for research purposes but specialized clinics are now increasingly using it for clinical assessments. Even if the standardized half-hour assessment is not used clinically, the principles are certainly relevant to any form of clinical diagnostic interview with children or adults for whom the diagnosis of some form of pervasive developmental disorder has been raised (see Lord & Bailey, Chapter 38). There is a similar need to adapt interview approaches for children with seriously impaired hearing or vision (see Hindley & van Gent, Chapter 50).

The need to consider how assessments should be adapted for particular purposes is exemplified by the approaches needed for the assessment of possible attachment disorders (see O’Connor, Chapter 46). The concept of these disorders is that they are char-

acterized by pervasive problems in selective attachment. The disinhibited variety of attachment disorder might be thought to comprise a relative lack of selective attachments, and the inhibited variety both a lack of security provided by established selective attachments and by various abnormal features. So far as the disinhibited variety is concerned, there are two features that particularly require attention. The first concerns the child's response to a stranger and the degree to which this lacks the normal wariness, plus the extent to which there is an inadequate appreciation of social boundaries and an unusual degree of physical closeness or contact before a relationship has been established. In addition, there may be a lack of selectivity in going to the principal caregivers for security or comfort and it is important that the child's response to family members be observed, as well as the response to a stranger. It might be thought that the Strange Situation (Ainsworth *et al.* 1978) ought to be the most appropriate way of determining whether or not there is an inhibited attachment disorder, but it has severe limitations for this purpose. On the face of it, the category of 'disorganized' attachment might seem to be the nearest equivalent of a clinical diagnostic concept. However, it seems that the category of disorganized attachment occurs much more frequently than would be expected for the diagnosis of inhibited attachment disorder (van Ijzendoorn *et al.* 1999). It is clinically appropriate to base assessments on the way the child responds to reunions after separation, but the Strange Situation procedure was designed only for very young children and it is not likely to have the same meaning in older ones. What is needed clinically is a form of assessment that provides the opportunity to assess the child's reaction to strangers (the clinicians fill that role), responses to separations from and reunions with the parents (taking the child to be seen on his or her own and returning later serves that purpose); and the child's use of the parents as a secure basis (a joint family interview is useful in that connection).

Whatever the age of the child, and whatever the clinical issue, it is important that the interview combines an appropriate degree of structure and standardization (which is essential for comparability across children) and sensitivity to the unexpected and to the individual issue. The latter have been most studied in relation to the interviewing of parents in a clinical setting (Cox *et al.* 1981; Rutter *et al.* 1981) in which one of the most striking findings was the very high frequency of clinically significant information of an unusual kind that would be most unlikely to have been picked up by confining questioning only to predetermined topics. The same consideration certainly applies to interviews with children. It is very important for clinicians to be sensitive to the cues provided by children and these will need to be followed through in whatever way seems most appropriate to the individual situation. This need applies even more to what children say about their psychosocial circumstances than it does to what they say about psychopathology (see below).

Parental interview

Angold (Chapter 3) outlines in some detail the approach that

needs to be taken when interviewing parents. The main focus in Chapter 3 is on the assessment of psychopathology and the additional point that needs to be made here is that, in planning therapeutic interventions, several other features need to be considered. To begin with, it is essential to determine what it is about the child's behaviour or feelings or social interactions that is of the greatest concern to the parents. It may not necessarily be the feature that the clinician considers to be of the greatest psychopathological importance but, ordinarily, it is sensible that early therapeutic interventions be recognized by the parents as addressing their concerns. In addition, it is important to find out how the parents, and other people, have tried to deal with the concern. How have they tried to respond and what success or otherwise have their approaches achieved? If adequate use is to be made of this in therapeutic planning, it will be essential to move beyond a general answer (such as admonish the child, or comfort him or her, or try to be understanding) and, instead, obtain a more detailed sequential account of *how* this has been done. What did they do and what was the child's response? If certain approaches did not work, did they persist (and if so, for how long and under what circumstances) or did they keep changing? A closely related issue is the impact that the child's disturbance has had on them and on the rest of the family.

In dealing with the development of the disorder, attention needs to be paid to possible predisposing factors in life circumstances or physical state. Before proceeding with specific questioning, it is usually better to elicit the parents' views on what might have been important. There is then the functional analysis of the behaviour that is causing concern (see Herbert, Chapter 53). In other words, what are the features that seem to make the behaviours of concern more likely or less likely to occur? What circumstances seem to improve the situation? Questions regarding the degree to which behaviours are situation-specific or pervasive are important, not only for their implications with respect to severity (see Angold, Chapter 3) but also in terms of features in the environment that may act as a risk or protective factor.

There are important advantages in making sure that children are seen with their parents for part of the diagnostic assessment. However, people do not behave, or talk, in the same way when seen on their own as when seen as part of a family group. Accordingly, it is usually desirable for part of the assessment time to be spent in seeing the child on his or her own and similarly for the parents to be seen separately. Not only may this provide information that would not be obtained quite so readily in a family setting, but it also makes explicit a concern to pay attention to family members as individuals as well as part of a group. Some clinicians prefer to conduct the whole of the diagnostic assessment interview in a conjoint family setting but, in our view, this has disadvantages with respect to information gathering. A similar decision needs to be made as to whether both parents should be seen together or whether there should be some time with each parent separately. Our usual practice is to follow parental preferences in the first instance but to be alert to cues that suggest that it may be necessary to see parents on their own for a brief period in addition. However, it should be noted that

one study (Cox *et al.* 1995) showed that families did not respond well to a change of style from family to individual, or vice versa, when making the transition from diagnostic assessment to therapeutic intervention.

School reports

It is always desirable to obtain a school report, preferably in advance of the first interview with the family, but after obtaining their agreement that the school may be contacted. Children may well behave differently at school from the way they do at home and it is important to obtain an account of scholastic functioning; educational difficulties are frequently associated with psychopathology. There are some advantages in using a standard questionnaire as part of the reporting from school (see Verhulst & Van der Ende, Chapter 5). However, a questionnaire is never adequate on its own: it is crucial for teachers to be able to express their own concerns which may involve features that are outside the coverage of the questionnaire; it is important to consider changes over time and not just present behaviour; and it is important to find out how school has dealt with difficulties and how the child has responded to whatever actions were taken. There may be specific queries that arise out of the diagnostic assessment and, when that is the case, it may be useful for a member of the clinical team to contact the school directly in order to discuss the points that have arisen. Particularly when there seems to be a major discrepancy between the accounts of the child's behaviour at home and at school, visits to both settings to observe what is happening may be informative.

Psychological testing

Sergeant & Taylor (Chapter 6) provide an account of both the approach that needs to be taken to psychological testing and of its role in the overall diagnostic assessment. As they note, a key part of the psychological evaluation concerns the psychologist's observation of the child's behaviour in relation to the tasks that have been given and in relation to the social encounter with the psychologist. This is important because of the information that it provides about the child's psychological functioning generally, and not just because of its importance in relation to the interpretation of the psychological test findings.

So far as the latter are concerned, it is essential in all cases to consider whether the scores are consistent with the account of the child's performance given by the parents and by the school and in keeping with the clinician's observations of the child. Of course, it is to be expected that there will not be perfect agreement across all assessments but, if there are major discrepancies, that always has to be a matter for further study. If the child's performance during standardized testing was markedly better or markedly worse than that expected on that basis of other people's reports, what is the explanation? Does it reflect differences in the cognitive demands in the several situations, or does it re-

fect social features of the situation? What are the implications for the situational factors that seem to facilitate better performance?

A crucial part of any psychological assessment concerns the evaluation of the likely validity of the findings. Attention needs to be paid to the extent to which it was possible to engage the child in the relevant tasks, noting whether disturbed behaviour may have interfered with task performance. Particularly in the case of young children for whom there is a query regarding possible severe mental retardation, it is important to note how the child dealt with the situation as a whole, and with the task presented. A clear enquiring curiosity about the environment, a systematic problem-solving approach, and initiative combined with imagination in dealing with test materials, would all raise questions about the validity of a very low test score. Obviously it is necessary to consider whether overall task performance has been constrained because of specific difficulties in functions such as language, motor coordination or vision. In terms of the predictive validity of scores, consideration also needs to be given to the possibility that current cognitive functioning has been impaired as a result of severely disadvantageous rearing experiences that no longer apply. In short, test scores provide invaluable information but they need to be interpreted in relation to the assessment as a whole.

Medical examination and testing

The considerations that apply to medical examination and possible testing are discussed by Bailey (Chapter 10). The principles that should underlie decision-making on this issue are those that apply in any clinical assessment. The most fundamental requirement is that a thoughtful and systematic history-taking should be used as a guide to the possibility that somatic problems may be relevant to the psychopathology that has been the focus of the referral. When there is nothing in the history to suggest the presence of a possibly relevant somatic condition, it is sufficient to measure the child's height and weight, and to undertake a screening neurodevelopmental examination that does not require the child to undress fully. Questions should be asked to determine pubertal status but, unless it appears likely to be specifically relevant, there is no need to undertake a physical examination for this purpose.

When the child has a possible global or specific developmental delay, or a disorder such as autism (see Lord & Bailey, Chapter 38) or hyperkinetic disorder (see Schachar & Tannock, Chapter 25), a rather fuller assessment is necessary (see Bailey, Chapter 10; Volkmar & Dykens, Chapter 41). This needs to be guided by leads provided in the history but routine assessment for somatic conditions (such as tuberous sclerosis or chromosomal abnormalities) for which there may not be leads in the history, and which have a significant association with psychopathology, need to be covered by the appropriate screening examinations and tests. It is important to bear in mind the possibility of relevant general medical conditions, as well as

those directly involving the central nervous system (see Goodman, Chapter 14). Possible endocrine problems in relation to the differential diagnosis of eating disorders should be considered (see Steinhausen, Chapter 34). Appropriate medical assessments are essential when there are symptoms affecting somatic functions, because this could result from somatic disease. Early studies of so-called hysterical conversion reactions in both children (Caplan 1970) and adults (Slater 1965) have shown the relatively high frequency with which these were wrongly diagnosed as psychogenic in origin, as shown by the clear emergence of underlying physical disease of a directly pertinent kind during the course of follow-up. With proper clinical assessment, such misdiagnoses nowadays should be much less common, but clinicians need to be aware of the possibility (see Mrazek, Chapter 48).

Presence/absence of clinically significant psychopathology

Because most psychiatric disorders do not include pathognomonic qualitatively abnormal features that cannot be found in normal children or adolescents, a key basic question has to be whether the severity or nature of psychopathology is such as to be clinically significant. Necessarily, that query comprises two somewhat different issues. First, there is the question of whether the problems being considered are causing significant suffering for the individual or significant distress for others. Secondly, there is the question of whether the psychopathology is such as to fall outside the normal range of behaviour, or which carries with it a significant likelihood of recurrent or chronic malfunction. Clinical intervention will sometimes be indicated when the answer to one of the questions is in the affirmative but in the negative to the other. Thus, a serious grief reaction following the death of a loved one is quite common in normal individuals but it may warrant offering appropriate counselling (see Black, Chapter 18), even though it may not be a psychiatric disorder in the normal sense of the word. Similarly, many parents present at health clinics with their child's difficulties in eating or sleeping, which are essentially normal, but are yet causing major family disruption. Appropriate guidance and help may well be needed in such circumstances (see Stein & Barnes, Chapter 45).

Angold (Chapter 3) considers the features that need to be considered when deciding whether emotional disturbance amounts to a clinically significant disorder. The question is an important one because anxiety, depression and fears are a normal part of the human condition that most people experience at some time. The considerations to be taken into account include: whether there has been a substantial change from the person's usual mental state; whether the intensity of the emotions goes beyond the range of normal variation; whether the person is able to control the unpleasant emotions by means of distraction or engagement in pleasurable activities; whether the emotions intrude into and interfere with normal life functioning; and whether the emotions are pervasive across situations. Somewhat similar criteria

apply to overactivity/inattention but with the difference that, because these are usually first manifest in the preschool years, there will not usually be a recognizable change from any previous normal pattern. The assessment of disruptive behaviour is rather less straightforward because the child may not perceive that there is a need to control such behaviour.

From the time of the Isle of Wight studies (Rutter *et al.* 1970) onwards, the degree to which psychopathology gives rise to impairment of psychosocial functioning has been a key consideration in the assessment of clinical significance. There was a further impetus to use such a criterion from the epidemiological evidence that some forms of symptomatology, particularly specific phobias, were present in what seemed to be an absurdly high proportion of the population if impairment was not taken into account (Bird *et al.* 1990; Bird 1999). This has appeared a reasonable approach because, if psychopathology is not impairing functioning, there would not seem to be much need for intervention. Epidemiological findings have been consistent in showing that there are substantial differences among different forms of psychopathology in the extent to which there is associated impairment. Quite a few children show psychosocial impairment associated with psychopathology but without the required number of symptoms to fulfil the criteria for a specific diagnosis (Angold *et al.* 1999b). When this is the case, intervention may well be justified. The presence of marked symptoms in the absence of impairment is most frequently seen in relation to specific phobias (Simonoff *et al.* 1997). Conversely, it is rather unusual for there to be multiple symptoms of depression without there being any impairment (Pickles *et al.*, 2001). However, the diagnosis here is made not just on the severity of negative mood, but also on associated phenomena such as self-depreciation, feelings of guilt, feelings of hopelessness about the future, and suicidal thoughts or actions. The need to consider associated symptomatology constitutes a key element in diagnosis.

Thus, clinically significant developmental disorders of language need to be differentiated from normal variations in language development on the basis of the breadth of affected language functions (e.g. including understanding as well as use of spoken language), impaired use of language-related skills in make-believe play, difficulties in the control of motor movements associated with spoken language (as with drooling), and associated socioemotional or behavioural problems (Rutter 1987). Although certainly a useful criterion to employ, there are both logical and practical problems associated with giving it too high a priority. First, from a medical perspective, it would seem foolish to say that a person did not have a disorder because they were not impaired if there were signs or symptoms (or test findings) indicating an obviously pathological condition. Thus, someone with diabetes, whose condition has been shown by the appropriate laboratory tests, would still be diagnosed as having diabetes even if functioning was unimpaired because symptoms were well controlled by diet or the use of insulin. The same would clearly apply in the case of schizophrenia that was well controlled by appropriate medication. In these instances,

however, the abnormality is evident in terms of qualitatively abnormal findings, as evident either by history or present status, or both. The second concern is that a person may cope successfully with their disorder to the extent that symptoms are not manifest because the situations that elicit them have been avoided. There will not be psychosocial impairment if the person's life is so organized that the issues do not arise. This most obviously applies in the case of certain phobias. Thirdly, the degree to which there is psychosocial impairment will inevitably be influenced by social circumstances. Many decades ago Wootton (1959) pointed to the absurdity of rates of disorders going up and down according to fluctuations in the employment rate. She noted too the major difficulties in basing a diagnosis of psychiatric disorder on the extent to which it caused problems for other people. This has been a problematic issue in deciding whether conduct disorders should be regarded as psychiatric conditions (Hill & Maughan 2001). In this case, what is a persuasive argument in favour of regarding it as a disorder is the extensive evidence of impaired personal functioning in both childhood and adult life, including an increased risk of suicide and of other forms of psychopathology.

Although qualitative abnormalities are not a feature of most psychiatric disorders in childhood or adolescence, they are present in some. For example, the pattern of socioemotional deficits shown by individuals with autism is one that would be abnormal at any age (see Lord & Bailey, Chapter 38). The same applies to the thought disorder, negative symptoms, and delusions/hallucinations found in schizophrenia (see Hollis, Chapter 37). The situation is not quite so clear-cut with obsessive-compulsive phenomena but, although ruminations and minor checking behaviour may be regarded as falling within the normal range of variation, that is not the case with overt compulsive rituals of a marked kind (see Rapoport & Swedo, Chapter 35). Somewhat similar considerations apply to Tourette syndrome and chronic multiple tics (see Leckman & Cohen, Chapter 36). Particular care needs to be taken in eliciting detailed descriptions of such qualitatively abnormal features because, if people have not experienced these phenomena, they may interpret the questions as referring to the more normal features that are within their experience (see Angold, Chapter 3).

Duration and timing of disorder

Classification systems have often used duration of disorder as a key criterion by which to determine whether or not psychopathology is clinically significant. For example, DSM-IV (American Psychiatric Association 2000) has specified a minimum duration of 2 weeks for a major depressive disorder, 1 month for a generalized anxiety disorder, 6 months for a conduct disorder or a generalized anxiety disorder, and 2 years for a dysthymic disorder (but no duration is specified for anorexia nervosa). It is immediately obvious that there is an essentially arbitrary nature to the choice of these time periods. Thus, most clinicians would regard 2 weeks as a rather short period of time

for a major depressive disorder, and it is noteworthy that the research diagnostic criteria specify 4 weeks, rather than 2 (Mazure & Gershon 1979). Also, 2 years seems an incredibly long time to require a dysthymic disorder to last in order to regard it as meeting criteria. A further problem is that, even with high quality research interviewing that involves a specific focus on personalized timing, the reliability of the timing of onset of disorder has proved rather poor (Angold *et al.* 1996). In all probability, this is not mainly because people find it difficult to remember some clearly identifiable time when a disorder began, but rather because many disorders do not have a clear-cut onset. Frequently, symptomatology builds up over time with several points at which new symptoms become apparent and/or when psychosocial impairment first becomes evident (Rutter & Sandberg 1992; Sandberg *et al.*, 2001). Clearly, it is important for clinicians to obtain as good an account as possible of how psychopathology developed over time and to seek to identify times that might be conceptualized as either an onset of disorder or a clear worsening of disorder. However, from a clinical perspective it is less appropriate to follow DSM-IV rules about duration in a slavish fashion than it is to decide that the symptoms constitute something that manifestly falls outside the range of normal variation for that person and which either involves qualitative abnormalities or has interfered with psychosocial functioning to a substantial extent.

Nature of the mental disorder

If the assessment has indicated that there is a significant psychopathological disorder, the next question is what form it takes, and what diagnosis or diagnoses may be applied to it (see Taylor & Rutter, Chapter 1). ICD-10 (World Health Organization 1992) and DSM-IV (American Psychiatric Association 2000) adopt different approaches to this issue. Both accept the frequency with which mixed patterns of symptomatology occur but they deal with them in different ways.

DSM-IV takes the line that, in most cases, good well-validated empirical evidence is lacking on how to decide on the precedence to be given among differing patterns of symptomatology. Accordingly, rather than make arbitrary decisions on some hierarchy, for the most part the clinician is expected to diagnose as present any pattern that meets the criteria for a diagnosis. The inevitable consequence of this approach is that comorbidity (the co-occurrence of two or more supposedly separate disorders) is exceedingly common (Caron & Rutter 1991; Angold *et al.* 1999a). Indeed, it is quite frequent for individuals to receive three or four or even more diagnoses. The merit of this approach is that it provides a means of noting the mixed patterns of psychopathology without having to invoke hierarchical rules for which there is a lack of good supporting evidence. The disadvantage is that it implies that a high proportion of patients have multiple separate conditions. Common sense indicates that that is not likely to be true with most children in community clinics.

ICD-10, by contrast, takes the line that, ordinarily, one should assume that there is just one condition, unless there are good grounds for supposing the true occurrence of several. What this means in practice is that the clinician is expected to consider the psychopathology as a whole and then decide which diagnosis constitutes the 'best fit' to the pattern seen in the individual case. There is little doubt that this conceptualization is likely to be valid, but the problem lies in the lack of good empirical bases for many types of decision-making that are required.

Two particularly common examples may be used to illustrate the dilemmas. Numerous studies have shown the high frequency with which anxiety symptomatology and depression symptomatology co-occur (see Harrington, Chapter 29; Klein & Pine, Chapter 30) and the same applies to the overlap between oppositional/defiant behaviour and conduct problems (see Earls & Mezzacappa, Chapter 26). In both cases, research findings clearly point to the need to take a developmental perspective. Longitudinal studies have shown that a common sequence is for anxiety disorders in middle childhood to lead on to depressive disorders in adolescence or early adult life (Kovacs *et al.* 1989; Weissman 1990; Orvaschel *et al.* 1995; Wickramaratne & Weissman 1998). Twin studies in both children (Thapar & McGuffin 1997) and adults (Kendler 1996) have shown that to a very considerable extent anxiety and depression share the same underlying genetic liability. This is probably indexed to a considerable extent by the personality trait of neuroticism (Kendler 1996). That does not necessarily mean that anxiety disorders and depressive conditions should be regarded as synonymous because both involve environmental, as well as genetic, risk factors. There is some evidence in both children and adults (see Sandberg & Rutter, Chapter 17) that they are associated with rather different forms of precipitating stress experiences (psychological loss predominating in the case of depression and threat in the case of anxiety). Longitudinal twin data (Silberg *et al.*, 2001) are informative in showing that early anxiety problems are associated with postpubertal depression and that a shared genetic liability is important in that link. The diagnostic problem at the time of clinic assessment, however, has to focus on the slightly different issue of overlapping symptomatology at the same point in time. Regardless of which diagnostic convention is followed, it is important for the clinician to assess the relative importance of anxiety and depression in relation to the clinical picture as it presents at that time. It will be necessary to take account of both sorts of psychopathology in deciding how to intervene therapeutically but, in so far as medication is used, it is clear that antianxiety drugs are not a good way of treating depression, but that antidepressants may be effective in reducing anxiety as well as depressive phenomena (see Harrington, Chapter 29).

Somewhat comparable issues arise with respect to oppositional/defiant conduct problems. The two frequently co-occur, but longitudinal studies show the frequency with which oppositional/defiant behaviour in early childhood leads on to conduct disorders in later childhood or adolescence (Hinshaw *et al.* 1993). Because transitions in psychopathology tend to take

place over lengthy periods of time, it follows that it is likely that there will be many instances in which the child has a mixture of the two types of problem behaviour but below the threshold for each, because one disorder is gradually being taken over by the other. That is exactly what the field studies for DSM-IV showed (Lahey *et al.* 1998). Moreover, twin studies have shown that the two forms of symptomatology share the same genetic liability to a very considerable extent (Eaves *et al.*, 2000). The implication is that, in reality, these are probably somewhat different manifestations of the same basic psychopathology, rather than two different conditions with different causes and different implications for treatment (see Earls & Mezzacappa, Chapter 26). Similar issues arise with respect to the evidence that overactivity/inattention in early childhood carries with it a substantially increased risk for later antisocial behaviour (Rutter *et al.* 1998a). These associations extend well beyond the diagnostic boundaries, at least of hyperkinetic disorder as conceptualized in ICD-10. It is noteworthy that the strong genetic component in hyperactivity seems to apply across a broad range (to a dimensional variation in this characteristic) and not just to an extreme disorder (Thapar *et al.* 1999). There may well be good grounds for retaining a concept of hyperkinetic disorder as a separate categorical condition (see Schachar & Tannock, Chapter 25) but there is also a need to recognize the prognostic importance of patterns of overactivity and inattention that fall short of the diagnostic criteria for that disorder. Again, the clinical need, regardless of which set of diagnostic conventions are followed, is for the clinician to try to decide the meaning and mechanisms underlying the mixed pattern of symptomatology. Twin data indicate that both forms of symptomatology share a common genetic liability to a considerable extent (Nadder *et al.*, in press), even though oppositional/defiant and conduct problems are, to an important extent, separate from hyperactivity (Nadder *et al.*, 2001).

The need to sort out meaning and mechanisms goes well beyond decisions on which diagnostic conventions to follow. A more basic hypothesis-testing approach to diagnostic assessment is fundamental to the diagnostic enterprise. For example, although not well reflected in either of the two main classification systems, it is important to differentiate among the various causes of faecal soiling (Rutter 1975). This may arise, for example, because the child has failed to gain bowel control. Alternatively, control may well have been achieved and maintained, with the disorder lying in the deposition of faeces in inappropriate places, rather than in any lack of or loss of control. A third possibility is that there has been faecal retention leading to gross distension of the bowel and partial blockage. In these circumstances, faecal soiling may arise because there has been an overflow of faeces stemming from the prior distension. In order to differentiate among these possibilities, careful assessment is needed of whether or not the faeces are normal in form and consistency; whether there is a history of previous normal bowel control; whether the soiling has been preceded by patterns of retention or other abnormalities in bowel functioning; and whether the deposition of faeces is essentially random, accord-

ing to where the child happens to be at the time that the bowels are opened, rather than selectively placed in situations having psychological meaning. Clearly, the therapeutic interventions need to be chosen on the basis of the type of disorder represented by the soiling (see Clayden *et al.*, Chapter 47).

A decision tree approach may also be very useful in the assessment of developmental disorders of language (see Bishop, Chapter 39). When the diagnostic issue concerns some pattern of psychopathology associated with the language delay, it is helpful to tackle the decision-making in stepwise fashion (Rutter 1985). Thus, it is usually best to begin by determining the child's overall level of cognitive functioning, going on to consider whether language skills are significantly below those of other aspects of cognitive functioning. The question then is whether the psychopathology shown is outside the range of normal behaviour expected in relation to the child's overall mental age and overall level of language functioning. If it is outside that range, rather than move on straight away to consider the complete list of possible psychiatric diagnoses, it is generally helpful to question whether the behaviours are of a kind that might be found in any child (the usual run of emotional problems and disorders of disruptive behaviour, etc.) or whether the pattern is qualitatively different in a way that is associated with pervasive developmental disorders. It is then easier to move on to a consideration of which particular diagnostic concept best fits the picture in the light of that decision.

The possibility that the disorder is not represented at all in the current classification system should also be considered. As Kanner aptly put it in the title of one of his papers on differential diagnosis, 'The children haven't read those books' (Kanner 1969). The point that he was making was that there is a most imperfect match between the neat diagnostic descriptions given in textbooks and the clinical presentations seen in referred patients. The usual explanation will be that the person has a somewhat atypical variety of a well-recognized well-validated disorder. Nevertheless, the last half century has seen the recognition for the first time of several disorders of considerable importance. Kanner's (1943) identification of autism is the most striking example, but it is closely followed by the identification of Rett syndrome (Rett 1966; Hagberg *et al.* 1983). Both Asperger syndrome (Asperger 1944) and Wolff's concept of schizoid disorder of childhood (Wolff & Chick 1980; Wolff 1995) constitute other variants within the realm of what might be regarded as autism-spectrum disorders. 'New' conditions are by no means restricted to this group of pervasive developmental disorders. Russell's (1979) identification of bulimia nervosa and Meadow's (1977) account of the Munchausen by proxy syndrome constitute other important examples of a very different kind. The concept of attachment disorders (see O'Connor, Chapter 46) constitutes yet another example. More recent, and therefore less validated, examples are also provided by the quasi-autistic pattern seen in some children who have experienced profound institutional deprivation (Rutter *et al.* 1999a); the social abnormalities that have been found to be associated with severe developmental disorders of receptive language

(Howlin *et al.* 2000; Mawhood *et al.* 2000); and the autistic-like patterns seen with some cases of congenital blindness (Brown *et al.* 1997). Not all of these patterns of psychopathology constitute well-validated syndromes but the general point remains: clinicians must always be on the alert for unusual patterns that do not fit existing diagnostic conventions.

In some cases, the clinical question may refer to a particular phenomenon rather than a pattern of psychopathology. For example, during the 1980s there was some excitement over reports that autistic children who could not speak could nevertheless communicate at a high level when given assistance through a range of techniques that came to be called 'facilitating communication'. The children were said to communicate by guiding someone else's arm to point to letters to spell out words, or some other comparable means of communicating via another person, called a facilitator. The key to sorting out the validity of these claims (in the individual case just as much as in the studies of groups) lay in setting up a situation in which the information available to the child and the information available to the facilitator was different. When this was done it became apparent that the communications were being determined by the facilitator rather than the handicapped child (Rutter *et al.* 1998b). Comparable issues arise in relation to the diagnosis of selective mutism (see Bishop, Chapter 39), a syndrome characterized by a high degree of selectivity in circumstances of talking. In both instances, as in experimental studies more generally, the need is to design a situation in which children can and do succeed but do so in ways that are informative on the mechanisms involved. Thus, in the case of selective mutism, the need is to be able to demonstrate that the children can use spoken language in particular circumstances, just as much as showing that they do not use spoken language in other situations.

Psychosocial assessment

Psychosocial risks are important in the development of psychopathology (see Friedman & Chase-Lansdale, Chapter 15; Sandberg & Rutter, Chapter 17). It is important therefore that the diagnostic assessment provides an efficient, reliable and valid means of assessing the presence of psychosocial risk factors. However, it should not be seen as exclusively related to questions of causation. In planning psychological interventions (when indicated) it is important to identify possible protective mechanisms, as well as risk features. Moreover, it is necessary to assess risk and protective factors, not only in terms of what is happening within the family, but also what is happening within the peer group, school and community (Rutter *et al.* 1998a; Shonkoff & Phillips 2000). Furthermore, the psychosocial assessment needs to include both past experiences and current circumstances. On the whole, most early experiences do not have enduring effects that are independent of later psychosocial circumstances (Clarke & Clarke 2000). Nevertheless, profoundly depriving experiences can have major sequelae that persist long after children have ceased to suffer deprivation and have had

good rearing experiences in a well-functioning family (Rutter *et al.*, in press, a). Similarly, there may be enduring effects of seriously abusive experiences (see Emery & Laumann Billings, Chapter 20; Glaser, Chapter 21). The same applies to some instances of very severely traumatic experiences in relation to persisting post-traumatic stress disorder (see Yule, Chapter 32).

A key consideration with respect to all these experiences, risk and protective, is the need to appreciate that the experiences cannot be thought of as impinging on a passive organism. Children, and adults, think and feel about what they experience and the cognitive/affective sets that they develop (or internal working models) may be very important in determining the consequences of such experiences. What this means is that the assessment needs to determine both how children have coped with their experiences (see Compas *et al.*, Chapter 55) and what they have thought about what has happened to them and how they view their current experiences.

Research over recent decades has made it abundantly clear that genetic factors play an important part in the origins and persistence of all forms of behaviour, including all forms of psychopathology (Rutter *et al.* 1999b,c; see McGuffin & Rutter, Chapter 12). The findings are of major clinical importance for several rather different reasons. They show the importance of recognizing the influence of genetic susceptibilities with respect to individual differences in the liability to psychopathology. That means, amongst other things, that any adequate diagnostic assessment will need to include systematic questioning with respect to a family history of psychopathology. Particular attention needs to be paid to disorders in parents and in siblings, not just because they are the closest relatives with respect to genetic inheritance, but also because mental disorders in the immediate family will involve environmentally mediated, as well as genetically mediated, psychosocial risks (Rutter 1989). Thus, parental mental disorder is associated with a substantially increased risk of family discord and family breakdown, and also focused hostility on individual children (Rutter *et al.* 1997). It is important to assess the ways in which parental mental disorder impinges on the family and not just be content with recognizing its presence. The risks may also involve physical risk factors in relation to substances that cross the placental barrier during pregnancy. Thus, high levels of alcohol ingestion in the early months of pregnancy may lead to the neurodevelopmental abnormalities associated with fetal alcohol syndrome (Spohr & Steinhausen 1996; Stratton *et al.* 1996). There may also be effects from taking recreational drugs or prescribed medications (Singer *et al.* 1997; Delaney-Black *et al.* 2000; see also Marks *et al.*, Chapter 51). The extent to which there is enquiry about mental disorders occurring in second- and third-degree relatives needs to be guided by the particular clinical problem. However, it should be routine to ask about the occurrence of major mental disorders or developmental problems in both sides of the family. Genetic testing (using cytogenetic and molecular genetic methods) is not part of routine assessment but it is important in some circumstances (see Skuse & Kuntsi, Chapter 13) and could become more generally applicable in the future.

Research methods that provide systematic standardized assessments of psychosocial features are too time-consuming for use in most clinics. Nevertheless, they do provide helpful guides on how such routine clinical assessments should be undertaken. As with the assessment of psychopathology, the agreement between the reports of parents and children tends to be modest to moderate at best (Rutter *et al.* 1970; Achenbach *et al.* 1987; Simonoff *et al.* 1997; Borge *et al.*, 2001). That is partly because parents will not know about the full range of children's experiences outside the home, partly because their perspectives may not be the same, and partly because some disorders may be relatively situation-specific (Cox & Rutter 1985). The implication is that some assessment of psychosocial risk and protective experiences needs to be obtained from both parents and children. The classification of psychosocial experiences developed by the World Health Organization (van Goor-Lambo *et al.* 1990) provides some guidance on the range of experiences that need to be considered and there are standardized interviews that cover most of the relevant experiences (Sandberg *et al.* 1993). However, the research findings from studies that have used designs that can separate environmental from genetic mediation (Rutter *et al.*, in press, b) suggest that the experiences carrying the greatest psychopathological risk mainly concerns marked negativity in close personal relationships, a lack of continuity in personalized caregiving, a lack of appropriate learning experiences, and participation in social groups with a deviant ethos, attitudes or styles of behaviour (Rutter 2000a). Although not much investigated in genetically sensitive designs, it is likely that parental monitoring and supervision of children's behaviour are also important in relation to antisocial problems (Rutter *et al.* 1998a; but see Stattin & Kerr 2000 with respect to the role of children's disclosures). In relation to all these experiences, it is necessary to determine the ways in which such experiences impinge on the individual child, and are responded to, and not just the experiences as they affect the family as a whole. Although excessive claims have been made about the preponderant importance of child-specific experiences (Rutter *et al.* 1999a; Reiss *et al.* 2000), it is the risks as they affect the individual child that are important, even if they impinge similarly on other children in the same family.

In that connection, the research evidence suggests that it is often useful to make direct comparisons among children in the family with respect to features such as whether one is more likely to be criticized than others, or is more frequently favoured, or is more likely to be involved in relevant risk or protective experiences in the family (Carbonneau *et al.*, 2001 & submitted). In addition, research has shown how much can be inferred from the ways in which a parent talks about the children. This was first demonstrated in the Camberwell Family Interview (Brown & Rutter 1966; Rutter & Brown 1966) but has been developed as a much briefer assessment in relation to the 5-min speech sample (Magaña *et al.* 1986). The implication is that it is important to have a time during the assessment when parents are asked neutral questions about their children, not just questions focusing on problems. Thus, it is helpful to get parents to talk about what

their children are like as individuals, how easy they are to be friendly and affectionate with, what is their most striking individual characteristic, etc. The same, of course, applies similarly to the ways in which children talk about their parents and about their siblings.

Diagnostic formulation

Diagnoses serve the important role of providing a succinct summary of the key clinical features that are held in common with disorders experienced by others (see Taylor & Rutter, Chapter 1). This is a most important purpose and one that is central to communication among clinicians, just as much as among researchers. Multiaxial systems of classification can go somewhat further because they serve to classify relevant psychosocial situations that may have played a part in either causation or which may be pertinent with respect to therapeutic planning, as well as intellectual level and a level of adaptive functioning. By considering the information included across a complete range of axes, quite a lot of clinically relevant information can be summarized succinctly.

Nevertheless, that is not quite the same thing as developing hypotheses about causal processes and hypotheses about therapeutic interventions. For example, suppose it has been found that the child has cerebral palsy. As outlined by Goodman (Chapter 14) there is good epidemiological evidence that this is associated with a substantial increase in psychopathological risk in groups of children with this condition. However, the risk could come about through several different routes, each of which have different implications for intervention. Thus, in some instances, the main risk may derive from the electrophysiological disturbance associated with frequent, poorly controlled epileptic attacks. In other cases, the risk may stem from impaired cognitive skills and from the educational difficulties to which they may give rise. In some cases there may be relatively direct neural effects of brain dysfunction, as exemplified in so-called frontal lobe syndromes exhibiting social disinhibition that sometimes occur after severe head injuries (Rutter *et al.* 1983). In yet other cases, the psychopathological risk may derive from the child's negative self-image as a result of his or her physical limitations, or perhaps from parental overprotection that came about as a way of dealing with a physically handicapped child. In yet other cases, the cerebral palsy may be a relatively incidental finding that has no particular relevance to the mental disorder. When dealing with a single case, it is difficult to have hard evidence to enable a choice between these alternatives, but it is important for the clinician to have a view on the likely importance of different mechanisms.

Closely comparable issues arise with respect to psychosocial risk factors. If the mother is alcoholic, did the psychopathological risk derive from the child's *in utero* exposure to high levels of alcohol, from the genetic susceptibility, or from the family disruption and poor parenting to which the alcoholism may have given rise. In considering causal processes, crucial distinctions

need to be drawn between distal and proximal risk processes (Rutter *et al.* 1998a) and also between influences on the initiation of the child psychopathology and the processes that are currently maintaining it. Thus, poverty and social disadvantage are associated with an increased risk of mental disorders in childhood, but most of the risks seem to be indirectly mediated. The overall disadvantageous social circumstances do not, in themselves, cause psychopathology but they do make good parenting more difficult and the main risks stem from the parenting problems (Conger *et al.* 1992, 1993). In the same sort of way, parental loss and parent-child separations are associated with an increased risk of antisocial behaviour but, again, this seems to be largely because of the associated family discord and conflict (Rutter 1971; Fergusson *et al.* 1992). Furthermore, although family conflict is associated with an increased risk of psychopathology, it seems that this largely comes about when the conflict leads to negativity that is focused on that particular child (Reiss *et al.* 1995). In these examples, the global family situation needs to be thought of as a risk indicator, rather than an immediate risk mechanism. It is implicated in the causal processes but largely because it predisposes to other psychosocial features that constitute a more direct psychopathological risk. It is by no means easy to make these distinctions in the individual case, or even at a group level, but it is important when trying to decide how best to intervene.

The distinction between initiatory or provoking risk factors and factors concerned with the maintenance of a disorder is somewhat different. For example, an extremely traumatic experience may precipitate a post-traumatic stress disorder (see Yule, Chapter 32) but some individuals recover quite quickly whereas others go on suffering for several years afterwards. In most cases, the difference between recovery and persistence is likely to lie less in the severity of the initial experience than in how the person thinks about that experience and how they have dealt with it. The original traumatic experience cannot be taken away but the person may be helped to deal better with both the thought patterns and emotional reactions to which the experience gave rise. In other cases, it may be helpful to differentiate between the factors that played a major part in the timing of the onset of disorder and those that were responsible for the increased liability that led to the disorder occurring at all (see Sandberg & Rutter, Chapter 17). Thus, severely threatening life events (such as psychological loss or humiliation) may precipitate the onset of a depressive reaction or the initiation of a particular behaviour such as a suicidal act (see Shaffer & Gutstein, Chapter 33). On the other hand, the overall susceptibility to disorder may have more to do with the associated chronic psychosocial adversity than with the time-limited acute event itself. One of the important findings in life events research is the high frequency with which seriously negative events derive out of chronic psychosocial adversity. Both are important but they may serve a somewhat different risk role.

Clearly, the proximal risk mechanisms involved with the maintenance disorder must play a major part in determining the therapeutic hypotheses that constitute the basis for planning

treatment. However, several other matters have to be taken into account. To begin with, it is necessary to consider possible protective mechanisms, as well as risk processes (Rutter 1990). As in the broader consideration of features associated with resilience (Rutter 1999, 2000b), such possible protective processes may reflect a quite diverse range of features. Thus, the strengths may lie in the child's temperamental qualities and/or coping skills (Sandler *et al.* 2000), in the presence of a particularly good close relationship in or outside the family, of compensating good experiences at school or in the peer group, or in a possible change of pattern in family functioning. Thus, if one parent is particularly under stress, the other parent may be encouraged to take a greater role in parenting. The point is that the clinician needs to think broadly about the child's psychosocial situation in order to identify possible strengths and protective possibilities.

In planning any intervention, it is as necessary to decide which features are modifiable as it is to determine which are the risk and causal mechanisms. Thus, it is necessary to decide whether the intervention should focus primarily on working with the child, the parents, the family as a whole, the school, or trying to change other aspects of the broader environment. Of course, the treatment strategy may involve more than one of these avenues. One aspect of deciding about openness to modifiability concerns different perceptions of the child and of what needs to be done. Part of the same issue concerns a decision on what are realistic goals. The aim must be to provide relief for the child's suffering in the first instance, but restoration of full normality may not be a realistic goal (for example, only rarely would it be so in the case of autism; see Lord & Bailey, Chapter 38). Similarly, the intervention may not necessarily focus on the hypothesized basic causal process. Again, to use the example of autism, there would be general acceptance that this is a neurodevelopmental disorder but, equally, the evidence suggests that behavioural/educational interventions working with parents and teachers currently provides the best opportunities for reducing handicaps, even though autism has clearly not been caused by the lack of such experiences.

Another decision concerns whether or not to use medication and, if medication is used, how it should be employed and when it should be introduced. There are no drugs that are curative for child psychiatric disorders but there are several conditions for which medication has been shown to produce worthwhile benefits. These include depressive disorders (see Harrington, Chapter 29), obsessive-compulsive disorders (see Rapoport & Swedo, Chapter 35), tics and Tourette syndrome (see Leckman & Cohen, Chapter 36), schizophrenia (see Hollis, Chapter 37) and hyperkinetic disorders (see Schachar & Tannock, Chapter 25). They may also provide symptomatic benefits in other disorders. Decisions on drug usage are influenced, among other things, by the severity of overall impairment and the particular pattern of symptomatology. Thus, stimulants seem to work less well when hyperactivity is accompanied by marked anxiety (see Schachar & Tannock, Chapter 25), and antidepressants are more likely to be effective when the depression is accompanied

by vegetative symptoms, such as sleep and appetite disturbance, and psychomotor retardation (see Harrington, Chapter 29). In most cases, medication needs to be combined with some form of psychological or educational intervention. Although medication brings marked benefits, it does not restore normality by itself and steps may be needed to help the child and/or family cope more effectively and deal with any life situations or circumstances that provide psychopathological risk. Such interventions may only involve guidance or counselling of some kind but, in other cases, more intensive psychological intervention may be indicated. Decisions should be guided by what seem to be risk features, either in the psychosocial situation or the child's style of thinking, or perhaps of behaviour. It should be added, however, that the use of medication will carry psychological messages and that, unless carefully handled, these can undermine the psychological intervention (see Craighead *et al.* 1981 for an example in relation to dieting). The implication is not that different forms of intervention should not be combined, but rather that the clinician needs to present the combination in an appropriate way.

However, it should not be thought that drugs will only influence somatic features and not cognitions. The use of antidepressants in adult depression makes it clear that this is not the case (see Harrington, Chapter 29). Equally, it should not be supposed that psychological treatments cannot influence somatic functioning. The effects of psychological treatments in obsessive-compulsive disorder, in terms of their effects on functional imaging findings, negate that expectation (Baxter *et al.* 1992). Nevertheless, in relation to hypotheses about maintaining factors, the clinician will wish to take decisions on the appropriate choice, and mixture, of therapeutic interventions. It is important that this is done in a way that will indicate whether the therapeutic hypothesis is correct or needs modification as a result of the response to intervention.

Research findings are not as helpful as one might wish in the choice of which particular kind of psychological treatment to use. Although the evidence is reasonably consistent that focused goal-orientated interventions work better than more general open-ended ones (Rutter 1982), that would seem to suggest that the specifics of the treatment are important and that general support is not enough. On the other hand, although the range of comparisons remains more limited than one would like, the evidence does not indicate that, for any disorder, one particular style of psychological treatment is clearly generally better than others. Moreover, even when treatment is given by experienced clinicians with an investment in more intensive treatments, studies with both young people (Le Grange *et al.* 1992) and adults (Wallerstein 1986) have shown that skilled counselling may be as effective as more intensive psychological interventions that are designed to get more into the heart of the psychological problem. Although it should certainly not be supposed that simple treatments are always to be preferred, the findings do indicate that more complicated and intensive ones are not necessarily better. Decisions on the particular form of psychological intervention need to be guided by the nature of the

psychological difficulties, the personal characteristics and preferences of the individual child and family, and the preferences of the clinician in terms of skills, experience and preferred mode of working. Nevertheless, cost–benefit considerations are important and the choice of a more prolonged treatment over a shorter one always needs to be justified.

Conclusions

In this chapter, we sought to bring together some of the main considerations that should guide the approach to diagnostic assessment and the planning of treatment. Research findings are informative in providing guidance on some of the methods of assessment that work better than others and undoubtedly indicate the value of a systematic approach to the degree of standardization. But it is essential to be responsive to the individual needs and circumstances of each patient, to pick up cues and adapt assessment procedures accordingly. With respect to both diagnosis and the planning of treatment, it is also important to adopt a problem-solving hypothesis-generating, and hypothesis-testing, style. The gathering of factual data on psychopathological signs and symptoms and on risk and protective circumstances constitutes the essential basis. On this basis, it is important to seek to tell a ‘story’ about causal processes and to use that ‘story’ to plan a treatment strategy and to do so in a way in which the response to treatment indicates whether or not the therapeutic hypothesis was correct.

Diagnostic Interviews with Parents and Children

Adrian Angold

The purposes of the diagnostic interview

The clinical interview is the primary diagnostic tool in child and adolescent psychiatry, as in the rest of clinical medicine. Its first purpose is to collect information that will assist in the tasks of making a diagnosis and formulating and implementing a treatment plan. With the official adoption of more fully defined phenomenologically based official psychiatric nosologies (World Health Organization 1992, 1993; American Psychiatric Association 1994) and the introduction and increasingly widespread use of structured interviews, the diagnostic process has become more consistent over the last 20 years. Phenomenological diagnosis requires that information be collected in a coherent and consistent fashion, and thus sets the predominant style of the interview. The basic format is one of *sensitive guidance* by the clinician, rather than a free format in which parents or children simply play or discuss whatever occurs to them. The clinician guides, organizes and structures the collection of information in a way that is sensitive to the child's and parent's problems and concerns. This approach is very different from that of the 'non-directive' interviewer, who attempts to act as a sympathetic observer or sounding board and 'interprets' the material presented by the respondent. It has been shown that even supposedly 'non-directive' interviews are more directed than was once thought (Truax 1966, 1968), because the use of 'uh huh's' and the timing of reflections on what the patient has said, serve as strong indicators of the clinician's real interests.

However, a good interview also aims to achieve several other objectives apart from discovering the 'facts' about a patient. A diagnostic interview is often the initial contact between child or parent and clinician, and then it is the first step in establishing a treatment alliance with the clinical team. The same clinician may provide psychotherapy for one or more family members later on, so the diagnostic interview also represents a first step in the formation of a therapeutic relationship. All too frequently the initial diagnostic assessment is the only contact an individual or family has with the clinical team, as many never return for treatment. With this in mind, it is important to avoid increasing the barriers to future treatment-seeking by providing a good experience of psychiatric services. For all these reasons, and because of the need to ask about emotionally sensitive material, the clinician should approach the task of collecting information in such a way as to assure the family of a genuine interest in their problems and sympathy with their difficulties. Under the best circumstances, the product of such interviews is not only much

relevant information, but also the family leaving the office with a sense that something important about their problems has been understood by someone who cares and is willing (and perhaps able) to help. The respondent's behaviour in the interview is another important source of diagnostic information. Thus, the art of good clinical interviewing lies in the ability to combine the efficient collection of reported information, an observant eye, and the projection of interest and concern about the child's problems.

The need for multiple informants

Until the late 1960s, in both clinical practice and research, interviews and questionnaires directed to a parent or teacher about a child's behaviour and *observation* of the child's behaviour were the predominant methods of assessment in child and adolescent psychiatry. Verbal information from the child was typically regarded as being only supplemental, or material for psychodynamic interpretation (Lapouse 1966). In standard texts, much more attention was paid to playing with the child than to the collection of information through direct questioning. In 1968, a key transitional paper reported on the reliability and validity of the Isle of Wight interview with the child (Rutter & Graham 1968). Here the behaviour of the child in a face-to-face interview was examined directly, but it is notable that not much was made of the factual content of what the child said. Herjanic *et al.* (1975) answered the question 'are children reliable reporters' of factual information in the affirmative, on the basis of findings from the use of an early structured interview.

Since then, a great deal of work has confirmed the importance of children's self-reports as a source of factual information, with the result that fact-finding (as opposed to interpretative) interviews with both parents and children are now regarded as being of equal weight in the diagnostic process, at least from late childhood to late adolescence. The one exception is in the evaluation of attention deficit hyperactivity disorder (ADHD) symptoms, where child reports have been found to be of little help (Loeber *et al.* 1991). Even here the growth of interest in ADHD in adolescence and adulthood has led to the development of new measures in this area, as in the recent revisions of the Conners' rating scales (Conners 1997). This emphasis on the factual content of the history given by the child does not imply that clinical observation of the child's behaviour is not of great value; it is, as we shall see later.

Disagreement among informants and implications for combining information from multiple informants

Until the 1980s, agreement between child and parent reports of symptomatology was widely regarded as being a test of the *validity of child* reports (Rutter & Graham 1968; Herjanic *et al.* 1975). However, subsequent research using all sorts of measures soon showed that only low levels of agreement among informants (correlation coefficients around 0.3 for agreement among children, parents and teachers) could be expected (Reich *et al.* 1982; Stanger & Lewis 1993). It is now considered that low levels of agreement amongst different informants about the child's clinical state are to be expected and do not invalidate the reports of any of them. Rather, each key informant (typically, child, parent and teacher) is seen as presenting a particular view of the child's problems. Indeed, it is precisely because agreement among informants is low that multiple informants are needed. Were agreement very high, taking the history from more than one informant would be redundant.

The problem is that disagreement among informants means that one has to decide how to weight the information from each informant in arriving at a diagnosis. Because it is uncommon for informants to invent fictitious symptoms (though sometimes they do, and it is as well to be on the lookout for inconsistencies that may tip one off here), the simple rule of regarding a symptom as being present if any informant reports it usually suffices well enough. When symptoms are combined to make diagnoses, the usual procedure is to 'ignore' the source, and to add up all positive symptoms from any source. Thus, a diagnosis of a major depressive episode (which requires the presence of at least five symptoms) might be made on the basis of three relevant symptoms being reported by the child (say, depressed mood, anhedonia and excessive guilt), with two other relevant symptoms (perhaps sleep and appetite disturbances) being reported by the parent. Though some interview developers have recommended 'reconciliation' discussions involving the interviewer, the parent and the child to clear up discrepancies between their reports, such discussions are problematic in several ways. First, to achieve their purpose, one informant must modify his or her story, but that means admitting being wrong, or at least uninformed. Requiring such admissions at the start of the therapeutic process will often not be helpful, although confronting individuals with different perceptions of their behaviour may be an important part of the therapeutic strategy beyond the initial diagnostic stage. Secondly, it offers a chance for family members to become engaged in arguments with one another—again, something not helpful to the initial phenomenological diagnostic process. Thirdly, the knowledge that such a discussion will occur could cause informants (e.g. drug-using adolescents) to withhold important information that they did not wish other informants (such as their parents) to hear about. Finally, in most research applications, one wishes to assure informants that what they say will not be revealed to anyone else, in which case a 'reconciliation' interview is ruled out.

There are also situations in which consideration of the differ-

ences between informants' reports may be of interest. Another way of saying that different informants present different 'views' of a child's problems is that different informants provide information about different *aspects* of the child's emotions and behaviour, even when each provides that information using the 'same' scale. Looked at in this way, it comes as no surprise that sometimes the correlates of reports of child psychopathology from different informants differ. For instance, the enormous increase in the rate of depression in girls during puberty seems to be accounted for by changes in *self*-reports of depressive symptoms, while parent reports do not change very much (Angold *et al.* 1991). An even more striking example is provided by the substantial differences in patterns of genetic and environmental effects resulting from the analysis of ratings of the 'same' phenomena by different reporters (mothers, fathers, teachers and children) in the Virginia Twin Study of adolescent behavioural development (Eaves *et al.* 1997). Such differences raise a number of interesting scientific questions about exactly what different informants are telling us about, but in everyday clinical practice, the usual 'either/or' combination rule suffices for the most part. However, it is worth noting an important exception—the case in which parental reports are uncorroborated by any other source, including the clinician's observation of the child. Here, the possibility of Münchausen syndrome by proxy should come to mind (Schreier 1997).

Implications of comorbidity for diagnostic interviewing

Research over the last decade or so has demonstrated beyond doubt that diagnostic comorbidity (the presence of symptoms meeting criteria for multiple diagnoses) is extremely common (Angold *et al.* 1999a), so the task of the assessment is not to find the *single* diagnosis that best accounts for all the symptoms. Rather the question is *which* disorders can the child be said to suffer from, no matter how many they may be. As far as assessment is concerned this means that once one has decided that the child is depressed, one cannot then skip over the assessment of, say, disruptive behaviour, because a depressed child is also very likely to be oppositional, or conduct disordered, or a substance abuser as well.

Potential problems with using children younger than 9 as key informants

After the age of 9, the diagnostic interview with the child proceeds along much the same lines as is familiar from interviews with adults, as far as its structure is concerned. However, substantial differences in the case-mix to be expected in child psychiatric clinics and adult clinics (and in the child and adult general populations for that matter) have a substantial effect on the content of a typical child evaluation. In children, for instance, psychotic disorders are rare, but attention deficit/hyper-

activity problems are common. Although it is possible to demonstrate increased rates of forgetting in younger children in formal memory tests (Brainerd & Ornstein 1991; Ornstein *et al.* 1992) it seems that rates of forgetting are not markedly different, at least from the age of 6 to adulthood. Even 3-year-olds have been shown to be capable of remembering some events that occurred as much as a year before the interview (Pillemer & White 1989), though many such memories contain erroneous elements. In both adults and children, there is a tendency to conflate memories of repeated events into ‘scripts’ that provide a generalized memory of such events (Nelson *et al.* 1983; Saywitz 1987), incorporating features from a number of specific instances. Though there have been concerns about the accuracy with which children and adolescents can *date* events and the onsets of symptoms in their lives, there is little evidence that after the age of 9 they are any worse than adults at this task (Angold *et al.* 1996a). The adult literature suggests that it is easier to recall that something happened than when it happened, and major events are more likely to be remembered than minor events. The work of Cannell *et al.* (1977) in relation to the adult household survey suggests high rates of forgetting minor health problems (like headaches) over periods as short as 1 week, and substantial under-reporting of even major events by 1 year.

Before the age of 8 or 9, ‘adult-style’ diagnostic interviews work very poorly. The problem is that younger children are incapable of providing the detailed information about onset, timing, duration and co-occurrence of symptoms that are required to meet standard criteria for a full diagnosis. However, we should also remember that older children and adults also often have difficulty with providing this sort of information (Breton *et al.* 1995; Schwab-Stone *et al.* 1994; Angold *et al.* 1996a), so the problem is one of degree, rather than kind. Nevertheless, children 8 years old and younger can describe fears and worries, mood states and covert antisocial behaviours (such as substance use, lying or stealing) that may not be apparent to any adults. If questioned sensitively and carefully, and without leading, they can often provide sufficient detail to help with diagnostic evaluation. Children themselves may also be the only available sources of information about physical and sexual abuse, though here particularly careful interviewing is needed (Steward & Steward 1996; Bruck *et al.* 1998; see also Ceci *et al.*, Chapter 8). Progress has also been made in developing approaches to collecting information from children that go beyond the ‘adult-style’ question and answer formats, such as the MacArthur Story-Stem Battery (Warren *et al.* 1996, 2000) in which the interviewer uses toys to act out the beginnings of stories which the child is then asked to complete. The videotapes of these interactions can then be scored to provide indices of a variety of internal states. The Berkeley Puppet Interview (Measelle *et al.* 1998) employs two puppets to express two moods/states, and the child then indicates the puppet most like him- or herself, thereby providing self-report assessments of perceived academic functioning, social relationships, depression, anxiety and aggression/hostility. Some simpler ‘questionnaires with pictures’ have also shown promise with preschool-age children in relation to

the assessment of depression and anxiety (Martini *et al.* 1990; Ialongo *et al.* 1993). However, none of these methods is capable of yielding all the information necessary for a DSM-IV (American Psychiatric Association 1994) or ICD-10 (World Health Organization 1992, 1993) diagnosis, and there is no general agreement about how such information should be incorporated into the overall diagnostic assessment. A great deal of work needs to be carried out to place the diagnosis of younger children on an equal footing with that of later childhood.

From the age of 3 until the teenage years, there is an increase in the amount of information provided in free recall situations. Though younger children provide less information, they are no less accurate in their recall than older children and adults. The use of open questions is therefore the starting point for good interviewing, whether of children or adults about their children.

When closed questions, and especially forced-choice question formats are used, younger children (including preschool-age children) can usually provide more information than in the free recall situation (Ornstein *et al.* 1992). However, they are also more likely to provide *erroneous* information (Bruck *et al.* 1998). This is not to say that closed questions do not have an important place in the clinical interview, but they are best used to fill in the gaps in the information provided in response to open questions, or to clarify confusion, rather than constituting the basic approach. While preschool-age children are more likely to incorporate erroneous material introduced through repeated questioning, suggestion and leading questioning than older children, such techniques also induce reporting errors in older children, and even adults. There is no place for such techniques in psychiatric interviewing at any age (Bruck *et al.* 1998).

The need for a structured approach to diagnostic interviewing

It should be noted that structured interviews were originally developed because researchers were aware that clinicians unaided by such instruments tended to operate in an idiosyncratic fashion (Cantwell 1988; Gould *et al.* 1988; Remschmidt 1988), and to adopt inefficient decision rules in coming to a diagnosis. It was also apparent that there was a tendency to focus on a particular set of problems without giving adequate weight to an exploration of the full range of symptomatology. Both of these problems are typical of unstructured medical decision-making in general. Other general human information processing characteristics that may endanger the diagnostic process include ‘illusory correlation’ (Chapman & Chapman 1967), in which the expectation that a correlation exists between two phenomena leads to the imputation of the presence of a second phenomenon from the observed presence of the first. People also appear to have great difficulty identifying correlations when they really do exist in the phenomena that they are observing (Chapman & Chapman 1971). Thus, the observation that a child had made a suicide attempt might lead a clinician who believes that such actions are related to depression to assume that the child must be

depressed, and to interpret any hint of sadness as confirming this supposition. This latter tendency to weight information that fits in with expectations is also called the ‘confirmatory bias’ (Tversky & Kahneman 1974). Its corollary is that information that does not fit in with expectations tends to be ignored (thus our clinician might fail to take a careful history of behaviour problems, which would be a serious mistake, because suicidality is also strongly related to conduct problems). Confirmatory bias has also been identified as a real problem in the collection of evidence of abuse from young children (Bruck *et al.* 1998).

The ‘representativeness heuristic’ (Tversky & Kahneman 1974) may also bias clinical judgements when a child has the characteristics of a particular group (say, children with conduct disorder), leading the clinician to impute to the child other characteristics of conduct-disordered children, which actually do not apply to that individual (see Achenbach 1985 for a basic introduction to the application of decision-making analysis to the assessment of psychopathology; Sox 1987; Dawes 1988 for more advanced treatments). That these effects occur in ordinary clinical practice is indicated by Costello’s (1982) examination of diagnostic case conferences at a major child psychiatric centre (described in Cantwell 1988), whereas Bird *et al.* 1992) found that clinicians were less likely to assign certain comorbid diagnoses than a computer algorithm incorporating the DSM-III diagnostic rules, when both made diagnoses based on the same information. In arguing that a structured *approach* to diagnostic interviewing is necessary, I do not mean to imply that the use of any recognized structured interview is mandatory, although I do believe that the growing practice of using such interviews in clinical situations is to be applauded. Rather, I mean that good diagnostic practice demands the adoption of an organized, coherent, repeatable interview structure that avoids the information collection biases inherent in the unstructured diagnostic process. In this the psychiatric history is no different from the history taken in any other branch of medicine. As a variety of structured interviews have been developed to deal with these problems, they provide helpful information about ways that individual clinicians can develop their own structured approach to diagnostic interviewing.

Review of the current status of structured diagnostic psychiatric interviews for child and adolescent disorders

All structured diagnostic interviews seek, by whatever means, to achieve the following goals (which should also be the goals of every diagnostician):

- 1 structure information coverage, so that all interviewers will have collected all relevant information from all subjects;
- 2 define the ways in which relevant information is to be collected;
- 3 make a diagnosis only after all relevant confirmatory and disconfirmatory information has been collected; and
- 4 structure the process by which relevant confirmatory and

disconfirmatory information is combined to produce a final diagnosis.

Goals 1, 3 and 4 are achieved by all the major diagnostic interviews in rather similar ways; all cover at least the most common DSM or ICD diagnoses, and all have a set of rules, often computer algorithms, for combining the information collected to make diagnoses. However, goal 2, defining how the information is to be collected, has led to two quite different approaches to structured interviewing. These two methods have been dubbed ‘interviewer-based’ (or sometimes ‘investigator-based’) and ‘respondent-based’ (Angold *et al.* 1995). Respondent-based interviews have often been referred to as being ‘highly structured’, while interviewer-based interviews have been called ‘semistructured’. These are misnomers, because the issue is not *how much* structure is present, but *what* is structured.

Interviewer-based and respondent-based interviews

Interviewer-based interviews

In an interviewer-based interview, the *mind of the interviewer* is structured. In essence, the interview schedule serves as a guide to the interviewer to help him or her determine whether a symptom is present; the interviewer makes that decision on the basis of information collected from the patient or other respondent. Definitions of symptoms are provided, and the interviewer is expected to question until he or she can decide whether a symptom meeting this definition is present. This group of interviews includes the Anxiety Disorders Interview Schedule (ADIS; Silverman & Nelles 1988; Silverman & Rabian 1995), the Child and Adolescent Psychiatric Assessment (CAPA; Angold & Costello 2000), the Child Assessment Schedule (CAS; Hodges *et al.* 1982; Hodges 1993), the paper and pencil (not the computerized) versions of the Diagnostic Interview Schedule for Children and Adolescents (DICA; Reich 2000) and its close relative, the Missouri Assessment of Genetics Interview for Children (MAGIC), the Interview Schedule for Children and Adolescents (ISCA; Sherrill & Kovacs 2000), the various versions of the Kiddie Schedule for Affective Disorders and Schizophrenia (K-SADS; Ambrosini 2000), and the Pictorial Instrument for Children and Adolescents (PICA-IIIIR; Ernst *et al.* 2000). All of these interviews, except the PICA-IIIIR, make a wide range of DSM-IV diagnoses, and have components for assessing psychosocial impairment resulting from psychiatric symptoms and disorders. The PICA-IIIIR is unusual in that it provides a series of pictures meant to illustrate particular forms of psychopathology around which the interview is structured. However, it is suitable for use only by clinicians and has been little tested. The DICA has also been used with children younger than 6 years, although special training is required for its administration in such situations. Interviewers are instructed to ignore the usual questioning format laid out in the schedule and use their own questions. The result is that much of the usual structure of the DICA is jettisoned, with unknown results for reliability or validity. Various other interviews exist for specialized purposes (such as the

Autism Diagnostic Interview, ADI; Lord *et al.* 1994), but they will not be discussed further here.

Among interviewer-based interviews there are two subtypes: glossary-based and non-glossary-based. The K-SADS-P IVR and the CAPA (and the ADI) are glossary-based. They provide detailed written symptom definitions and rules for coding level of symptom severity and impairment resulting from symptomatology. The MAGIC provides a detailed *procedural* glossary (as opposed to the *definitional* glossaries of the CAPA and K-SADS-P IVR), which is a mine of information on good interviewing technique. The other interviews mentioned above (including various other versions of the K-SADS) provide much less definitional information to guide the interviewer and can be regarded as being non-glossary-based. More detailed comparisons among the members of this group of interviews can be found in Angold & Fisher (1999).

Respondent-based interviews

In a respondent-based interview, it is the *questions* put to the *respondent* that are structured; prescribed questions are asked verbatim in a preset order, and the interviewee's responses are recorded with a minimum of interpretation or clarification by the interviewer. Thus, although one knows exactly what has been asked in each interview, there is no control over differences in how subjects interpret questions or respond to them. It has been shown that, in the case of 'bizarre' phenomena (such as obsessive-compulsive symptoms), respondents' thresholds for answering questions about them in the affirmative are much lower than is helpful (far more cases are identified than really exist; Breslau 1987).

There are two types of respondent-based interviews: pure verbal interviews and pictorial interviews. The former are like adult diagnostic interviews, and most of the interviewer-based interviews, in that they rely solely on verbal questioning without visual aids. The pictorial interviews involve showing children cartoon pictures intended to illustrate the questions being asked. The Diagnostic Interview Schedule for Children (DISC; Shaffer *et al.* 1999, 2000) is the most widely used pure verbal interview. The current version is the DISC-IV. A great advantage of the respondent-based approach is that it lends itself easily to computerization. Questions are arranged in unvarying logical sequences in such an instrument, with stem questions followed by sequences of further questions contingent upon the answers to the stems. Software is available to allow the presentation of such interviews on a personal computer. Computerization can be achieved at two levels. Computer-*assisted* psychiatric interviews (CAPI) employ an interviewer to read questions from the screen and enter the appropriate codes into the computer as the interview progresses. The machine takes the interviewer to the appropriate stem questions, and stores the responses in a database. There is no need for bulky interview schedules to be copied and carried around, and data entry is completed during the interview. Furthermore, the computer will not accidentally skip parts of the interview, or vary the order of its presentation.

The next level of computerization is referred to as computer-*administered* survey interviewing (CASI). Here no interviewer is used at all; digitized audio recordings of the questions (sometimes even with digitized video of an interviewer) are played back by the computer as the written form of the question is displayed. The respondent enters a response to the question, which is saved to the database. The DISC has become progressively more complex over the last 20 years (largely because of the ever-increasing complexity of the DSMs), and the DISC-IV is now expected to be completed in its CAPI format, because it is really too difficult to administer it effectively in a paper-and-pencil format. There is also a CAPI version of the DICA, but this differs from paper-and-pencil version of the interview in being fully respondent-based (Reich *et al.* 1995).

The advantage of computerizability is somewhat offset from a clinical perspective by the fact that clinicians find the task of completing a long respondent-based interview rather tedious. If they go off interview to follow-up on particular clinical leads in their own way, the strengths of a respondent-based interview are vitiated. In general, the interviewer-based format is more suitable for clinical use by clinicians. However, we have reached the point where it is feasible to have parents and children complete a diagnostic interview, such as the DISC, before they see a clinician at all. The possible output from the DISC is almost infinitely flexible, and requires only programming to allow the production of reports tailored to particular clinical needs that can be generated immediately the interview is finished. Equipped with such a report, a clinician familiar with one of the interviewer-based interviews would then be starting with a very respectable initial diagnostic formulation to guide further elucidation of the clinical status of the child.

The Children's Interview for Psychiatric Symptoms (ChIPS; Weller *et al.* 2000) was designed as a screening tool covering 20 DSM-IV Axis 1 disorders. 'Cardinal questions' concerning symptoms most often seen in children with a particular disorder are asked at the beginning of each section. If the answers to these screening questions are in the negative, then the rest of that section is skipped.

The pictorial interview that makes the nearest approach to a DSM diagnosis is the Dominic-R (Valla *et al.* 2000), which is intended for use with 6–11-year-olds. Pictures representing psychopathology relevant to seven diagnoses are shown to the child, and questions about whether each symptom is present are read at the same time. Because no frequency, duration or onset data are collected, it is not yet clear how such information should be combined with diagnostic information from other sources. However, this should not be seen as a criticism of the measure, rather it shows how limited our understanding of psychopathology in younger children really is.

Interview time frames

One very important difference among the interviews considered here is the wide range of time frames they cover. The K-SADS interviews, the ADIS, the CAS, the Dominic and the ISCA all focus

on the child’s ‘current’ status, though the definition of ‘current’ is largely unspecified. The K-SADS-PL and K-SADS-E also explore lifetime histories of ‘worst’ episodes, while the ISCA also provides for assessment of lifetime disorder, and an ‘interim’ version provides an assessment of current status plus the child’s status in the interim between the current assessment and the last assessment, for use in follow-up studies. The DICA and MAGIC adopt a lifetime time frame as their standard format. Here there is always a lifetime focus, but for some disorders an additional shorter time frame is also included. For instance, in the depression section, the MAGIC asks about the ‘past month’ as well as whether the child has ‘ever’ had symptoms. The CAPA covers a ‘primary period’ of 3 months, but also asks whether certain uncommon symptoms (such as suicide attempts) have ever occurred, and a version that provides lifetime coverage of major episodes of certain disorders is also available. The full DISC-IV can be used to assess either the last month or the last year, and also offers a module to determine whether certain syndromes that did not occur during the preceding year had occurred at any point since the age of 5.

Reliability and validity of structured diagnostic interviews

Table 3.1 shows the results of studies of the *test–retest* reliabilities (kappas) of diagnoses measured by the instruments considered in this chapter. It can be seen that all do a reasonably good job, and that there is not much to choose between them, so far as test–retest reliability of diagnosis is concerned. These reliability coefficients are similar to those reported for psychiatric interviews with adults. Reliabilities for scale scores derived from these interviews are typically rather better than they are for diagnosis, and it is important to remember that some of the unreliability of diagnostic measures is a product of the diagnostic system itself, with its numerous details relating to onset dates, durations of symptoms and the like – information that humans do not remember very well, no matter what their age. One often sees reports of *interrater* reliabilities in the interview literature. However, interrater reliability is not a very useful index of interview performance. With respondent-based interviews it tests nothing but whether one interviewer can read aloud adequately while another fills in a form containing the answers to the questions. In an interviewer-based interview the questions are not fixed, and so different interviewers could use different questions to elicit the same information. As the interrater reliability paradigm uses multiple raters to score the same videotaped interview, this major source of potential unreliability is eliminated, with the result that the interrater reliability is likely to substantially overestimate the reliability of the interview in actual use.

A problem with the test–retest assessment of reliability is that it requires that the interview be repeated within a short period of time. With both questionnaires and interviews one finds that fewer symptoms are endorsed at the second interview than at the first (Angold *et al.* 1996b; Lauritsen 1998; Lucas *et al.* 1999;

Table 3.1 Test–retest reliabilities (kappas) of diagnoses in clinical samples from the instruments considered in this chapter (where available).

	MDD	Dysthymia/minor depression	Any depression	GAD/OAD	Separation anxiety disorder	Simple phobia	Social phobia	Any anxiety disorder	PTSD	ADHD	CD	ODD	SAD
K-SADS-P	0.54	0.70						0.24					
K-SADS-P IIIR	0.77	0.89						0.72	0.91			0.46	
K-SADS-PL current	0.90			0.78				0.80	0.67	0.63		0.74	
K-SADS-PL lifetime	1.0			0.78				0.60	0.60	0.55	0.83	0.77	
CAS	1.0	0.85	0.83	0.38				0.72	0.43				
DICA			0.90					0.76	1.0			0.61	
CAPA child only	0.90	0.85	0.82	0.79				0.64	0.64		0.55		1.0
ISCA child only				0.82	0.81	0.84	0.73	0.75					
ADIS combined P & C				0.64		0.86	0.48						
DISC-IV combined P & C	0.65			0.58	0.51				0.62		0.55	0.59	

Abbreviations: ADHD, attention deficit hyperactivity disorder; ADIS, Anxiety Disorders Interview Schedule; CAS, Child Adolescent Schedule; CAPA, Child and Adolescent Psychiatric Assessment; CD, Conduct disorder; DICA, Diagnostic Interview Schedule for Children and Adolescents; DISC-IV, Diagnostic Interview Schedule for Children-IV; GAD, generalized anxiety disorder; ISCA, Interview Schedule for Children and Adolescents; K-SADS, Kiddie Schedule for Affective Disorders and Schizophrenia; MDD, major depressive disorder/episode; OAD, overanxious disorder; ODD, oppositional/defiant disorder; PTSD, post-traumatic stress disorder; SAD, substance abuse or dependence.

Piacentini *et al.* 1999). There are many possible explanations for this effect (Jensen *et al.* 1992), but current evidence suggests that the results of the first interview are probably the most accurate representation of reality. The usual interpretation of test–retest reliability statistics—such as Cohen’s kappa for categorical data (such as diagnoses) and the intraclass correlation coefficient (ICC) for continuous data (such as scale scores)—involves the supposition that the relationship between scores at the first interview and those at the second involves two components: agreement and random error. The presence of a *consistent difference* between first and second interviews indicates that such statistics underestimate the ‘true’ (and unmeasurable) reliability of both interviews and psychopathology scales. Despite enormous efforts on the part of interview developers, it cannot be said that the reliability of diagnostic interviews has increased much over the years. We now have a fairly mature interview technology, and new developments leading to major increases in reliability are unlikely to occur. The current arsenal of diagnostic interviews probably offers as good reliability as can be achieved with this approach.

The problem with trying to assess the validity of psychiatric interviews is that there is no non-interview test for most psychiatric disorders. The structured interview itself has become the closest approximation we have to a ‘gold-standard’. So how are we to ‘validate’ the diagnoses obtained from such interviews? This is a version of a very old problem in psychology; one that led to the concept of *construct validity*. The key idea is that the validity of an instrument for the measurement of a psychological construct resides not in some single agreement coefficient with one external standard, but in the instrument’s performance within the *nomological net* of theory and empirical data concerning the construct or constructs that the instrument purports to measure (Jenkins 1946; Anastasi 1950; Gulliksen 1950; Peak 1953; Cronbach & Meehl 1955; Weitz 1961; Wallace 1965; Novick 1985; Anastasi 1986). As Gulliksen (1950) remarked, ‘at some point in the advance of psychology it would seem appropriate for the psychologist to lead the way in establishing good criterion measures, instead of just attempting to construct imperfect tests for attributes that are presumed to be assessed more accurately and more validly by the judgement of experts.’

Structured interviews were developed because of the poor psychometric properties of unaided clinical diagnosis, so comparisons with clinical judgement are a flawed test of diagnostic interview validity. In considering the validity of any interview, we should take a construct validation approach, and describe what we currently know about it in relation to the nomological net pertaining to child and adolescent psychiatric diagnosis. So far, only the developers of the CAPA have explicitly laid out the evidence for the validity of the CAPA using this approach, but most of the interviews considered here can point to similar chains of evidence. To give a flavour of the sort of evidence relevant to construct validation, the following findings have been adduced as construct validators of the CAPA.

1 Diagnostic rates and age and gender patterns of disorder

given by the CAPA are consistent with those found using other interviews.

2 Patterns of diagnostic comorbidity are consistent with those found by other interviews.

3 Symptomatic diagnoses are associated with psychosocial impairment.

4 Parent and child reports of psychopathology on the CAPA are related to parent and teacher reports of problems on well-established scales for detecting psychopathology.

5 Children with CAPA-identified disorders use more mental health services than children without diagnoses.

6 CAPA-diagnosed children tend to come from families with a history of mental illness.

7 There is genetic loading for a number of CAPA scales scores and diagnoses.

8 CAPA diagnoses show consistency over time.

9 CAPA diagnoses predict negative life outcomes (Angold & Costello 2000).

10 Different CAPA diagnoses are differentially related to the physiological changes of puberty (Angold *et al.* 1999b).

The need is for a change from concentration on single correlation coefficients, describing the interview’s level of agreement with ‘experts’ as evidence of validity, to concentration on comparisons of the information collection properties of different measures. In deciding which interview will be best for any clinical or research application, the key question is ‘Which collects the information I want in the way that I want to collect it in a reasonably reliable and efficient manner?’ A second useful question is ‘Is there any strong reason (practical or based on research on the instrument’s properties) why I should *not* use this instrument?’ The current evidence certainly does not support the notion that any single interview is ‘best’ for all applications. It is worth bearing in mind that low ‘validity’ coefficients may also be the product of the *diagnostic system*. A perfect measure of an invalid diagnosis will still produce an invalid diagnosis, so some of the problems with validity typically attributed to our interviewing technology should probably be placed at the door of the nosologies instantiated by the interviews (Robins 1985).

Clinical interviewing style

Open and closed questions

The distinction between open and closed questions is not absolute, but open questions are those that offer the chance to provide a wide range of answers or free-recall descriptions of phenomena, while closed questions call for one of a limited set of responses. For example, an open question response to being told by a child that he or she had received a bad school report might be ‘how did you feel about your bad grades?’, whereas ‘did your bad grades make you feel unhappy?’ would be a closed question. If a child had just admitted to stealing, responding with ‘tell me more about that’ involves an open question, whereas ‘what did you steal’ is a closed question. Basically, closed questions call for

a yes/no answer or a date, frequency, duration, or other quite specific piece of information, while open questions give the opportunity for the child to provide a description of his or her behaviour and feelings.

The work of Cox and Rutter and their colleagues offers some direct guidance on the best ways to use these different sorts of questions with adults and, in the light of the literature on children's memory cited above, there is little reason not to use a similar approach with children. In general, most factual information was collected when a systematic approach that relied heavily on open questions was used. Furthermore, this approach was also conducive to parental expressions of emotion, because it involved less talking on the part of the interviewer and gave more time for parents to discuss their concerns. A non-interventionist approach resulted in the provision of less relevant information, while challenging interpretations and a confrontational style proved less effective in eliciting emotions (Cox *et al.* 1981a–c; Hopkinson *et al.* 1981; Rutter & Cox 1981; Rutter *et al.* 1981). This is not to say that closed questions do not have an important place in the clinical interview, but they should be used to fill in the gaps in the information provided in response to open questions, or to clarify confusion, rather than constituting the basic approach. Sometimes it seems as though it might be quicker to ask a set of specific questions, especially when working through a set of diagnostic criteria; however, this is rarely the case. If open questions are well thought out, respondents will often provide much of the necessary information spontaneously, so that only a few follow-up questions need be asked. Thus, open questions may actually save time, and simultaneously avoid a barrage of closed questions that may seem to respondents to reflect the clinician's needs more than their own.

Leading questions

Leading questions are sometimes confused with closed questions, but whereas the latter are a necessary part of interviewing technique, leading questions have almost no place at all in psychiatric interviewing, for the simple reason that one can never believe the answer to such a question, especially in the case of young children. A leading question is one that directly suggests its answer. For example, to return to the child with problems at school, a response like 'I expect that made you feel pretty unhappy, didn't it', places the child in the position of having to disagree with the interviewer if he or she really did not care about his or her grades. We have already noted that young children may be prone to respond with what they believe is being demanded of them, so we can expect agreement, even if the child was, in fact, angry or completely unconcerned. On the other hand, such a question provides a golden opportunity for an oppositional adolescent to demonstrate how wide of the mark the interviewer was, regardless of his or her actual feelings about school.

Double and multiple questions

A double question asks about two different things at the same

time. Consider the question, 'When you got your school report were you worried, or angry, or didn't you care?' Such a question will often draw an answer like 'yes' or 'no', but one cannot tell what that answer refers to—it could refer any combination of worrying, anger or insouciance. The operation of the recency effect means that it is quite likely that the response refers to the last part of the question, but the only way to be sure is to ask specific questions about worrying, anger and not caring. As this could have been done in the first place, the multiple question has only served to waste time. Double and multiple questions also place an increased load on the cognitive capacities of the respondents, because they must remember several options in order to choose among them. Thus, double and multiple questions join leading questions as major interviewing sins.

Though multiple questions cause problems, the same cannot be said of 'redundant' questions: questions that contain two presentations of the same item, as in 'Did you feel angry about your report . . . did it make you angry at all?' The adult survey literature (Cannell *et al.* 1977, 1992) suggests that such redundancy can actually be helpful, and the same may be true in interviewing children, though this issue does not appear to have been studied specifically.

Multiple choice questions

Multiple choice questions are a subset of closed questions that have a place when regular open and closed questions fail to provide an adequate answer. For instance, if one asks about the frequency of temper tantrums, and the child says he or she 'doesn't know', a question like 'Well, is it every day, once a week or once a month?' can be helpful. However, such multiple choice questions may not include the proper range of choices. What is the right answer if tantrums actually occur only a couple of times a year, or if they occur many times a day? It is usually necessary to ask a supplementary question or two to clarify these points, so multiple choice questions are relatively inefficient, though they may be the only way to get the necessary information. They also have a second drawback in that, like multiple questions, they require the child to hold the available choices in memory before selecting among them. It has already been noted that the multiple choice format leads to the reporting of more incorrect information in younger children.

Repeated questions

Asking the 'same' question with some rewording can be helpful in allowing increased time and cognitive processing to be allocated to providing an appropriate answer. However, frequently repeated questioning, especially when combined with leading questions or other suggestive techniques, and failure to pay attention to disconfirmatory information also appears to be a good way to generate *false* reports. Indeed, in the sexual abuse arena, some authors have suggested that the retraction of previously made accusations is a typical part of the process of dealing with having been abused (hence, such retractions appear almost

to become confirmatory evidence). However, studies of *confirmed* sexual abuse have found that such retractions are uncommon (occurring in 3–8% of cases) (Bruck *et al.* 1998). As with other sorts of statements, inconsistency in the reporting of abuse by a particular informant should lead one to question the accuracy of those reports.

Inappropriately worded questions

In most circumstances, it is best to use simple words and short sentences. It is also important to be on the alert for possible misunderstanding. Here again the open question approach, with its emphasis on getting descriptions of experiences and behaviour, helps to ensure that both interviewer and interviewee are talking about the same thing.

Organizing the interview

So far, we have examined some basic interviewing techniques. The next question is how to organize these into a coherent interview in a clinical setting.

Beginning the interview

The first task is to get the interviewee into a conducive situation: somewhere quiet, private and undistracting. The presence of large numbers of interesting toys should be avoided in interviews with children.

The child often does not know why he or she is talking to the interviewer, as parents may have told the child that he or she is going to the dentist or some other fiction. The first step, then, is to clarify why the child thinks he or she is seeing you, and to allay fears that injections or extractions are just around the corner. Even if the child has a reasonable notion of where he or she is, his or her ideas about why he or she is there may differ dramatically from the actual reasons for referral. The next step is to explain why you think that the child is there, to explain the purpose of the interview, and to give a brief description of what it will be like. Similarly, parents who have come at the behest of another agency may have only a dim understanding of why they are there, so, again it is helpful to outline what the purpose of the visit is at the beginning.

As an immediate barrage of questions about emotionally loaded topics is likely to be very off-putting, it is usually best to begin with some questions that allow the respondent to describe the family situation, the things the referred child enjoys doing and is good at, and what his or her social life is like. If the child is aware that he or she has problems, a brief description of how he or she sees those problems can be helpful. By this point, both the respondent and the interviewer should have a fairly good idea of what to expect from one another, so the interviewer can formulate a plan for the rest of the interview. If it has become clear that some topics are a source of discomfort or avoidance, it is best to steer away from these at the start, and to begin with less threatening material, allowing a sense of

trust to develop. On the other hand, some respondents (especially parents) are keen to get right down to a description of what bothers them most. In either case, following the respondent's leads and exploring his or her problems in the order in which they come up is a good strategy. However, in being sensitive to the respondent's ordering of the material, it is important not to allow the interview to become incoherent. Once a topic (such as symptoms of depression) has been begun, it is usually best to continue with it until all the necessary information has been collected. Otherwise it is very likely that important questions will be forgotten in jumping from topic to topic. There is nothing wrong with telling the respondent that you will come back to a different topic later (as long as you do).

Those just beginning work in child and adolescent psychiatry usually do not know what all the relevant symptoms are, and here the use of a simple checklist (for the interviewer, not the respondent) based on the DSM or ICD criteria can be very helpful. However, these criteria give no guidance as to how to turn them into suitable questions, and familiarity with a well-structured interview helps to fill this gap. If the respondent has previously completed a symptom checklist, it is a good idea to have looked it over before starting the interview. It is vital that the diagnostic criteria are not allowed to become a strait-jacket for the interview. It is all too easy to emerge with more or less accurate diagnoses but little idea of what the child is actually like. Much goes into good treatment planning besides the diagnosis.

Common child psychopathology is divided into two broad domains: emotional and behavioural disorders, and the next two sections discuss some general principles for assessing symptoms in these areas.

Emotional disorders

The central distinctions to be made here are between *moods* or *affects*, *thoughts* and *behaviours*, and *impairments* secondary to the first three. The distinction between moods and thoughts is the most difficult to maintain in practice, largely because English does not clearly distinguish between them in everyday speech. For instance, it is usual to ask whether someone 'felt' guilty rather than whether they 'had guilty thoughts', though the latter is more accurate. When interviewing one must use everyday language, but it is important to be clear that while 'feeling guilty' may be evidence of a depressive disorder, it is not the same thing as depressed mood. It is quite possible to have an overdeveloped sense of guilt without depressed mood and vice versa. Thus, some common questions like 'Did you feel bad about that?' must be treated with caution, because an affirmative response could refer either to a mood state (as in 'That made me feel unhappy'), or a cognitive state (as in 'That induced the thought that I had done something bad or wrong'). Similarly, worrying (a cognitive symptom) must be distinguished from anxiety (a mood state). While at first these distinctions may seem to be splitting psychopathological hairs, they are diagnostically important, and of direct relevance to treatment; consider, for example, cognitive

therapy for depression, which focuses directly on thought processes, rather than the mood state itself.

When is an emotional 'symptom' abnormal?

One problem with emotional symptoms is that they are often extremes of normal emotions. This presents no problem when someone reports that they have been depressed all day, every day, for 2 months, and that before that they were of a cheerful disposition. Unfortunately, things are not always so simple. In the absence of a detailed epidemiological literature describing how much time the average child spends feeling depressed, or worrying, it is necessary to have some general rules of thumb for deciding what is abnormal.

1 *Look for changes in state or failure to make normal developmental progress.* A description of a marked change in state, especially if it is of relatively acute onset, is strong evidence for the pathological status of a symptom. However, it has to be said that in developmental psychopathology, acute onsets are the exception rather than the rule. Symptoms may also have begun years before the child presents for help. However, if care is taken to get adequate descriptions, and the respondent is encouraged to think hard about whether and when a change occurred, it is usually possible to determine whether a symptom represents a change from some previous state.

Some symptoms represent the inappropriate continuation of a state that is normal in earlier life. Separation anxiety is the paradigmatic example here. Most children show separation and stranger anxiety in their second year, and many are unhappy about leaving their parents on first going to school. However, much more independence is expected of teenagers, and in a 12-year-old a wish to sleep with her parents, because she is afraid to sleep alone, would be distinctly abnormal.

2 *How long do bouts of the symptom last, and how often do they occur?* Most people worry or feel depressed sometimes, but these are evanescent phenomena. They are only symptomatic when present for an inordinate amount of time. Once again, we lack data on how much worrying is normal, but can determine how much time (average length of bout of worrying × number of bouts per week) has been spent worrying and make a common sense judgement about whether this is pathological.

3 *Is the symptom intrusive into other thoughts and activities?* A symptom that disappears as soon as something comes along to take an individual's mind off it, is unlikely to be of psychopathological import, so it is important to ask whether symptoms intrude into, or interfere with, other activities. Worrying that interferes with concentrating on schoolwork represents a problem, whereas worries that disappear as soon as there is a job to be done probably do not.

4 *Is the symptom controllable?* If a child can get rid of a symptom by thinking about, or doing, something else, then one can usually be fairly sure that it is not psychopathologically significant. Intrusiveness and uncontrollability are very closely related ideas and, in general, both will be reported in relation to important symptoms.

5 *Is the symptom generalized across more than one activity?* A 'symptom' that is restricted to a single activity (such as worrying about a maths test just before it, but only then) is usually not a marker for a clinically relevant problem. In the case of specific phobias, a child who is frightened of dogs only when a dog is barking at them, is unlikely to encounter many problems, while the child who is afraid of dogs whenever he or she is out in the street, regardless of the presence of a dog, can be regarded as being symptomatic.

Behavioural problems

An overlapping set of considerations is of primary relevance for behaviour problems. Some undesirable behaviours are normal (such as disobedience or lying) when they occur at low frequency, and should only be regarded as 'symptoms' when they occur often. In such cases, frequency, controllability and generalization are relevant, but bout duration and intrusiveness are not. Until recently, information about the frequency of oppositional/defiant disorder (ODD) symptoms in the community have not been available, so clinicians have had no choice but to rely on their own judgement in determining whether such symptoms were present. Angold & Costello (1996) recently presented general population norms for ODD symptoms in 9–14-year-olds and, based on 90th percentile cutpoints, suggested that these symptoms should be regarded as 'often' occurring as follows. *Spitefulness and vindictiveness* and *blaming others* should occur at least once every 3 months; *being touchy or easily annoyed, losing temper, arguing with adults, and defying or refusing adults' requests* should occur at least twice a week; and *being angry and resentful* or *deliberately annoying others* should occur at least four times per week. Now we can expect that, at other ages, different normative values would be more appropriate, and it is to be hoped that such norms will be forthcoming. However, it is also important to consider some other characteristics of antisocial behaviours.

1 *Response to admonition.* Here, two levels of non-response may be discerned; some children simply do not do as they are told, while others actively challenge their admonisher (for instance by swearing at, or hitting, a teacher).

It is also worth noting that clinical experience indicates that many children with marked attentional and activity problems are poor reporters of their behaviour in this respect. It is not uncommon for such children to report that they are not fidgety and have no difficulty remaining seated when told to do so, despite the fact that they have spent most of the interview wandering around the office, in the face of repeated requests that they should sit down. They may also seem to be unaware of their social skills defects, so it is important to get detailed descriptions of how they interact with their reported 'best friends'.

2 *In what situations did the behaviour occur?* Three general settings may be distinguished as: (a) home; (b) school; and (c) elsewhere. Determining where problematic behaviour occurs has important treatment implications, and also seems to have some

prognostic importance, in that pervasively disturbed children appear to have more persistent problems and do worse in young adulthood.

3 *Was the child usually alone or in company when performing antisocial acts?* Such information is helpful in determining the degree to which the child's social environment may be contributing to his or her antisocial behaviour.

4 *Who was the victim of the antisocial acts?* Here distinctions may be made between (a) community property (as in vandalizing park benches); (b) the property of individuals not known to the child (as in shoplifting); and (c) the property of individuals known to the child (as in stealing from mother's purse).

Many types of antisocial acts are considered abnormal whenever they occur (armed robbery, for instance), and are not at all uncommon in some psychiatric settings (such as substance abuse treatment programmes), so it is important to ask teenagers about these sorts of activities. In many areas, it is also common for teenagers, and even younger children, to carry weapons, and to use them, so it is worth asking about this as well. In countries where guns are freely available, it is also important to know whether the child has access to guns, especially if the child is at risk of making a suicide attempt. Parents should then be advised to eliminate the child's access to weapons (preferably by removing them from the house).

Delusions, hallucinations and other symptoms of serious psychopathology that may be confused with normal phenomena

Children and adolescents may manifest all the symptoms characteristic of adult disorders such as schizophrenia or bipolar disorders. Disorders involving hallucinations and delusions are uncommon in childhood, but both become more common in adolescence. In childhood especially, great care must be taken in establishing the presence of delusions and hallucinations, because a number of other phenomena can easily be confused with these very serious symptoms. In particular, hypnogogic hallucinations (vivid true hallucinations occurring when falling asleep) and hypnopompic hallucinations (vivid true hallucinations occurring on waking up) are normal phenomena. In general, hallucinations occurring only when the child is in bed should not be regarded as evidence of the presence of major disorders, even if the child insists that he or she was not falling asleep or waking up when they occurred. Care also needs to be taken not to mistake eidetic imagery, imaginary companions, elaborated fantasies, perceptual illusions, seizure phenomena, drug-induced experiences, subcultural beliefs, and hallucinations accompanying toxic encephalopathies, for manifestations of delusional or hallucinatory psychopathologies.

Déjà vu, jamais vu, derealization and depersonalization are states that most people experience from time to time, but sometimes occur in schizophrenia, schizo-affective states and bipolar disorders. Once again, it is important to get a clear description of the phenomena, and to pay particular attention to how often they occur and how long they last. Derealization and deperson-

alization are also common effects of certain drugs (such as cannabis and LSD) and the possibility of drug use should be investigated when these states are reported. Premonitions of events are also often described by quite normal people, and should only be regarded as being psychotic phenomena when they clearly fall outside the normal range of experiences for the cultural group to which the child belongs. In most cases, consideration of the overall clinical picture will ensure that these phenomena are interpreted appropriately.

Many of these psychopathological distinctions are relatively subtle, and parents can usually provide only very limited descriptions of such phenomena. Here (as with adults), there is no substitute for the direct face-to-face mental status evaluation of the child, supplemented by longer term clinical evaluation.

Impairment of psychosocial functioning

Psychiatric disorders impact on a person's ability to function at their highest level in the psychosocial environment, and it is vital to assess the degree to which such functioning is impaired. Here the main areas of concern are school (or work) performance and behaviour, peer relationships, social and spare-time activities, and relationships within the family. Relying solely on symptom ratings and DSM-III for diagnosis has been found to lead to ridiculously high rates of diagnosis in epidemiological studies using respondent-based interviews and one strategy for producing more sensible estimates has been to require some degree of psychosocial impairment to be present if a diagnosis is to be made (Bird *et al.* 1988). In clinical settings, most patients have some degree of impairment, so the issue of using impairment as a measure of severity looms larger there. The same may be said of glossary-based interviewer-based interviews (CAPA or K-SADS-P IVR) that do not require the use of additional impairment criteria to compensate for symptomatic overdiagnosis.

Several approaches have been adopted to the measurement of impairment (reviewed in Costello *et al.* 1998). The first is to consider the patient's overall level of functioning, by combining information about symptomatology and psychosocial impairment into a single rating. The Children's Global Assessment Scale (Shaffer *et al.* 1983; Bird *et al.* 1987) and the Columbia Impairment Scale (Bird *et al.* 1993, 1996) are the best examples. These instruments, based on the DSM-III-R Axis V, provide simple, reliable scales, and can be coded after all the symptom information about the child has been gathered.

More molecular assessments of impairment are available from the Social Adjustment Inventory for Children and Adolescents (SAICA; John *et al.* 1987), which is a 20-min interview schedule that includes ratings of a number of psychosocial problems. It also includes items that are ordinarily regarded as conduct problems, and usually covered in the exploration of symptomatology. However, it is quite possible to use the non-symptom items alone, although the usual scoring system does not adopt this approach. The same applies to the more extensive Child and Adolescent Functional Assessment Scale (Hodges *et*

al. 1998). When the developmental impairment of younger children and those with mental retardation is at issue, the Vineland Adaptive Behaviour Scales (Sparrow *et al.* 1984; Sparrow & Cicchetti 1989; Cicchetti *et al.* 1991) are without peer, although some scales also include what, from a psychiatric perspective, are better regarded as being symptoms rather than impairments.

An alternative approach is provided by the CAPA and DISC-IV, which calls for separate ratings of psychosocial impairment, secondary to psychiatric symptomatology, in a number of domains. In this case, the symptom ratings are separated out from the impairment ratings and the contributions of particular symptom areas to the overall degree of impairment are assessed. This can be helpful with children with multiple problems, because it gives an idea of which areas of symptomatology are most responsible for any psychosocial difficulties, and this may help in deciding where to begin as far as treatment is concerned.

The K-SADS-P adopts a somewhat different approach by including aspects of psychosocial functioning in a number of the ratings of specific symptoms (Chambers *et al.* 1985). The strength of this combined technique is that it provides an overall clinical summary of how ‘disturbed’ the child is, and it is widely used in both clinical practice and research. However, because symptoms and psychosocial impairments are conflated in the ratings, it is impossible to look at each dimension separately.

Lifetime histories

Two studies (Orvaschel *et al.* 1982; Fendrich *et al.* 1990) have found that the kappas for child reports of known depressive episodes reported on between 6 months and 2 years later were around 0.6. Fendrich *et al.* (1990) also present evidence of reasonable stability for diagnoses of conduct disorder, attention deficit disorder and substance abuse, but poor stability for anxiety diagnoses. However, it is important to remember that the usual form of instability is failure to recall a previous episode; few symptoms are ‘invented’. The use of scripts means that a series of events may be conflated into a single memory, so very accurate dating may not be attainable. However, recent work in the survey literature suggests that attempts to ‘decompose’ such memories into a series of more specific instances can be surprisingly successful. Likewise, tying the onsets of symptoms to events, such as birthdays and school terms, can also lead to finer-grained dating than seemed possible at the beginning of the interview. It is usually possible to determine the age by which a symptom was definitely present, which is certainly better than nothing. In general, the further back in time one goes the more information is lost although, for events of major significance, the degree of decrement after the first year may be small. It is also important to remember that in adults, for most memories, there is a ‘brought forward’ effect, by which events are remembered as having happened more recently than was the case, although there are exceptions to this rule, as in the case of memories for certain developmental milestones in one’s children (Hart *et al.* 1978), and there is no reason to suppose that this is not the case in children too. In fact, the situation may be more complicated

than this in children because it has been found that the age at which children and adolescents were interviewed about their depressive psychopathology had a significant effect on the rates at which they reported depressive symptoms and the reported timing of their first episodes and worst episodes of dysphoria, with girls around the age of 16 reporting earlier episodes than either younger or older girls (Angold *et al.* 1991). This age group also reported a higher level of current symptoms, so it may be that the finding from adults that being currently depressed increases the chance of reporting a previous depression holds in children too. As long as these caveats are borne in mind, a lifetime history is well worth taking, but it must be remembered that negative responses are not as reliable as positive ones.

Special interviewing situations

Children with limited understanding: the young and the mentally retarded

Any interview is an exercise in verbal skills, and it is important to be sensitive to verbal limitations in those being interviewed. Young children are unlikely to provide much information in a free-recall setting, and the same is true of the mentally retarded. These groups also have shorter attention spans, and usually cannot be expected to sit for 2 h of interview without breaks. However, they may well be the only available sources of information about their inner lives.

The temptation for the clinician when dealing with individuals who can provide only limited detail in response to open-ended questions is to ask a lot of closed questions, and this often leads to the use of leading questions in order to make it ‘easier’ for the individual to respond. However, these groups are particularly likely to respond to such questioning by supposing that they are expected to agree with the interviewer, and mistakenly trying to oblige in this way. While there may be no way around the need to ask greater numbers of closed questions, every attempt should be made to get as good descriptions as possible of the phenomena that the child is referring to, so as to avoid confusion. It is also important to try to check that the words that the child is using to describe their inner world are being used in the same way that we would use them. Thus, a 4-year-old’s ‘worry’ might be our ‘frightened’ or ‘depressed’. It can be helpful to find situations in which one can be fairly sure that a child was feeling a particular emotion (like sadness), and then ask whether the feeling they are talking about now is the same as that. In fact, this problem is not qualitatively different from the general issue of making sure that both parties in the interview mean the same thing, but it is quantitatively more demanding.

Additional tools may be helpful in getting descriptions of events that occurred; using play-like materials, such as puppets, toy houses, or photographs of individuals involved in events may be useful. Drawing is also a time-honoured modality in child psychiatry, and can be useful here. The aim is to

provide a focus for cognitively reconstructing the situation to be remembered. However, it is important to recognize that the aim, in this case, is to help the child to remember and not to make interpretations. The degree to which these aids generate misleading, as well as accurate information has not been adequately tested.

Investigation of abuse

Now that greater attention is being paid to the problems of physical and sexual abuse, an increased load has been placed upon the clinical interview, and a new set of demands are being made on the 'evidence' collected. In collecting material that may be called into evidence it is particularly important that leading questions or other 'suggestive' strategies should be avoided because, in some well-publicized cases, such material has led to children's testimony being rejected (Cole & Loftus 1987). In dealing with issues that may be frightening or embarrassing, or about which the child may have been threatened should he or she ever reveal what happened, there is naturally a wish to make it as easy as possible to give a full description. Furthermore, as most young children lack an adequate anatomical vocabulary to describe sexual abuse, the use of anatomically 'correct' dolls or pictures to allow children to demonstrate what happened has become fashionable, and has received research support (Steward & Steward 1996). However, some have argued that such dolls (with their obvious protuberances and orifices) themselves suggest certain forms of play that may then be misinterpreted as evidence of sexual abuse (King & Yuille 1987). Indeed, experimental studies have found that, while the use of props such as dolls can increase accurate positive reports, they can also increase the incidence of problematic reports (reports of things known not to have happened) (Ornstein *et al.* 1997; see also Ceci *et al.*, Chapter 8). Case reviews of sexual abuse records have suggested that fabrications of stories of sexual abuse are rare, and that such fabrications are usually begun by an adult when they occur (Jones 1985).

The definitive answers to the best way to collect evidence of abuse are still some way off, but at present an acceptable approach seems to be to use ordinary good interviewing strategies as far as possible and to supplement these with descriptions using anatomically correct dolls or pictures when necessary, always bearing in mind that the child must understand that one is asking 'What actually happened' rather than 'What can you do with these dolls' (Steward & Steward 1996). As defence lawyers are almost certain to make the claim that evidence of abuse was obtained by the use of leading questions and techniques that relied on the child's supposed suggestibility, it is important to be sure that this was not the case, and the best way of doing this is to record (preferably on videotape) exactly what happened in the interview. When this is not possible, it is important to record both the *questions asked* and the answers obtained (see Bruck *et al.* 1998 for helpful discussions of the implications of memory development research for children's testimony; Leippe &

Romanczyk 1987 on juror's reactions to child witnesses; also Ross *et al.* 1987; Ornstein *et al.* 1997).

Children who 'don't know'

All child psychiatric clinicians have been faced with children who resolutely 'don't know'. In such cases, persistence can make a huge difference, particularly with information about duration, frequency and the timing of symptom onsets. It may also be the case that some children really do not know how to answer questions like 'How have you been feeling lately?', because they are unfamiliar with describing their feelings. In such cases, more focused questions (such as 'Have you been feeling miserable?') can help by providing a series of categories that children can use to describe their feelings. Thus, the ubiquitous 'boredom' of adolescence may be reducible to a number of more sharply focused states, when a framework for more accurate descriptions is offered.

The psychodynamic interview

Psychodynamic psychotherapy uses an interview format as its central modality. However, the aims of such interviews are rather different from those of the diagnostic clinical interview. The emphasis is not on collecting 'facts' in an efficient manner, but on engaging the child in an exploration of his or her own inner world and attempting to understand how that world combines fantasy and reality in relation to experience and behaviour. It is therefore usual for the therapist to be much less active and to allow the child to play and draw quite freely. The therapist provides interpretations that represent attempts to understand the meaning of the child's experiences within the framework of psychodynamic theory. This is not the place to explore the intricacies of psychodynamic technique, but it should be borne in mind that these differences in aim and practice mean that a psychodynamically orientated interview is unlikely to provide the best means of collecting the information necessary to make a phenomenological diagnosis; that is not its purpose. Although the phenomenological interview is not the best method for psychodynamic interpretation, it is important that a sense of trust and understanding be generated in such interviews, so as not to compromise later psychodynamic work. Many of the techniques involved in a good phenomenological interview may be seen as laying the groundwork for psychodynamic therapy and there is no reason to see the two as being in opposition (see Jacobs, Chapter 58, for a discussion of some further aspects of psychodynamic psychotherapy).

Projective testing

The aim of projective testing is to provide a child with an ambiguous stimulus, and then to use the responses to indicate underlying problems. At the simple end of the spectrum, children have been asked for years what their 'three magic wishes' would

be, and it has been shown that the magic wishes of psychiatrically referred children differ in content from those of normal controls (Winkley 1982) in frequently containing wishes related to real problems. However, it has not been shown that these same problems could not have been uncovered by simply asking the child about his or her problems in a straightforward way. The same applies to the standardized scoring schemes developed for the Thematic Apperception Test (TAT; Winter 1999) or the Rorschach Inkblot Test (Exner & Weiner 1995), and herein lies the issue with projective testing in general. In a thorough review of the literature on the subject, Gittelman-Klein (1978) concluded that there was no evidence that such testing revealed any information that was either not already known to the clinicians before testing or could not have been discovered by the simpler means of asking about it directly. If the aim is to explore a child's fantasy life, particularly as part of psychodynamically orientated play therapy or psychotherapy, then projective techniques clearly have an important part to play, and Winnicott's (1971) famous interactive squiggle game and talking about drawings can certainly serve to initiate and maintain psychotherapeutic interactions.

Observations of behaviour

Observation of the child's behaviour is a central focus of the diagnostic interview. Indeed, with some very disturbed children, it may contribute the most significant material. All clinicians associated with the child should make a point of keeping in mind a checklist of the behavioural areas outlined below, so that the child's behaviour can be compared across the various settings or 'stimulus conditions' provided by the clinic. Such observations should begin in the waiting room, which may offer an opportunity to observe the child's initial mode of interaction with completely unfamiliar adults and peers. A number of dimensions should be considered, including separation responses, physical appearance, motor behaviour, form and content of speech, the quality of social interactions, affective behaviour, level of consciousness and developmental level. Although this section concentrates on observation of the child, it is also important to bear in mind that an interview with a parent about the child also provides an opportunity to conduct a mental status examination of the parent. As parental psychiatric disorders are major risk factors for child psychiatric disorders, such an evaluation is important for the development of a full diagnostic formulation. Child psychiatric disorders also have significant impacts on parents' lives, emotionally, socially and financially (Angold *et al.* 1998), and the clinician should also take care to find out whether such impacts are present in each case.

Separation responses

The younger the child, the more likely he or she is to protest against separation from parents, so the interviewer may also

need to engage parents in helping the child to separate, and this provides an opportunity to observe parental responses. During the interview a child will often become more anxious, and ask to see his or her parents. If this anxiety seems likely to disrupt the interview, then a quick visit to the parents will usually settle things down for a while. Sometimes the level of anxiety is such that a child simply cannot be interviewed when the parents are absent, in which case there is no alternative to conducting the interview with them in the room. Other children who have experienced multiple caregivers will separate with undue ease, and may end up trying to sit on the interviewer's knee and shower him or her with kisses. A firm, but friendly, attempt to get the child to adopt more suitable seating usually has the desired effect.

Physical appearance

The physical appearance of the child may provide indications of abuse (e.g. bruising) or neglect (such as dirty, ill-fitting clothes or signs of malnourishment). Signs of genetic abnormalities (such as low-set ears) or other deformities should also be looked for (see A. Bailey, Chapter 10). Sometimes oddities of dress, hairstyle or make-up may be helpful in identifying deviant subculture membership, or even psychosis.

Motor behaviour

A number of motor abnormalities that may have psychiatric significance may be observed. The most common example is the restlessness, fidgetiness and distractibility of hyperactivity, which needs to be distinguished from manic motor excitement. Depression may be accompanied by motor slowness and underactivity and, in very rare cases, primary obsessional slowness may occur in severe obsessive-compulsive disorder. Obsessive-compulsive disorders may manifest as compulsive acts or rituals, which must be distinguished from motor stereotypies, tics and mannerisms. Potentially self-injurious behaviour such as head-banging or self-biting may occur (usually in mentally retarded subjects), and catatonic states may even more occasionally be observed. The clinician should also be on the alert for medication-induced movement disorders (such as the tremor of lithium intoxication or the choreo-athetoid movements of tardive dyskinesia), and symptoms and signs of drug or alcohol use.

Form of speech

Speech disorders, such as stuttering, cluttering and articulation defects, should be noted if they occur, because they may require specialist treatment. A number of psychiatric disorders also produce abnormalities in the form of speech, such as the low volume mumbling of some socially anxious or depressed individuals, the slowness of speech of psychomotor retardation, manic pressure of speech, and the prosodic abnormalities that may occur in

some psychotic states or autism. Vocal tics may occur alone or in combination with motor tics.

Content of speech

A range of speech content abnormalities may be observed, including the neologisms, incoherence and poverty of content that may occur in schizophrenia, and manic flight of ideas. Unusual grammatical forms (such as the pronominal inversions of autistic children) may occur, and verbal stereotypies and the occurrence of self-directed speech should also be watched for.

Social interaction

An interview is a social interaction, and can provide a good deal of information about a child's social abilities. Both verbal and non-verbal social functioning should be considered.

How readily does the child provide information? Does the child engage in normal reciprocal social communication with good articulation of both verbal and non-verbal interchanges? Are the child's overtures and responses appropriate to the interview situation or is the child overly withdrawn, overly friendly or socially inappropriate or odd? Is the pattern of eye contact unusual in any way? Does the child maintain an appropriate social distance? Is the child unusually disinhibited, aggressive or oppositional during the interview? Is there unusual preoccupation with idiosyncratic special interests? What is the overall quality of the rapport between the interviewer and the child?

Affective behaviour

Though many children are shy, anxious or sullen at the beginning of an interview, most 'warm up' after a little while and it then becomes possible to determine whether there are signs of affective dysfunction.

Does the child smile and laugh appropriately and show a normal range of facial expressions and emotional responses? Are there any signs of overly expansive mood? Is the predominant facial expression one of sadness or anxiety? Are there any visible signs of autonomic disturbance, such as sweating or hyperventilation? Is the child frequently tearful, irritable, suspicious or perplexed? Is affective behaviour appropriate to the material being discussed, and does the child show a full range of affective responses? Is the child's mood abnormally labile?

Level of consciousness

In most circumstances, clouding of consciousness will be obvious. However, on rare occasions, previously unrecognized *absences* can be spotted by a careful interviewer.

Developmental level

A full developmental assessment requires expertly administered standardized testing, but a brief evaluation of a child's verbal,

reading, writing, mathematical and drawing abilities can indicate the presence of obvious delays or deficits.

How long should the interview last?

This chapter has indicated that diagnostic interviews are intensive and extensive data-gathering exercises. They cannot therefore be completed in a few minutes. A proper psychiatric assessment cannot be encompassed within the frame of a typical paediatric consultation. With good interviewing skills, a full diagnostic interview can usually be completed in an hour and sometimes much less, but when substantial comorbidity is present considerably longer than this may be needed. Allowance also needs to be made for the poor attention spans of many disturbed children (and many of their parents), and it is better to allow breaks during the interview than to plough ahead in the face of waning attention. As elsewhere in medicine, the failure to take a good history, and conduct an adequate examination, leads to diagnostic and treatment mistakes. Indeed, in psychiatry, which relies much less on laboratory studies than many other branches of medicine, it is even more critical to spend the necessary time and effort to learn how to interview proficiently, and then to apply this learning to every patient.

Family interviews

So far, this chapter has considered interviews mostly from the perspective of gathering reported 'facts' from multiple informants, using more or less structured approaches. However, in clinical practice it is important to be aware that information of a different sort can be obtained from interviews involving more than one family member. Given the difficulty of getting whole families to turn up for clinical assessments, such interviews will often involve only one parent and the child, but that is still a very useful combination. Here the focus is on observing how family members interact with one another, and the ways in which symptoms are manifested in such interactions. As a starting point, the clinician needs to provide a structure within which interactions can be observed, and the information collected in separate interviews with the parent and child is helpful here, because it will have indicated the key issues that have resulted in a clinic appointment. The fact that the parent and child often have not reported the same things provides one starting point. One can simply ask each informant why the other mentioned something that they did not (in the clinical setting one rarely guarantees confidentiality among family members). The aim here is not specifically to 'reconcile' reports (though that may be a useful by-product), but to observe how the family deals with the conflict implicit in the question. A well-known pattern often seen in families with children with behavioural problems is for disagreements to escalate into angry coercive exchanges (Patterson 1981). Such patterns are susceptible to amelioration by family behavioural techniques (Patterson & Reid 1973; Patterson *et al.* 1981). It will often be the case that information collected in

family interviews will have an important place in the design of the eventual treatment plan, regardless of the diagnosis.

If both parents are present, it is also important to keep an eye on the interactions between the parents (and each parent's apparent mental state), because the child's problems are often associated with parental and interparental problems, which may themselves merit specific treatment. Similarly, when the patient's siblings are also present, it is helpful to compare their behaviour with the referred child's. The ostensible patient may not be the only one with problems (or even the greatest problems).

More structured tasks that the mother and child or whole family are required to work together on can also be very revealing; for instance, in identifying the withdrawal, negativity and hostility often displayed by depressed parents towards their children (Zahn-Waxler *et al.* 1990). For research purposes, a huge variety of observational coding schemes is available but, in the clinical setting, straightforward observations of the characteristics of interactions still have an important place in the overall diagnostic assessment.

An interview with the family also provides a rather different sort of setting for the child than the highly formalized one-on-one diagnostic interview with the clinician. It is important to observe whether the child behaves differently in these two settings, and any others that may be encountered in the clinic; such as interactions during psychological testing. Sometimes a child whose behaviour was well under control in the one-on-one structured interview or testing setting manifests far more disturbed behaviour with the family. If it turns out that a similar pattern is manifested at school, then interventions aimed at providing more structured interactions at home and at school may be warranted. Different phases of the assessment process are often conducted by different individuals, and here again it is important to evaluate the degree of consistency of behaviour with different individuals across situations. If there is considerable variation across settings and individuals it is important to try to identify the characteristics of those settings and individuals that are associated with problematic as opposed to adaptive behaviour.

Cultural and subcultural variations in behaviour

Any assessment of type and severity of psychopathology, no matter how structured or unstructured, relies upon explicit or implicit suppositions about the limits of 'normality' and the borders of pathology. As the vast majority of empirical research on psychopathology has been conducted in the USA and Western Europe, most of the constructs familiar to clinicians dealing with child and adolescent psychopathology have been derived from clinical experience with children from those areas. Although there has been rather little cross-cultural research on psychopathology, there are indications that there are national differences in patterns of presentation. For instance, Thai parents report lower levels of conduct problems in their children

than do Western European or American parents. Thus, a given level of conduct disturbance may be more deviant (compared with the rest of the population) in a Thai child than a Dutch child. In such a circumstance it is easy to imagine that a Thai parent, aware that the child was highly deviant within his or her culture, could seem to be making a fuss over nothing as far as a Dutch psychiatrist used to Dutch norms was concerned. A second example concerns sleep patterns. Nearly all of the literature on sleep and its disorders concerns sleep patterns typical in the industrialized West, but there are many populations where sleeping continuously for 8 h at a fixed time each day would be regarded as being highly abnormal (Worthman & Melby, *in press*). Indeed we have only to consider what 'good British parents' thought of as a proper bedtime for a 2-year-old in the 1950s and the typical practice of parents today, to realize that 'good parenting' is a moving target, not a fixed pattern of practice.

Even within cultures there are subgroup differences in what is regarded as being appropriate parental behaviour. For instance, in the areas of the rural southeastern USA where much of my research is conducted, many well-adjusted parents of well-adjusted children, heeding the biblical injunction not to 'spare the rod and spoil the child' are willing to take a belt to their child for serious infractions of discipline. My experience is that few British social workers would be comfortable with such behaviour. However, such disciplinary practices were pretty much universal in the West until the second half of the twentieth century, and it is by no means apparent that reductions in the use of physical discipline in many quarters have led to reductions in child psychiatric morbidity. The point here is not to encourage the use of corporal punishment, but to emphasize that as clinicians and researchers we need to remain aware that the boundaries of individual and family pathology are to some extent culturally determined, and that we should not make the mistake of labelling all differences from today's middle-class, Caucasian, industrialized Western norms of behaviour as 'pathology'. By that standard, most of our own great grandparents bordered on being child abusers.

Future directions

It is my opinion that structured psychiatric interviews for parents and children aged 9 and above are now probably as good as they can be. Many years of work have gone into producing the interviews we have today, and there is little evidence that recent enormous efforts to further 'improve' such measures have had much effect on their reliability, although they have succeeded in making some interviews much longer than they used to be. As we learn more about psychopathology we need to modify our measures' content to reflect what we need to measure, but the basic principles used to design new or revised modules will remain the same (and will work just as well or poorly as they do now). What is needed is to extend the range of structured assessments down to younger ages. There is startlingly little research

on preschool psychopathology, for instance, and it was only in 2000 that the first structured parent report diagnostic interview specifically designed for use with this age group became available. A good deal of work still needs to be carried out to determine what forms of information from the child and caretakers other than parents can usefully be integrated into diagnostic assessments.

Now that a range of very extensive diagnostic measures is available, it is time to move them out of the research field and into ordinary clinical practice. It seems odd that the unstructured clinical interview has been almost entirely supplanted for research purposes because of its well-documented inadequacies as a data-gathering and diagnostic procedure, but continues to be the main assessment tool in clinical practice, where good phenomenological assessment is of the greatest importance. All clinicians dealing with psychopathology can benefit from training on an interviewer-based structured interview (particularly one of the glossary-based interviews), and it is to be hoped that such training will soon become part of all training programmes for clinicians who deal with child psychopathology (as it is already in some). However, it must be admitted that the time to conduct a full psychiatric assessment is not always available, and when that is the case it would be helpful to have shorter interviews available to serve as screening tools. At the time of writing, work is happily beginning on a version of the DISC to fulfil this function. The idea here is not to encourage slavish dependence on any particular structured interview or other assessment technique, but to use the strengths of standardized interviews to underpin further explorations of the nature and meaning of psychopathology by clinicians with a solid understanding of the principles of good interviewing and the phenomenological approach to psychiatric diagnosis. Methodologically, we have come a long way in the last 30 years, and it is time to bring the benefits of methods first derived for research purposes to all of our patients and clients.

Case Identification in an Epidemiological Context

Eric Fombonne

Introduction

This chapter addresses the issues raised by the assessment of psychopathology within a broader, epidemiological context. The principles underlying the clinical assessment of children in a clinical context are addressed in a preceding chapter (Rutter & Taylor, Chapter 2). The focus here is on the use of assessment methods within studies requiring the investigation of large samples of children seen in their natural home and school environments.

Some achievements of 40 years of epidemiological research in child psychiatry are reviewed briefly. Attention is paid to the design of surveys and to prevalence findings on global psychiatric morbidity (findings on specific disorders are discussed in other chapters). In the second section, key concerns are addressed regarding: the definition and assessment of child psychopathology in relation to the differentiation between normal and abnormal development; the use of dimensional or categorical approaches to case definition; the need to use impairment measures and to combine data from multiple informants; the need to take into account the high rates of comorbidity between disorders; and the implications of pervasiveness or situational specificity of behaviours in estimating rates and risk associations for psychiatric disorders. The third section addresses more specialized issues pertaining to psychometric theory and the measurement of performances of instruments; the assessment of special groups, such as young children or those from different cultural backgrounds; the use of computerized assessments and the development of clinical databases useful for clinical epidemiology.

Epidemiological investigations of child psychopathology

Conceptual/methodological issues

Child psychiatric epidemiology started in the mid-1960s with the British Isle of Wight surveys (Rutter *et al.* 1970, 1976). Prior to this landmark study, there had been few investigations of rates of psychopathology in general population samples. The survey by Lapouse & Monk (1958) is a notable exception. It emphasized the high prevalence of fears and worries and the discrepancies in rates of problems according to the informant. Most knowledge at the time relied on observations drawn from

clinical case series. Behaviours were interpreted and theoretical inferences were made without having a proper calibration system allowing a focus on those behaviours that discriminated best between children seen in clinics and non-referred children. Epidemiology, with its focus on general population samples and on comparisons between individuals with or without disorders, provided an obvious tool for the empirical investigation of child psychopathology.

The Isle of Wight surveys had key design characteristics that provided a model for surveys in the years after (Rutter 1989). A two-phase design was used with a systematic questionnaire screening of a large sample, followed by in-depth assessments administered in a subsample selected according to their positive and negative results at screening. Multiple informants were used at both phases, involving parents, teachers and children. The value of asking children direct questions was established and interviews subsequently replaced the old indirect techniques (projective tests and free play) as investigation tools. Questionnaires and diagnostic interviews of known reliability and validity were employed to gather data. Caseness was defined according to both a recognizable behavioural pattern and evidence of impairment in the child's functioning. The surveys also adopted longitudinal approaches to measure prospectively risk factors and chart the natural history of disorders, and behavioural measures were related to neurological and educational risk factors. These methodological advances have been developed further in the series of surveys conducted since.

The planning of epidemiological studies requires precise methods to ascertain 'cases' of the disorder under study (Verhulst & Koot 1995). This implies two related activities. First, a definition of 'caseness' must be adopted at the outset. Its nature should be shaped by the goals of the survey. A survey of autism to identify representative cases for inclusion in genetic studies will require detailed phenotypic assessments, precise diagnostic subtyping and exclusion of autistic syndromes associated with known medical disorders. If, on the other hand, the goal of the study is to generate estimates of special educational needs for service planning, then a less detailed and broader approach to 'caseness' such as the 'triad of impairments' (Wing & Gould 1979) may be sufficient. Following the adoption of the most appropriate concept of the disorder, decisions must be made about the choice of various assessment procedures and instruments. Guidelines to select instruments are provided in Appendix 1.

Secondly, once a case definition has been established, case

identification methods are selected. This involves sampling techniques that aim to provide a sample that will allow inferences about rates and correlates of disorders in the target population. Adequate sampling techniques are mandatory in order to provide unbiased estimates of the rates and the risk factors associated with disorders. The drawing of a sample requires the availability of a sampling frame and of sampling units covering the population of interest (Boyle 1995). In child psychiatry, surveys have often relied upon school rosters (Fombonne 1994) because, with compulsory education, they provide comprehensive sampling frames. Alternatively, households may be used as sampling units (Bird *et al.* 1988; Meltzer *et al.* 2000). These will still miss a small proportion of children, such as homeless or street children (Bird *et al.* 1988) or children from families who migrate seasonally for employment reasons. Children in long-term residential facilities may also be overlooked. The extent to which these sampling limitations will bias findings will depend on the strength of the association between a psychiatric disorder and these psychosocial circumstances.

Sampling techniques vary from simple random sampling to more complex stratified or cluster sampling strategies that aim to increase the precision of estimates, while optimizing survey resources and reducing costs. In selecting children for inclusion in the study sample, it is crucial to note the probability for each child to be selected, so that subsequently these probabilities can be used to weight the figures (usually with weights that are the inverse of the sampling fraction) for extrapolation to the target population. This allows oversampling of some subgroups without distortion of the final estimates provided that proper weights are devised and applied. The analysis of two-phase or more complex survey designs is discussed by Pickles (1998) and by Dunn *et al.* (1999).

Methods for dealing with missing data are crucial and have been addressed more efficiently in recent surveys. Survey participation rates have generally been high, often well over 80%. Bias in the estimates of prevalence and risk associations might result, nevertheless, if those who do not participate have higher rates of disorders, more severe disorders or disorders arising through different mechanisms. Empirical findings indicate that it should be expected that non-respondents will differ systematically from respondents (Cox *et al.* 1977). Fombonne (1994), in a French survey, found that behavioural disturbance was some 60% higher among non-participants than participants, but it was possible to correct for this bias in the final prevalence estimation. Similarly, attrition bias in longitudinal studies may attenuate predictions regarding the persistence of disorders over time (Boyle *et al.* 1991). However, it will be possible to correct for non-respondents' levels of psychopathology, when there are data on them either from records or from earlier points of data collection.

Missing data can also occur at the item level with respondents omitting items on a checklist or failing to answer all questions in an interview. This may jeopardize data collection (if incomplete screens are deemed ineligible for further interview) or analysis (if incomplete interviews are not dealt with separately). Sophis-

ticated statistical techniques are available to take account of missing data according to the reasons that they are missing (Kalton 1983; Little & Rubin 1987).

Findings from cross-sectional epidemiological surveys

Epidemiological surveys to assess prevalence usually rely on cross-sectional methods. Numerous prevalence surveys have now been conducted across the world (Brandenburg *et al.* 1990; Canino *et al.* 1995; Verhulst & Koot 1995; Bird 1996; Roberts *et al.* 1998). Table 4.1 presents the main results of some selected recent surveys. The rates for specific disorders are discussed in the chapters dealing with them. Some key findings from longitudinal investigations are noted in Rutter, Chapter 28; Rutter, Chapter 19; and Taylor & Rutter (Chapter 1).

The rates of disorder in Table 4.1 results underscore the most important finding, that psychopathology in young people is common, most studies estimating the prevalence to be between 10 and 20%. Verhulst & Koot (1995) reviewed 49 surveys and computed an average rate of 12.9%. Emotional disturbances and disorders of disruptive behaviour are equally common (with rates of 6–8%; see Table 4.1). It should be noted that many of these surveys will not have included neurodevelopmental disorders, such as autism, and may not have picked up psychotic disorders with an onset in late adolescence.

Community samples have also shown that only a small proportion (typically between 10 and 30%) of children with disorders have had contact with specialist mental health services. Thus, in the recent British nationwide survey of 10 000 5–15-year-olds (Meltzer *et al.* 2000), 27% of children with a psychiatric disorder had been in contact with specialist health care services and 30% had had no contact with any sort of professional. Similar figures have been reported in other studies (Offord *et al.* 1987; Costello & Janiszewski 1990; Zahner *et al.* 1992; Leaf *et al.* 1996). Disorders involving disruptive behaviour (Verhulst & Koot 1992; Meltzer *et al.* 2000), and those that are severe or of long duration (Whitaker *et al.* 1990), are more likely to be referred. However, contextual factors (such as parental psychopathology) and family features also influence referral (Jensen *et al.* 1990). The findings indicate the need for caution in extrapolating from clinical samples or experience. Children seen in clinics often differ in systematic ways from non-referred children with comparable levels of psychopathology. Epidemiological findings are needed for the development of psychopathological models.

Issues in case definition

Normality and disorder

All epidemiological surveys have shown the high frequency of individual items of emotional or behavioural difficulties (Rutter *et al.* 1970; Shepherd *et al.* 1971; Achenbach & Edelbrock

Table 4.1 Prevalence findings from recent epidemiological surveys.

C, based on child as informant; P, based on parent as informant.

1981). However, whereas some have a strong association with psychiatric disorders, others do not. Thus, in the Isle of Wight survey, thumb-sucking, nail-biting and bilious attacks all had very weak associations with psychiatric disorders (Rutter *et al.* 1970). Similarly, item scores for *asthma* and *allergy* have been removed from the computation of the total score of the Child Behaviour Checklist after consistent evidence that these were not associated with psychiatric referral. By contrast, the symptom of *depressed mood* has been shown to account for much of the variance in comparisons of matched samples of non-referred and referred children (Achenbach & Edelbrock 1981; Fombonne 1992).

However, continuities and discontinuities between individual symptoms and disorders may involve crucial transitions. Thus, depressed mood is experienced by about a third of adolescents in the general population (Petersen *et al.* 1993) but the rate of depressive disorder is only about 5% (see Harrington, Chapter 29). Similarly, some half of female adolescents diet but anorexia nervosa occurs in less than 1% (Fombonne 1995; see also Steinhausen, Chapter 34). The situation with substance use and abuse (see Rutter, Chapter 28; Weinberg *et al.*, Chapter 27) and with disruptive behaviour (see Earls & Mezzacappa, Chapter 26) is directly comparable. Many problem behaviours have a continuous distribution in the population and quantitative, rather than qualitative, deviance often defines psychopathology.

Categories and dimensions

Because of this, most epidemiological studies use a mixture of dimensional and categorical approaches. The former are needed both to assess symptom severity and to allow the adoption of different cut-offs for different purposes. The latter is required for clinical decision-making with respect to individual diagnosis and service planning (see Taylor & Rutter, Chapter 1). The issues are not specific to psychopathology; rather, they apply throughout most of medicine (as exemplified by asthma, hypertension, anaemia, diabetes and occlusive coronary artery disease—all of which have dimensional parallels). It is sometimes assumed that dimensional measures are synonymous with questionnaires and categorical ones with interview assessments, but that is not so. All standardized interviews (see Angold, Chapter 3) provide for various forms of quantification of severity or numbers of symptoms. Conversely, most questionnaires (see Verhulst & Van der Ende, Chapter 5) provide the means for deriving categories from dimensional scores.

The most appropriate choice of measure constitutes a crucial step in any epidemiological study (Table 4.2). Choice should be driven by the main purposes of the study. Questionnaires have all the advantages of economy and simplicity and may be the first preference if the goal involves only group differences and trends. They will almost always be used in the first screening phase of multistage studies. However, they are less suitable for individual diagnosis or for the assessment of uncommon disorders involving qualitative departures from normality. Standardized interviews have the opposite set of strengths and

weaknesses. The chief decision issue with interviews is whether to use an investigator-based interview that obtains descriptions of behaviour that are rated using a standardized research-driven concept or a respondent-based approach that obtains yes/no answers to carefully structured questions. As Angold (Chapter 3) discusses, each has its own merits and researchers will need to consider carefully which is most likely to meet the needs for the particular investigation to be undertaken. A further decision is needed on whether to choose a broad-based measure designed to tap all the common varieties of psychopathology or rather to use one or more focused instruments. The former will meet most needs but is less suitable for uncommon or unusual disorders, such as autism, schizophrenia or Tourette syndrome. Whatever the particular choice of instrument, investigators will usually need to test their chosen set of measures and data collection procedures in pilot studies of adequately sized samples to determine the procedural feasibility and its acceptability by respondents. Pilot studies should be analysed carefully using quantitative methods whenever appropriate.

Impairment

The importance of including impaired functioning in case definition was well shown in Bird *et al.*'s (1988) general population epidemiological study. The prevalence of psychiatric disorder was 50% if assessed on the basis of symptoms alone, without taking account of impairment, but 18% if the latter was required for case definition (Bird *et al.* 1988). Similar results have been found in other studies (Bird *et al.* 1996; Simonoff *et al.* 1997).

The need to assess functional impairment is now generally accepted, but it has proved more difficult to define and measure it in a valid fashion. Impairment is related to concepts of role performance that reflect the individual's adaptation into his social environment (Bird 1999). This must be related to developmental level and sociocultural context. Typically, impairment resulting from psychopathology is assessed in four domains: interpersonal relationships; academic/work performance; social and leisure activities; and ability to enjoy and obtain satisfaction from life. These need to be evaluated with respect to functioning at home, school and in the community.

In earlier epidemiological surveys (Rutter *et al.* 1970), and in most classification schemes (World Health Organization 1992; American Psychiatric Association 1994), the assessment of impairment was largely left to a global clinical judgement by the interviewer. In the early 1980s, instruments were developed to address this issue with the development of the Children's Global Assessment Scale (Shaffer *et al.* 1983). This instrument was shown to have adequate psychometric properties but it still relied on an experienced clinician, and did not specify how impairment data should be obtained. Further developments of this scale led to a simplified non-clinician version (Bird *et al.* 1996; Bird 1999). Another instrument, the Columbia Impairment Scale (CIS; Bird *et al.* 1993), was devised to be completed by both parent and adolescent respondents; it has the advantage of

being brief and providing scores for specific domains. Preliminary data suggest that it is a useful measure with the parent CIS having consistently better validity than the children's version. Other instruments, such as the Social Adjustment Inventory for Children and Adolescents (John *et al.* 1987) and the Child and Adolescent Functional Assessment Scale, were reviewed by Bird (1999).

The issues to be addressed still include: (i) the differentiation between impairment and psychiatric symptoms (for example, aggression to peers is both a symptom of conduct disorder and a reflection of impaired functioning with respect of peer relationships); (ii) how to determine causal connections between symptoms and impairment (preliminary findings suggest that informants found this difficult (Bird 1999) and interrater agreement was low (Sanford *et al.* 1992)); and (iii) the difference between impairment and symptom severity. Pickles *et al.* (2001) found that depressive symptoms predicted later depression equally well with and without the presence of impairment; by contrast, the predictive power of conduct symptoms was increased in the presence of impairment. Angold *et al.* (1999a) found, in a community study, that over a fifth of children showed impairment even though their number of symptoms fell below specified cut-offs for diagnosis. These impaired children with subthreshold disorders were likely later to be referred to services. Conversely, disorders without impairment tended to have a good outcome (Costello *et al.* 1999). The findings from the Ontario study tell much the same story (Sanford *et al.* 1992).

Diagnostic interviews now include separate measures of impairment associated with disorders and symptoms (Angold & Costello 2000; Shaffer *et al.* 2000; see also Angold, Chapter 3). However, research is still needed on the origins of impairment; it cannot be presupposed that they will necessarily be the same as for symptoms.

Age of onset

Age of onset is a definitional feature of several disorders. Enuresis cannot be diagnosed before the age of 5, attention deficit hyperactivity disorder (ADHD) symptoms must exist before age 7 and Asperger syndrome is differentiated from high-functioning autism by the absence of a significant language delay by the age of 3. Age of onset is usually assessed retrospectively. However, the interrater and retest reliabilities of age of onset have been found to be poor outside the last 3 months for disorders with a recent onset and outside 1 year for those with a longer duration (Angold *et al.* 1996). Imperfect measurement of onset and offset of disorder can therefore influence prevalence estimates which are contingent upon specific time periods.

Age of onset also indexes differential outcomes. Moffitt (1993) found that conduct disorders with an adolescent onset differed from early-onset conduct problems, with the latter more likely to be associated with neuropsychological impairments and with a worse long-term outlook. Similarly, adolescent-onset depression is associated with a particularly strong

risk of recurrence in adult life (Weissman *et al.* 1999a; Fombonne *et al.*, 2001) whereas the course and correlates of depression beginning before puberty is rather different (Harrington *et al.* 1997; Rende *et al.* 1997; Weissman *et al.* 1999b). The timing of onset is also crucial in order to explore the direction of causal effects in patterns of comorbidity (see Rutter, Chapter 28). The demonstration that ADHD is a risk factor for later conduct disorder, but that the reverse does not apply (Taylor *et al.* 1996; Taylor 1999), and that dysthymic disorder is a gateway to major depressive disorders (Kovacs *et al.* 1994), provide examples of this issue. Retrospective assessment of age of onset is also an issue in adult studies (Kessler *et al.* 1999), particularly as accurate assessment of this variable can influence results from familial studies (Schurhoff *et al.* 2000) and from studies of secular trends (Simon & Von Korff 1992). One way to avoid the problem of unreliability in the timing of onsets is to use lifetime prevalence estimates (Lewinsohn *et al.* 1993). These have the advantage of avoiding the problem of unreliability in the timing of onset and are probably the best approach for disorders present at the time of assessment. Doubts arise over the reliability and validity of reports of past disorders that are no longer present. Such doubts probably apply less to disorders in childhood than in adult life because time spans are shorter and because multiple instruments are available.

Comorbidity

The high frequency of co-occurrence of two supposedly separate forms of psychopathology was noted in the Isle of Wight studies over 30 years ago (Rutter *et al.* 1970). However, it is only in the last 15 years that it has received much conceptual attention and empirical study (Achenbach 1991a; Caron & Rutter 1991; Hinshaw *et al.* 1993; Nottelman & Jensen 1995; Rutter 1997; Angold *et al.* 1999b;). In their thorough review of the topic, Angold *et al.* (1999b) concluded that artefacts cannot account entirely for the frequency and patterns of comorbidity, and that mechanisms underlying comorbid presentations should be studied more systematically, preferably with epidemiological samples. The classification issues associated with comorbidity are discussed by Taylor & Rutter (Chapter 1) and the use of longitudinal data to study causal mechanisms is discussed by Rutter (Chapter 28) in relation to depression and substance abuse. Several research findings show how comorbidity may carry meaning. For example, the results of a family study of depression changed once comorbidity in the probands was properly taken into account (Merikangas *et al.* 1998) and a trend emerged for a positive drug response to tricyclic antidepressants in non-comorbid depressed subjects when results from a clinical trial were stratified according to the presence or absence of comorbid conduct disorder (Hughes *et al.* 1990).

However, in order to undertake research using comorbidity it is necessary that the epidemiological studies methods of measurement are adequate for dealing with the assessment of psychopathology that involves comorbid patterns.

Situation and multiple informant specificity

From the Isle of Wight studies onwards, it has been evident that the agreement on childhood psychopathology between different informants is typically low, and is only moderate at best. Thus, in an epidemiological survey of 6–11-year-olds, only a quarter of children scoring above the cut-off on at least one screening measure were scoring above threshold on both parent and teacher questionnaires (Fombonne 1994). In a meta-analysis of 119 studies, Achenbach *et al.* (1987) found that the agreement was best (≈ 0.60) when the pairs of informants had similar roles in relation to the child (such as with mother–father or teacher–teacher) whereas the mean correlation fell to the 0.20s for other types of pairs (such as parent–child or parent–teacher).

There are many possible reasons for this low agreement between informants. These include: random error in measurement; different perceptions of behaviour according to the perspective of the observer; different frames of reference; and variations in the child's behaviour according to both setting and interpersonal features. The relative importance of these different possibilities is not known. However, it is clear that multiple informants are essential for any adequate epidemiological study. That is partly because each informant contributes uniquely to the measurement of psychopathology, as well as contributing to shared variance; because when studying the correlates of disorder it is necessary to go across informants, or use composite ratings, in order to avoid halo effect artefacts; and because of the importance of differentiating between situation-specific and pervasive disorders (Schachar *et al.* 1981).

That leaves open the crucially important, but largely unresolved question of how to combine the data from different informants and from different settings. Although there is some evidence that different informants have different strengths, only rarely will it be desirable to adopt a hierarchical approach in which the report of one informant is automatically given precedence over those of others. Nevertheless, child self-reports are particularly important for the assessment of mood disturbances (see Harrington, Chapter 29). Conversely, they are of very limited use for the assessment of hyperactivity (see Angold, Chapter 3; Schachar & Tannock, Chapter 25). On the whole, teachers are better at the assessment of disruptive behaviour than they are of depressed mood. As the findings from Verhulst *et al.* (1997) show dramatically (see Table 4.1), prevalence findings are often hugely affected by how multiple ratings are dealt with.

Clinical interviewers usually use their 'best' judgement in order to weigh the symptoms endorsed by each informant, resolving discrepancies by personal rules derived from a combination of experience and theoretical predictions. This is likely to result in different clinicians combining data in different ways.

Another approach is trying to seek to resolve discrepancies between informants through a conjoint interview involving different informants (such as parent and child). This might be helpful in eliminating some errors brought about by mis-

comprehension and 'reconciling' the informants (Angold *et al.* 1999b). However, the method is far from free of problems, most especially in giving rise to delicate situations that threaten to breach confidentiality. Nevertheless, this judgement method is recommended for the use of some diagnostic interviews, such as the Kiddie Schedule for Affective Disorders and Schizophrenia (K-SADS; Ambrosini 2000), in order to allow the generation of a single unique score for each symptom rating.

A third commonly used approach uses computer generation of diagnoses based on predefined algorithms. The method has the advantage of accuracy and speed. However, the algorithms must deal with differences in reporting by informants according to specified rules. Usually, a symptom is counted as positive when it is reported by at least one informant: the so-called 'or' rule (Bird *et al.* 1992). This technique typically leads to high numbers of generated diagnoses.

For dimensional assessments, Achenbach (1991b) has revised the data collected through his set of questionnaires in order to solve this cross-informant problem. Based on systematic analyses of the Child Behaviour Checklist (CBCL), the Teacher Report Form (TRF) and the Youth Self Report (YSR), he identified common syndromes on each of these questionnaires, and core syndromes that appeared consistent across sex and age subgroups. He then selected a set of cross-informant core syndromes that spanned at least two instruments. These were subsequently scaled with the relevant normative sample. This approach does not resolve the problem of how to combine data from discrepant informants but it helps in increasing the interpretability of a profile of scores for a given child (Achenbach 1991b, 1995). More sophisticated statistical techniques are available to researchers to deal with the measurement problems associated with multiple data sources and discrepancies between informants (see below).

Measurement

At the core of medicine, and of any scientific enquiry, is measurement theory (see also Sergeant & Taylor, Chapter 6). In essence, this specifies the relationship between a conceptual construct and empirical measures. With respect to psychopathology, the construct cannot be directly observed, as through a pathognomonic test. There is a good deal of evidence for some of the key psychiatric diagnostic concepts, such as autism or schizophrenia (see Taylor & Rutter, Chapter 1). Nevertheless, there has to be an empirical means of going from observables (whether those be signs or symptoms), to the postulated diagnostic entity. Child psychiatry research has progressed tremendously in that direction over the last two decades. Far from being a question mattering uniquely to researchers, the same measurement considerations and needs apply to everyday clinical practice. In that sense, the choice is not between measuring or not (or between research and clinical practice), but rather between measuring with known and replicable procedures or not.

Concepts of validity and reliability

Two major properties, validity and reliability, are examined in the evaluation of assessment procedures (instruments or simple clinical judgement) for which Fig. 4.1 provides a convenient representation. Data collected as part of clinical or research assessments can be seen as empirical indicators of the underlying (unobserved) constructs of interest.

Reliability is the tendency of measures to yield consistent results over repeated trials. Reliability concerns the replicability of measures and the extent to which each measurement is affected by random error. Reliability can therefore be examined empirically (see bottom level on Fig. 4.1). Typical procedures to estimate reliability are the test–retest paradigm, interrater agreement, and techniques based on correlations between subsets of instruments (split-half reliability) or among items composing a questionnaire (internal consistency). The reliability of the measurement is assessed within each procedure by specific statistics, such as the kappa coefficient for categorical measurements (Spitzer & Fleiss 1974), the intraclass correlation coefficient for quantitative scores (Bartko 1976) and other statistics (e.g. Cronbach's (1951) alpha coefficient). Reliability is a necessary condition, but not a sufficient one, for validity. If empirical indicators are unduly contaminated by random error (so that measurements cannot be replicated), then the question of their relationship to the constructs that they are purported to tap cannot be assessed meaningfully. On the other hand, high replicability does not necessarily mean good validity.

Validity concerns the crucially important relationship between the empirical observables and the postulated latent construct (in this case diagnosis) as represented by the connections between the bottom and top levels on Fig. 4.1. Several types of validity have been described. *Content* validity is concerned with the extent to which an instrument is representative of the universe of indices that are related to the concept measured. It is usually assessed by reliance on experts or on agreement with established instruments tapping the same concept. *Criterion-related* validity is the most empirical form of validity. It allows

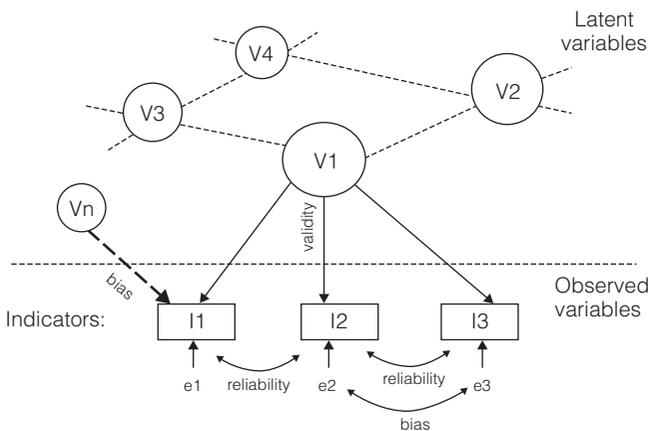

Fig. 4.1 Measurement model.

an index to be compared to an independent external criterion thought to assess the same concept. This can be either *concurrent* or *predictive*.

Construct validity is the most elusive and theoretical type of validity. It concerns the extent to which individual items or measures intercorrelate or group together to produce derived higher order constructs. Factor analysis has often been used for this purpose in the field of psychopathology. Thus, numerous factor analyses of questionnaires have consistently identified separate dimensions (or constructs) of psychopathology (such as attention problems, conduct symptoms or emotional disturbances). These tend to map onto a broad bipartite division into internalizing/emotional problems and externalizing/disruptive behaviours (Achenbach & Edelbrock 1978; Elander & Rutter 1995). Consistency of these factor analyses results has been taken as evidence of the construct validity of these psychopathology dimensions.

Diagnostic reliability

Since the first collaborative efforts sponsored by the World Health Organization to improve diagnosis in psychiatry, reliability studies have been undertaken to examine interrater agreement and to improve the definition, and thereby the diagnostic reproductibility of disorders (Rutter *et al.* 1969, 1975). In the late 1970s, with the development of research diagnostic criteria (Spitzer *et al.* 1978) and of standardized diagnostic interviews, emphasis was placed on the development of operational diagnostic criteria. This was embodied in the DSM-III (American Psychiatric Association 1980) and its successors and in the clinical and research versions of ICD-10 (World Health Organization 1992, 1993). Studies of the reliability of child psychiatric diagnoses have been conducted with various schemes and instruments, giving rise to broadly similar overall conclusions (Rutter *et al.* 1988; Shaffer *et al.* 1999).

The concept of reliability involves three rather different potential sources of error or variability: *information* variance (features to do with how data are collected); *interpretation* variance (how data are weighted and put together); and *criterion* variance (how algorithms are used to produce diagnoses). These need to be assessed in different ways. The first may be examined through test–retest studies to examine the extent to which the same answers are obtained on two consecutive occasions. On the whole, the findings have been of moderate to good reliability that is higher for symptom dimensions than for categorical diagnoses (Shaffer *et al.* 1999). It is affected, however, by the tendency for informants to report less psychopathology on the second occasion (Piacentini *et al.* 1999; Shaffer *et al.* 1999). This is more pronounced with highly structured interviews but can be reduced somewhat by attention to details of wording of questions and interview organization (Lucas *et al.* 1999).

Interpretation variance can be assessed by determining the extent to which two informants agree (see above), or two investigators agree on their ratings of behavioural descriptions (Strober *et al.* 1981; Werry *et al.* 1983; Gould *et al.* 1988; Pren-

dergast *et al.* 1988), or two different diagnostic instruments give the same answer. Typically, this form of variance is greater—particularly across informants and across instruments.

Criterion variance needs to be evaluated by comparing different ways of putting the data together. Standardization aims to keep this to a minimum but it is clear that different systems often give different answers (see, for example, the findings with respect to age of onset in ADHD (Applegate *et al.* 1997), number of symptoms in antisocial diagnoses (Lahey *et al.* 1994) or diagnostic algorithms in autism (Volkmar *et al.* 1994)).

Diagnostic validity

Diagnostic validity concerns the extent to which a diagnostic construct truly reflects a syndrome that is different from others. The testing of validity therefore requires research that examines correlates of diagnosis with respect to basic features that are external to the behaviours that define the hypothesized diagnostic construct (Rutter 1978). Such correlates might include genetic influences, neuropathology, biological indices, course and response to specific treatments. The evidence on such validity is discussed by Taylor & Rutter (Chapter 1).

From a measurement perspective, validity concerns the extent to which empirical measures tap the crucial features that provide the basis of the diagnostic construct: the vertical connections between the top level (the latent construct) and the bottom level (empirical measures) in Fig. 4.1. The main measurement issue concerns the possible operation of biases in those vertical connections (expressed as V_n in Fig. 4.1).

The main, possibly biasing factor considered up to now has been the mental state of the informant. Thus, there has been concern that a depressed mother might over-report psychopathology in her child (Brewin *et al.* 1993). To test that possibility it is necessary to determine whether maternal depression alters the pattern of associations between maternal reports of child psychopathology and teacher or child reports (Chilcoat & Breslau 1997). The key statistic here relates to pattern differences and not to correlations as such. Thus, with respect to maternal depression the issue is whether a difference in child psychopathology is found on maternal reports that is not evident on reports from others. If there is, a bias is suggested. The weight of evidence from a range of studies indicates that there is some biasing effect, although not a great one. Recently, attention has broadened to consider whether depression in one parent alters the rating of the *other* parent by virtue of its influence on the overall family context (Borge *et al.*, 2001). Preliminary findings suggest that possibly it may, although further research is needed to investigate the matter. A comparable rating bias concern was raised with respect to possible *contrast* effects in parental ratings of twins. Thus, it was hypothesized that parents, in their ratings, might exaggerate differences between dizygotic (non-identical) twins. Again, the test involves pattern effects in relation to the others. Such contrast effect biases have been found with respect to parental ratings of hyperactivity but, interestingly, not of other forms of disruptive behaviour (Simonoff *et al.* 1998).

Other examples of such possible rating biases concern the effects of a person's current social situation and mental state on their retrospective rating of negative childhood experiences (Maughan & Rutter 1997). Findings suggest that there is a slight tendency for people who are doing well to *under-report* past adversities but no tendency for people who are doing well to *over-report*. Obviously, to test this possibility, it is necessary to have longitudinal data involving contemporaneous measurement of the adverse experiences. Yet another example concerns the possibility that people with a mental disorder may over-report comparable disorders in relatives (Kendler *et al.* 1991; Rende & Weissman 1999). In all these examples the tests have involved some form of pattern difference that involves comparisons among different informants. Usually, the biases found have been small, but equally they have not been zero. The implication is that investigators need to use multiple informants and need to test for such possible biases, statistically correcting for them when required.

Latent variable models

Historically, researchers tended to deal with these measurement problems either by choosing what seemed to be the 'best' informant or alternatively by combining the ratings in some way (such as by adding them together or counting a report of a behaviour if it comes from just one of a number of informants). Such composite strategies have the advantage of simplicity and, for this reason, they continue to have a worthwhile place in research. However, they fail to make use of all the data, they do not deal quantitatively with possible biases, and they do not remove random measurement error. Latent variable models were developed to deal with these issues (see Fergusson 1995, 1997 for clear descriptions of the rationale and the assumptions involved). In brief, multivariate statistics are used to *infer* the latent construct (which can be either dimensional or categorical) that underlies the associations among a variety of behavioural measures. The focus is on the variance that is *shared* across measures—in effect putting to one side that which is unique to just one measure on the ground that, whatever its intrinsic importance, it is not measuring that which is common across measures. This 'special' element is not 'thrown away' but, rather, it can be isolated and examined in its own right.

Latent variable methods have another key feature: they take into account prior probabilities. For example, let us take a child in a longitudinal study who has three positive ratings, one negative, and then two more positive ones and compare him with a child who has six negative ratings. Intuition and common sense tells one that the fourth rating of the first child is much more likely to be a false negative than the fourth rating of the second child. In coming to that judgement, we use what we know about the findings at other data points. Latent variable methods do the same but in a quantitative mathematical fashion. Although certainly not a 'cure-all' for measurement problems, latent variable methods have very considerable strengths and are likely to be employed more in the future. The main 'health warnings'

regarding their use is that there should be caution if the shared variance among measures is very low (because the latent construct will tap so little of the individual differences in the psychopathology of interest; see Simonoff *et al.* 1998 for an example), and that there needs to be an awareness that modelling methods will sometimes discard features because their effects fall short of statistical significance, even though the evidence limits tell one that there might be a substantial true effect (see Rutter *et al.* 1999, 2001 for a discussion of the matter in relation to genetic modelling).

Applications of latent construct measures in child psychiatry include studies of the impact of maternal depression on ratings of child psychopathology (Boyle & Pickles 1997a,b), the cross-informant correlations of behavioural reports (Fergusson & Horwood 1987a,b), or the adult outcomes of antisocial behaviour (Zoccolillo *et al.* 1992).

Cut-offs, sensitivity and specificity

Dimensional measurements (whether by questionnaire or interview) lead to total scores ranging from a minimum (usually implying normality) to a maximum (mostly implying psychopathology). For both clinical and research reasons, investigators may want to transform these scores into categories (e.g. inferred normality vs. inferred disorder). Note that the category has to be inferred, rather than measured directly (unless of course there is a pathognomonic test, which there is not so far for any child psychiatric disorder). The measurement question concerns the probability that any given score on a measure means that the psychopathology warrants a ‘caseness’ designation—in other words, what score provides the best discrimination between cases and non-cases as assessed in some other way. All cut-offs, of course, result in some degree of misclassification. Figure 4.2 depicts a fairly common situation in which scores among normals (non-cases) are plotted next to those with a disorder (cases). Any cut-off will partition a sample into four groups, designated false and true positives and false and true negatives. Various indices can be used to summarize the data in this situation (see Appendix 1). A Receiving Operating Characteristics (ROC)

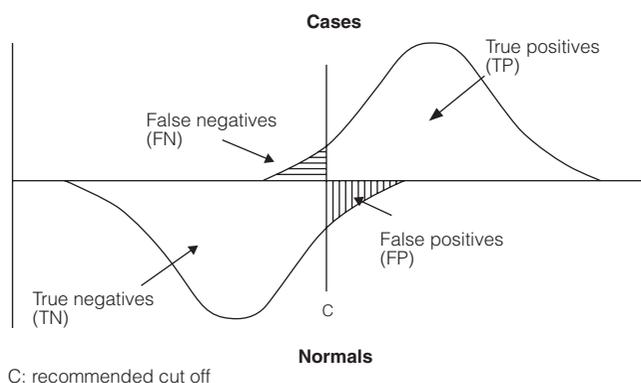

Fig. 4.2 Distribution of scores in normals and cases.

analysis provides a convenient way of assessing this trade off mathematically in order to select an optimal threshold (Fombonne 1991; see also Verhulst & Van der Ende, Chapter 5). It simply plots sensitivity on one axis of a graph and specificity on the other and uses the resulting curve to identify the best cut-point. However, it does more in that it takes into account the prevalence of the disorder, the severity of cases under detection, and the consequences of all types of misclassification errors (Hsiao *et al.* 1989; Fombonne 1991).

ROC analyses have been a huge help in decision-making with respect to using scores to infer categories. However, two points require emphasis. First, measurement error is the rule rather than the exception and its influence must always be recognized in any interpretation of data. Scores above a cut-off point that has been empirically set by ROC analyses do not mean that a disorder is definitely present. All they indicate is that, using the particular measures in question, the probability of a good differentiation between caseness and normality is optimal; but it is a probability and not a certainty. A mechanical use of instruments to provide diagnoses should be proscribed.

Secondly, the various properties of sensitivity, specificity, positive predictive value and so forth (see Appendix 2) are context-specific and *not* inherent qualities of the instrument. A cut-off that works well in a clinical context may not be at all satisfactory in a community survey. That is because probabilities are greatly influenced by population base rates for the disorder being measured. For example, Berument *et al.* (1999), in their analysis of the Autism Screening Questionnaire (ASQ) found that the score that best differentiated autism from other spectrum disorders was much higher than that which was best differentiating autism from uncomplicated mental retardation or developmental language disorders. Some instruments are much more valid than others and attention needs to be paid to their technical properties. Nevertheless, the measuring device has no absolute intrinsic validity. Rather, its validity will fluctuate according to the goals and context of the assessment.

Norms

Reference to normative data is implicit in the assessment of psychopathology. However, it was only in the late 1950s that systematic surveys of children’s behaviours and emotions were undertaken on large samples of non-referred children (Lapouse & Monk 1958, 1959). The epidemiological surveys of child psychiatric disorders that followed helped to promote knowledge of normative behaviour at different ages with the useful development of standardized questionnaires for use with multiple informants (Rutter *et al.* 1970; Achenbach & Edelbrock 1981; Verhulst & Koot 1995; see also Verhulst & Van der Ende, Chapter 5). Increasingly, data from large representative samples of non-referred children have been used to calibrate measures in order to provide the best identification of probably psychopathology. Verhulst & Van der Ende (Chapter 5) summarize both the research approaches and the findings for a range of measures. Much has been achieved, yet some care is needed in

using these norm-referenced assessments. Not all standardizations have used fully representative general population samples. There must be reservations about generalizability when convenience samples have been used.

Norms are derived from particular regional or national samples and the query is whether it is justifiable to extrapolate to other regions or countries. For example, a 10–15-point difference in mean CBCL total scores has been reported among American, Australian (Achenbach *et al.* 1990a), French (Stanger *et al.* 1994) and Puerto Rican children (Achenbach *et al.* 1990b). The question is whether these differences reflect true regional differences in psychopathology or rating tendencies that have been influenced by cultural contextual features. Both possibilities have to be considered seriously but their differentiating requires the use of external validators of some kind. The Isle of Wight–Inner London comparison indicated that a true difference in rate of psychopathology was likely (Rutter & Quinton 1977) whereas the UK–Hong Kong comparison with respect to hyperactivity suggested a rating difference effect (Leung *et al.* 1996). Investigators are well advised to be cautious about assumptions that one set of norms can be generalized to different populations.

Similar issues concern extrapolations from one large representative population to subgroups within. For example, are associations between social class and behavioural disturbance (Achenbach & Edelbrock 1981; Fombonne 1992) a true reflection of valid differences or a contextual rating bias effect? The same applies to age and gender differences. An automatic assumption that subgroup norms should be used or that any differences from total population norms are necessarily valid should be resisted. As ever, external validation is essential.

Norms apply to one particular point in time. Evidence has accumulated that there have been secular changes in the incidence of various psychosocial disorders (Rutter & Smith 1995; Fombonne 1998a,b) and of individual behavioural problems. Achenbach & Howell (1993) compared two large representative samples of American youth surveyed 13 years apart and found increased scores on 46 of 118 behavioural problems and on all scale scores (the mean total score increasing from 18 to 24.2) in the most recent birth cohorts. Periodic recalibration of instruments is necessary in child psychopathology just as it is for other measures, such as psychometric tests (Flynn 1987; Fuggle *et al.* 1992) or physical indices such height, weight, head circumference and pubertal maturation (Fredriks *et al.* 2000).

Assessment of young children

Epidemiological investigations of preschool samples have been surprisingly few (Earls 1980; Richman *et al.* 1982; Pianta & Castaldi 1989; Pianta & Caldwell 1990; Cohen & Bromet 1992; van den Oord *et al.* 1995; Lavigne *et al.* 1996). Nevertheless, studies have shown that psychiatric disorders starting in the preschool years show a high degree of persistence over time and that their course is systematically associated with identifiable risk and protective factors. For example, a difficult tempera-

ment in the child interacts with characteristics of family dysfunction to increase the risk of psychopathology 5 years later (Maziade *et al.* 1987); and a shy inhibited style of interaction predicts later onset of anxiety disorders in childhood (Kagan *et al.* 1998). Evidence has accumulated that developmental disorders usually identified in the early years have short (Stevenson *et al.* 1985) and long-term consequences (Mawhood *et al.* 2000) with respect to psychosocial disturbances and functioning. Long-term follow-up of birth cohorts have also shown continuities between preschool behaviour and adult psychopathology (Caspi *et al.* 1996). Thus, identification of preschool problems is important, especially because early intervention might be more effective in the case of some disorders (Rogers 1998).

However, there are particular challenges in the assessment of preschool-age children (Mayes 1999). Infants and toddlers present with disturbances that tend to be closely associated with somatic development. Thus, feeding and sleeping difficulties are common in this age group (see Stein & Barnes, Chapter 45). It is also an age when the effects of prenatal/perinatal risk factors may be particularly marked. As implied in Winnicott's (1965) remark that 'there is no such thing as a baby', infants' behaviour is closely intertwined with interactions with their caregivers. Accordingly, it is necessary to consider the extent to which any disturbance reflects psychopathology in the child rather than difficulties in a dyadic relationship (see O'Connor, Chapter 46). Specific developmental delays, such as language or social relationship, are first evident in the preschool years and call for a multifaceted developmental assessment (see Bishop, Chapter 39; Lord & Bailey, Chapter 38). The American Academy of Child and Adolescent Psychiatry (1997) has issued guidelines on standards of practice for the assessment of infants and toddlers. Very few dimensional measures assessing behavioural/emotional deviance have been properly validated for children below the age of 4. Current diagnostic schemes have acknowledged limitations for use with very young children (Emde *et al.* 1993). Scales such as the Temperament and Atypical Behaviour Scale (TABS; Bagnato *et al.* 1999) and classifications such as the Zero to Three Diagnostic Classification (Zero to Three 1994) have been developed for infants and toddlers but they are based on particular conceptual frameworks and are closely linked to intervention strategies. The value of these measures and systems remains to be established.

Cultural and ethnic minorities issues

Most industrialized societies today are multicultural, multiethnic and multilingual, which has important implications for clinical practice (see Rutter & Nikapota, Chapter 16; Rutter & Taylor, Chapter 2). It also has implications for the assessment of psychopathology by means of standardized interviews or questionnaires, as noted a quarter of a century ago by Warwick & Lininger (1975). It would be a mistake to exaggerate the methodological difficulties. Rating scales have usually been found to function in much the same way across cultures (Verhulst & Achenbach 1995; Weisz & Eastman 1995; Crijnen *et al.*

1999) with, for example, comparable gender differences (Achenbach *et al.* 1990a; Stanger *et al.* 1994; Crijnen *et al.* 1999).

Nevertheless, three issues require attention. First, there is a concern to ensure linguistic equivalence (see Verhulst & Van der Ende, Chapter 5). This is usually accomplished by a series of back-translations from one language to the other by independent bilingual translators who are familiar with the psychopathological concepts. The last specification is important to ensure that the appropriate words are selected to tap the intended meaning. This is relevant, too, in relation to the need to ensure equivalence between American and British versions of instruments. The problem does not mainly lie in there being different words for the same thing in the two countries; most people are aware of these. The main hazard is provided by words that are the same but have a different meaning in the two countries. For example, 'quite' adds emphasis in the USA, but usually reduces emphasis in the UK, although in certain contexts the reverse applies. The problem of moving across languages is even greater and it is crucial that the translators appreciate the intended meaning in relation to psychopathology. Issues in relation to the translation of diagnostic interviews for Hispanics were described by Canino & Bravo (1999) and examples of translation inaccuracies and of their effects on deviance scores were noted by Woodward *et al.* (1989).

Secondly, there is the question of conceptual and perceptual equivalence. Thus, Weisz *et al.* (1988) reported differences between Thai and American adults in their concern over particular behaviours; Lee (1991) queried whether a morbid fear of fatness had the same implications for anorexia nervosa in Hong Kong as it does in Western societies; and King & Bhugra (1989) posed the same question with respect to questions on dieting when used in cultures where this is part of religious practice. It cannot be claimed that there is an adequate database to show either the importance of these concerns or how they are best dealt with, but investigators need to be alert to their possible effects on measurement. They are likely to have effects because most ratings involve an explicit or implicit comparison with some norms, the behaviours being normal at a low level but abnormal at some higher level.

Thirdly, there is diagnostic equivalence. As Taylor & Rutter (Chapter 1) note, some cultures have syndromes that appear to have no obvious equivalent in other cultures, although systematic evidence on this is largely lacking. From a measurement perspective, perhaps the key point is that when different cultures express the same disorder through differently expressed manifestations, there needs to be caution in the application of diagnostic algorithms. For example, there is evidence that cultures vary in the extent to which they express depression in reports of feelings of misery; some are more likely to report these in terms of somatic complaints (Kleinman & Good 1985). Similar issues arise with respect to age variations, as reflected in the different role given to irritability in the diagnosis of depression in childhood and in adult life (American Psychiatric Association 1994). Once more, there is at least as much of a danger of wrongly as-

suming an age (or cultural) difference as of overlooking a real difference. The arbitration has to lie in empirical studies, most of which are still waiting to be undertaken.

Computerized assessments

Modern technology has allowed many assessment procedures to be computerized. For example, Berg *et al.* (1992) compared the reliability, concurrent and criterion validity of two standard and computer-assisted procedures to collect data using two common psychopathology scales, the Rutter A2 scale and the CBCL. Psychometric properties were similar with the two procedures, suggesting that computer-assisted technologies might be used more extensively in routine practice.

There are numerous advantages to computerization: it eliminates observer bias; it ensures that all respondents receive precisely the same instructions and questions; by having a voice read aloud the questions it avoids illiteracy problems; it allows more complex and flexible skip and branching patterns than possible with paper-and-pencil procedures; immediate checking of the consistency and range of responses is possible; and it provides error-free computation of scores with or without reference to existing norms. Data are readily stored in a format that allows for further analysis and computer storage also makes the data collection procedure less vulnerable to errors such as accidental loss of data, theft, or inadvertent disclosure of confidential materials.

Several structured diagnostic interviews already have computerized versions. The role of the computer does, however, vary considerably. Computers are sometimes used to assist interviewers in their task of conducting the interview. In this instance, the interviewer still performs a face-to-face interview and records the answers of the respondent on a (usually laptop) computer as the interview proceeds. This procedure has both the advantage and disadvantage of allowing some degree of interviewer judgement. Fully computerized diagnostic interviews tend to be highly structured, with restricted response options. Computer-aided administration is particularly useful in helping the interviewer to follow complex skip rules and to track respondent's answers that require follow-up questions in the course of the interview. The Diagnostic Interview Schedule for Children (NIMH DISC-IV; Shaffer *et al.* 2000) is typical of such interviews devised for large-scale epidemiological surveys. The Development and Well-Being Assessment (DAWBA; Goodman *et al.* 2000), used in the UK National Survey of Child Mental Health (Meltzer *et al.* 2000) provides another example, with the additional feature that space is allocated to record respondents' descriptions verbatim as well, so allowing a subsequent overarching clinical interpretation of all structured data and the addition of open-ended commentaries. However, this procedure detracts somewhat from the greater efficiency of the computerized interviews—a major 'selling' point. In other developments, computers are used to replace interviewers fully. Some sound versions of diagnostic interviews have now been developed for full self-administration, using headphones or speakers. The Voice DISC

Appendix 1 Selecting an instrument.

	Interview	Questionnaire
Purpose	Screening/diagnosis	Screening/assessment
Main use	Epidemiological/clinical	Epidemiological/clinical
Reliability	Test–retest Interrater	Test–retest Split-half, internal consistency
Validity	Content, discriminant, concurrent, predictive Cross-cultural	Content, discriminant, concurrent, predictive Factorial/construct validity Cross-cultural
Coverage/content	Diagnostic categories Number of disorders	Psychopathological constructs Number of items
Method	Face-to-face interview	Self-report (usually) or other informant (parent, teacher, clinician)
Response format	Yes/No (respondent-based) All informants' descriptions (investigator-based)	Interval Likert scaling Visual analogue
Completion time	Long (hours)	Brief (minutes)
Informant	Subject Parent Other	Subject (over 10 years) Parent, teacher Clinician, interviewer, other
Time frame	Current (last 3 or 6 months) Last year Lifetime	Current, last week Last 3–12 months
Age assessed	Depends on informant and content	Depends on informant and content
Training	Required: detailed for investigator-based limited for respondent-based Availability of training packages Availability of manual	None (self-administered) or minimal (interviewer-assisted) Literacy requirement Availability of manual
Version	Paper-and-pencil Computer-assisted Computer administered	Paper-and-pencil Computer administered
Data entry	Laborious (unless computerized)	Easy (optical forms)
Scoring	Diagnostic algorithms	Norms, centiles, cut-offs
Costs	High	Low
Repeat assessments	Modularity of the interview Scale scores available	Easy, demonstrated sensitivity to change
<i>Extra features</i>		
Other domains	Personal and family details, impairment, burden, etc.	Personal and family details, scholastic achievement, etc.
Suitability for longitudinal studies	Adult diagnostic interviews	Parallel adult forms
Observational assessments	Companion observational schedule	Parallel observational scale
Cultural context	Availability in other languages Validity in different populations	Availability in other languages Validity in different populations

(Shaffer *et al.* 2000) and a substance abuse module of the Child and Adolescent Psychiatric Assessment (CAPA; Angold & Costello 2000) are examples of such developments, which totally eliminate interviewer costs.

Investigator-based interviews have been, for obvious reasons, less amenable to computerization, although some attempts have been made, such as with the Diagnostic Interview Schedule for Children and Adolescents (DICA; Reich 2000). One diagnostic interview relying on displays of pictures or cartoons to elicit symptomatic data has been released in computerized form

(Interactive Dominic Questionnaire; Valla *et al.* 2000) but data are still needed on its basic properties.

Computerized interviewing does not usually decrease the time needed to administer the interview, but it can lead to substantial savings in terms of interviewer time (and costs) by eliminating that used for coding and interpretation. Successful use has been achieved in recent epidemiological surveys (Patton *et al.* 1999; Meltzer *et al.* 2000).

It is possible, too, that computerized interviews may be better at eliciting potentially embarrassing personal information

because it eliminates the interpersonal context. Reich *et al.* (1995) found that children enjoyed the computerized DICA-R interview, preferring it over a personal interview and said that they would tell things to the computer that they would not tell to a person. Survey research has shown that rates of at-risk behaviours involving sexual contacts and use of addictive substances were three times higher when questions were asked via audio-computerized methods than when asked face-to-face (Turner *et al.* 1998). Similar results have been found regarding suicidal behaviours (Reich *et al.* 1995).

It is too early to draw firm conclusions on the merits and demerits of computerized interviews. Clearly, they have very important advantages for some purposes and there is no doubt that they will be used more in the future. However, for some purposes their chief advantage of eliminating the need for interviewers may be a disadvantage just because it eliminates personal contact. The structural format, too, will be limiting in relation to the eliciting of important unexpected information (see Rutter & Taylor, Chapter 2).

Multiaxial systems and recording clinical data

Epidemiological investigations have contributed much to our knowledge and the use of standardized methods has played an important role in ensuring their success, as has attention to the measurement and sampling issues discussed in this chapter. However, many of the same principles also apply to databases used for clinical monitoring and clinical research (World Health Organization 1996). A good example of such a clinical data recording system is the Item Sheet that has been in place at the Maudsley Hospital for over half a century and which records diagnoses, symptoms, demographic details, psychosocial features, test findings, details of referral and rating of clinical outcome. As a result, a large computerized database has been available to facilitate clinical research. Examples of its use are the study of specific problem behaviours (Thorley 1987; Wannan & Fombonne 1998; Moore & Fombonne 1999); the sampling of subjects for long-term follow-up studies (Harrington *et al.* 1990; Fombonne *et al.*, 2001); patient comparisons between centres in different countries (Duyx & van Engeland 1993); the investigation of trends over time in specific behavioural problems and of their causes (Fombonne 1998a); and the study of comorbid patterns (Simic & Fombonne, 2001). More streamlined data recording systems could easily achieve the same goals if a core set of variables was defined. Also, centres could decide to add on, for specific groups of patients of interest, or for defined periods of time, more exhaustive data recording procedures, because databases can easily be managed on modularity principles. Progress in information technology has made it easy and cheap to set up such databases and to exchange data when appropriate. Indeed, the need to audit services and to be accountable of services activity for the health service will make such systems increasingly mandatory in most countries. Timely

recognition of these needs and of the usefulness of these databases will help mental health professionals to influence these information systems in a way that might be more clinically relevant and useful for their own research and practice.

Appendix 2

Hypothetical data from a screening study.

	Cases D	Normal \bar{D}	
Test positive (T+)	a	b	a + b
Test negative (T-)	c	d	c + d
	a + c	b + d	a + b + c + d = N

D, diseased; \bar{D} , non-diseased.

True positives, TP = a; True negatives, TN = d; False negatives, FN = c; False positives, FP = b.

Sensitivity (or rate of true positives, RTP): $Se = a/a + c = p(T+/D)$.

Specificity (or rate of true negatives, RTN): $Sp = d/b + d = p(T-/\bar{D})$.

Rate of false negatives: $RFN = c/a + c = p(T-/D)$.

Rate of false positives: $RFP = b/b + d = p(T+/\bar{D})$.

Prevalence: $P = a + c/N = p(D)$.

Positive predictive value: $PPV = a/a + b = p(D/T+)$.

Negative predictive value: $NPV = d/c + d = p(\bar{D}/T-)$.

This table provides the results of a hypothetical screening study (see also Fig. 4.2). Several proportions are used to summarize the data: sensitivity (proportion of cases above the threshold); and specificity (proportion of non-cases below the threshold). These two proportions can be regarded as indices of the criterion of validity of the instrument. Both proportions vary inversely and changes in the proposed cut-off to improve sensitivity would normally result in decreased specificity, and vice versa.

Another proportion of importance is the positive predictive value which expresses the probability that a subject with a positive screening has a disorder. The proportion varies as a function of the sensitivity and the specificity of the instrument, but also with the prevalence of the disease in the population:

$$PPV = (P \times Se) / (P \times Se) + [(1 - P) + (1 - Sp)].$$

It can be shown that the PPV associated with an excellent instrument (sensitivity = specificity = 90%) is very good (79%) if the prevalence of the disorder is high ($P = 0.3$), but poor (8%) when the prevalence falls to a low value of 1%. This reminds us that intrinsically good instruments might have poor performances, depending on the context of their use.

Introduction

Over the last 30 years or so, many rating scales have been developed to assess general child/adolescent psychopathology. Their number and variety creates a potential problem because of the uncertainties about generalizing findings from one study to another if different instruments have been used. In this chapter we consider the purposes for which such rating scales may be used, discuss their psychometric properties, note their similarities and differences, and outline the criteria by which to judge which instrument best suits a particular purpose.

The evaluation of rating scales does not result in a static conclusion. Many of the scales have developed over time in terms of content, age span covered, the production of parallel versions for parents, teachers and adolescents themselves, the means of administration and scoring, and the availability of standardized data.

Specific rating scales are referred to in the text by their abbreviations. Table 5.1 and Appendix 1 give the full name, author(s) and relevant information for each scale. Our focus is exclusively on scales to measure general psychopathology; those for specific disorders/behaviours and for psychosocial features are considered in the relevant chapter elsewhere in the book.

Our evaluation of general scales is based on four key assumptions:

- 1 that diagnoses are hypothesized latent constructs, the validity of which need empirical testing (see also Fombonne, Chapter 4; Taylor & Rutter, Chapter 1);
- 2 as follows from the first assumption, we do not regard agreement with a clinical diagnosis as the ultimate test of the validity of a rating scale;
- 3 that no single measure is ever a perfect index of the construct that it aims to tap (see Fombonne, Chapter 4); and
- 4 that the value of any rating scale needs to be considered in relation to the purposes to which it is to be put.

It is most unlikely that any one scale will be optimal for all purposes. To give an obvious example, the type of measure needed to examine changes over a short time (such as in a trial of treatment) is scarcely likely to be the same as that needed to assess continuing liability (as in a genetic study).

Issues specific to scales for child psychopathology

Age-relatedness

Many problem behaviours, such as temper tantrums or separation anxiety, are common and therefore statistically normal at a young age, but much less frequent and more likely to indicate psychopathology at older ages. Clinical significance has to take into account the child's developmental level. For young people within the normal range for cognitive and physical development, comparisons with normative samples of children of the same age (and sex) provide guidelines for evaluating behaviours. If the ages of children to be studied differ substantially from those in the standardization sample for the scale, valid comparisons are not possible.

Some rating scales employ the same version for different age groups. This has the considerable advantage that scores obtained for children at one age can be compared directly with scores obtained for the same children at a later age. Provided that there are age-standardized norms, comparisons can also be made on the relative levels of problems at different ages.

Other scales use different versions for different age groups. These have the advantage that behaviours relevant for one age group but not for another are included only in the age-relevant version. For example, alcohol and drug use, truancy or vandalism are applicable in adolescence but not in the preschool period. However, a disadvantage is that in the transition from one age group to another, there is loss of continuity of item and scale scores. This is especially problematic for longitudinal studies.

Informant and situational specificity

For both statistical and clinical reasons, it is necessary to obtain information from different informants that cover behaviour in different settings, such as home and school (see Fombonne, Chapter 4; Rutter & Taylor, Chapter 2).

Instead of viewing low agreement among different informants (the usual picture — Achenbach *et al.* 1987) as a nuisance, or systematically discarding one source of information, it is important to regard each informant as a potentially valid source of information. Each informant has their own unique, and potentially valid, contribution to the formation of an overall picture of the child's functioning (Verhulst *et al.* 1994, 1997; Van der Valk

et al. in press). Even disagreement among informants can be valuable (Jensen *et al.* 1999). An example of the potential value of information from different sources is the finding that children who are hyperactive at home *and* at school have a poorer prognosis than children who are hyperactive only at home *or* at school (Schachar *et al.* 1981).

Most rating scales for the assessment of child/adolescent psychopathology have parallel versions for parents and teachers. Some rating scales have versions for adolescents' self-reports, although sometimes the self-report version is not parallel to the parent and teacher versions and may tap other domains, such as personality (e.g. Behavioral Assessment System for Children (BASC); Millon Adolescent Clinical Inventory (MACI); Minnesota Multiphasic Personality Inventory (MMPI)). The advantage of rating scales with parallel parent, teacher and self-report versions is that the scores across the different informants can be compared. The Achenbach System of Empirically Based Assessment (ASEBA; Achenbach & Rescorla 1999) is an example of a rating scale with versions for parents, teachers and self-reports that yield scale scores that can be compared.

Dimensional nature of child/adolescent problem behaviours

The construction of rating scales is usually based on psychometric principles. The basic premise is that most problem behaviours in children and adolescents constitute quantitative variations rather than present/absent categories. To identify quantitative gradations, multiple items are rated by the respondent using standardized procedures. The items of rating scales are then usually aggregated into subscales. Thus, items can be grouped to derive scale scores for domains such as 'hyperactivity', 'anxiety', or 'oppositional' behaviour.

This quantitative approach allows assessment of the degree to which one child's behaviour differs from that of comparable children of the same age and sex in the normative samples. The quality of normative samples used varies considerably. Some scales have large representative standardization samples from the general population [e.g. ASEBA; Conners' Rating Scales-Revised (CRS-R); Devereaux Scales of Mental Disorder (DSMD); MACI]; others use samples of convenience [e.g. Revised Behavior Problem Checklist (RBPC); Paediatric Symptom Checklist (PSC); Strengths and Difficulties Questionnaire (SDQ)].

The advantage of using quantitative scores is that they contain more statistical information than categories (Streiner & Norman 1998; Goldberg 2000). This is because they use data across the whole range and not just around a particular cut-off point and because they avoid the major problems of classification error for scores just above and below that point. Thus, if a categorical diagnosis is made if a score is above, say, 10, scores of 10 and 11 are treated as radically different although the difference between them is as likely to be caused by measurement error as to the presence/absence of a disorder. All measures

include error (see Fombonne, Chapter 4). By focusing on the consistency of answers across many items, measurement error is reduced (Streiner & Norman 1998). The reliability of dimensional measures therefore tends to be greater than that for categories (Shaffer *et al.* 1999a). Nevertheless, if needed for decision-making purposes, it is a straightforward matter to transform dimensions into categories (see Fombonne, Chapter 4). Conversely, for most diagnostic categories, it is usual to bring in dimensional considerations (e.g. symptom severity or degree of impairment).

Overview of generic rating scales

We searched the literature for psychometrically sound rating scales for the assessment of general child/adolescent psychopathology (excluding those designed for very limited purposes such as the Achenbach, Conners, Quay questionnaire, ACQ; Achenbach *et al.* 1991). We contacted the authors and/or publishers and requested information on the format, administration, scoring and interpretation of questionnaires. Where appropriate, we sought feedback from the authors and/or publishers to detect any errors in the factual information we provided in the text.

Detailed information on individual questionnaires is available elsewhere (Maruish 1999; Shaffer *et al.* 1999b). Accordingly, we focus on the principles and quality criteria to be employed in the valuation of any rating scale. Table 5.1 provides an overview of the scales considered and Appendix 1 gives a more comprehensive description of each.

Item content

The content of an instrument is chosen on the basis of what it is intended to measure. Generic instruments seek to tap a broad range of psychopathology, using items likely to be relevant for all common types of mental disorder and giving priority to those that apply to several disorders and not just one.

For scales that have been developed over many years through successive revisions, empirical information obtained from earlier versions (for instance on content coverage or on the discriminative validity of specific items) is incorporated into the newer versions. Examples are the ASEBA (Achenbach & Rescorla 1999) and the CRS-R (Conners 1997). In CRS-R, Conners included items that were modelled on the DSM-IV criteria (American Psychiatric Association 1994).

Item response scaling

Most scales have items that can be scored on a 3-point scale (0, 1 and 2), but some use 4-point scaling (0, 1, 2 and 3), and a few use a 2-point 'true/false' scoring approach such as the MMPI-A (Butcher *et al.* 1992). From a psychometric point of view, some argue that the higher the number of scoring categories within the range of 2–10, the better the reliability will be (Streiner &

Table 5.1 Overview of generic rating scales for the assessment of psychopathology.

Instrument	Acronym	Current authors	Informants	Age range	Number of items	Time in minutes	Item scaling	Norms	Derivation of scales	Scales†

* For ASEBA and BASC adaptive behaviour are listed in addition to problem scales.

† If scales differ by informant, only parent scales indicated; if scales differ by age, only scales for broadest age range; see Appendix 1 for more complete information.

‡ The BASC includes a self-report personality inventory, which is not listed in this overview.

§ The MACI and MMPI-A include personality scales, which are not listed in this overview.

Norman 1998). However, with untrained raters (such as parents) and with relative phenomena (such as degree of misery or overactivity) raters tend to use scores only in the middle range. For example, Achenbach, Conners and Quay (Achenbach *et al.* 1991) developed a new scale (ACQ) which included items that originated from the three authors' original scales, choosing a 4-point item scoring format. However, it was found that the ACQ items that had counterparts on the Child Behaviour Checklist (CBCL; Achenbach 1991a) discriminated less well between clinically referred and non-referred children than the original CBCL items which have a 3-point scoring format. Whatever the theoretical psychometric advantages of many scoring points, 3-point scales are usually to be preferred. The psychometric advantages are better obtained through many items rather than through many scoring points.

Composition of scales

Empirical vs. a priori approaches

Two main approaches, the *empirical* and the *a priori*, may be used to select and group items. Empirical approaches employ multivariate statistical techniques, such as factor analysis or principal components analysis, to identify sets of problems that tend to occur together, and thereby make up syndromes. Each syndrome can be quantified by summing the scores of the items that compose the syndrome. This 'from the ground up' approach starts with empirical data derived from informants, without any assumptions about whether the syndrome reflects predetermined diagnostic categories.

The empirical-quantitative approach forms the basis of most of the rating scales listed in Table 5.1. It is not always clear from the description of the derivation of scales whether the authors used general population samples or clinical samples to compute their syndrome scales. For the construction of the scales for the ASEBA (Achenbach & Rescorla 1999) and the RBPC (Quay & Peterson 1996), scores derived from large clinical samples were used.

It remains a matter of controversy what kind of samples are needed to create the scales. Achenbach (1991b) has been a strong proponent of the use of clinical samples as the data source for multivariate analyses, because they yield items with frequencies high enough to be retained in reliable factor analyses or principal component analyses. Also, the use of clinical samples will result in scales that relate to aggregations of problems as encountered in clinical practice. Others, especially those who use rating scales in general population samples, argue that syndrome scales should be based on data derived from general population samples, because the factor structure should reflect the underlying structure of problems in the samples to be studied. Before using a factor structure in samples that are essentially different from the ones from which the factor structure was derived, it is important to test the applicability of the factor structure (De Groot *et al.* 1994, 1996; Koot *et al.* 1997).

The second approach is to take the diagnostic categories of

one of the two international classification systems as the basis for the syndromes to be scored with the rating scales. This a priori or consensus approach is a 'from the top down' method because it starts with experts' assumptions about which disorders exist and which symptoms are relevant for them.

The a priori approach formed the basis of the Child Symptom Inventories (CSI; Gadow & Sprafkin 1998). Like the DSM categories, the CSI syndromes can be scored as present vs. absent by using cutpoints that are based on DSM criteria. For computing the so-called Symptom Criterion score, the authors transformed the original 0–3 item scale into a 2-point present-vs.-absent category by combining the scores 0 and 1 indicating the absence of the symptom, and the scores 2 and 3 indicating the presence of the symptom. Unlike DSM, the syndromes can also be scored as dimensions using the so-called Symptom Severity scoring by retaining the original 4-point item scoring format.

The advantage of the empirical approach is that it does not start from unvalidated assumptions about the disorders; yet it can help to improve existing knowledge about nosology. Because the empirical approach starts with data derived from representative samples, its intrinsic validity is appealing. However, a disadvantage is that the empirically based syndrome scales vary as a function of the item content, the number of items, the statistical technique that was used to compute the syndromes, and the samples used to derive the data. As a consequence, the content and the number of scales differ across the different instruments.

An advantage of the a priori approach is that despite the lack of validity of most DSM and ICD (World Health Organization 1992) diagnostic categories, they represent a system that is widely accepted. This facilitates communication across researchers and clinicians.

Although the empirical and a priori approaches converge, they do not converge to a degree that one approach can replace the other (Edelbrock & Costello 1988; Jensen *et al.* 1993; Kasius *et al.* 1997). Both approaches are needed and can be combined. For example, the revision of the CBCL (Achenbach & Rescorla 2001), will make it possible to score the items on two sets of scales. One involves empirically derived scales, and the other scales related to DSM categories. Both sets can be scored quantitatively and categorically by imposing cutpoints to each scale (Achenbach & Rescorla 2000).

Overall index of psychopathology

If the main purpose is to decide only whether an individual has some form of psychopathology, syndrome scales may not be needed. The sum of the scores for all items (the total problem score) usually serves as a general indicator of the overall level of psychopathology. Most scales have this option in addition to syndrome scores. One, the 35-item PSC (Jellinek *et al.* 1986), designed for primary care settings, can only yield a total problem score.

Externalizing and internalizing scales

For some purposes, a level of precision that is intermediate between the fine-grained syndrome level and the crude total problem score may be desirable. For those purposes, a number of instruments use two broad band groupings: ‘externalizing’ and ‘internalizing’. Externalizing reflects interpersonal and societal norm conflicts, whereas internalizing reflects internal distress. These groupings are usually determined through second-order factor analyses of the correlations among the syndrome scale scores. Some rating scales, such as the CBCL (Achenbach 1991a), the DSMD (Naglieri *et al.* 1994) and the BASC (Reynolds & Kamphaus 1992), can be scored in this way.

Weighting of items

It might be thought that simple summation of all items will lose valuable information, because some items are more important than others and should be weighted accordingly. Differential weighting using weights derived from factor analyses or regression analyses may yield greater precision in that sample. However, applying weights to new samples does not usually increase precision (Wainer 1976). Because the use of differential weighting contributes relatively little, except added complexity, all rating scales considered here use non-weighted summation scoring.

Percentiles and T-scores

The various subscales of the same instrument have different mean scores in normative samples because of differences in the number of items of each scale, and resulting differences in mean scores. Because each scale is scored on a different metric, comparisons across syndrome scales are difficult. How can a score of 20 on a syndrome scale (e.g. of aggression) with a scoring range between 0 and 40, be compared with a score of 10 on a syndrome scale (e.g. of depression) with a scoring range between 0 and 20? They are measured on different yardsticks so any comparison would require transforming the raw scores into scores that have a similar metric.

One approach is the use of *percentiles*. A percentile is the percentage of individuals who score below a certain value. The height and weight charts used to assess the physical development of children provide a well-known example. Percentiles can be computed on the basis of questionnaire scores for a representative normative sample of children whose scores are ranked from the highest to the lowest. The advantage of percentiles is that they are easy to interpret. For instance, if a boy received a score on the aggression scale corresponding with the 90th percentile, this means that only 10% of normal boys of the same age obtain higher aggression scores.

A second approach to transforming scores into ones that can be compared across scales with different metrics is the use of *T-scores*. A T-score is a score with a mean of 50 and a standard deviation of 10. A T-score of 50 will correspond with the 50th

percentile. The advantage of both percentiles and T-scores is that they allow us to determine where an individual’s score stands in relation to scores of individuals of the same sex and age. The utility of both percentiles and T-scores depends on the size and the representativeness of the reference samples.

Most instruments listed in Table 5.1 have data on reference samples and provide T-scores, including the ASEBA, BASC, CRS-R, DSMD, MMPI-A and the RBPC. Some instruments provide T-scores based on representative clinical samples in addition to T-scores based on normative samples. This is true for the ASEBA and the RBPC. T-scores based on clinical samples enable us to determine where an individual’s score stands in relation to scores of individuals of the same sex and age who are referred for mental health services.

The MACI (Millon 1993) uses what the authors call ‘base rate’ scores that (arbitrarily) take account of the base rates of certain disorders in clinical samples.

Psychometric qualities of rating scales

Reliability

Any measurement is affected by both random and systematic error. The ratio of variability among subjects (true score variation) to the total measurement variability (the sum of subject variability, random error and systematic error) is called reliability. In practice, reliability refers to the replicability of measurement.

It is important to know the degree to which the same informants provide similar results on different occasions (see also Fombonne, Chapter 4). The time intervals used for assessing the *test–retest reliability* should be short enough to expect that the subject’s behaviour will not have changed. In case of teachers as informants it is possible to assess the level of agreement between scores obtained from two teachers—*interrater reliability*.

Because parents are such a central source of information on their child’s functioning, it is also helpful to know the degree of agreement between scores from fathers and mothers. Because reliability involves variation in assessments of the same phenomena, *interparent agreement* should not be treated as a reliability measure. Because ratings by mothers and fathers are based on somewhat different samples of the child’s behaviour, interparent agreement is not expected to be as high as test–retest or interinterviewer reliability.

Scores obtained through repeated measurements can be affected both by their rank ordering and by differences in level so it is important that reliability measures reflect both. Pearson correlation coefficients are often used as reliability measures but they are affected only by differences in rank ordering of the correlated scores, whereas *t*-tests are affected only by differences in mean scores (level of the trait). A measure that is affected both by differences in the rank ordering and mean scores is the *intraclass correlation coefficient* (ICC; Shrout & Fleiss 1979). When evaluating the psychometric qualities of an instrument, it is

important to be aware of the kind of reliability measure that is reported.

Reliability is often wrongly treated as an intrinsic characteristic of a measure. Reliability is highly linked to the population to which the measure is applied, and to the procedure with which the reliability was tested.

For most scales listed in Table 5.1, data on test–retest reliability are reported and, where appropriate, data on interrater reliability or interparent agreement. Reliability measures for these instruments are usually favourable for broad measures such as total problem scores. For some individual syndrome scales, reliability may be lower, and in fact problematic in some instances.

A somewhat different measure, also referred to as reliability, is the instrument's index of *internal consistency*, often presented as coefficient alpha, or Cronbach's alpha (Schmitt 1996). Alpha is a function of the interrelatedness of the items in a test. Internal consistency does not tell us anything about the degree to which an instrument will give us the same results over different occasions, such as the reliability measures discussed so far.

There is yet another problem with internal consistency in those instances where the scales are derived through principal components analysis. Because principal components analysis aims at arriving at scales with intercorrelated items, it is not surprising that measures of internal consistency for such scales are very high. In fact, measures of internal consistency for such scales are redundant as they do not give much new information. In most instances it is found that the shorter the scale, the lower the internal consistency.

Validity

Validity refers to the degree to which an instrument measures what it is designed to measure (see also Fombonne, Chapter 4). The most basic form of validity is *content validity*, meaning that the items tap the behaviours thought to be relevant because they map onto prevailing diagnostic concepts or because empirically they differentiate between clinically referred and non-referred children (if that is the purpose of the scale). The latter criterion may result in the conclusion on the scale of some rarely occurring, but usefully discriminatory, items. Thus, the CBCL has items dealing with self-harm, pica and faecal soiling.

Construct validity refers to the extent to which scores are related to external validating criteria, such as aetiology, outcome or response to treatment. Construct validation is an ongoing process of interrelated procedures through which we try to learn more about the construct. In this way, each new study can strengthen what Cronbach & Meehl (1955) called the 'nomological network' of interrelated procedures intended to reflect the underlying construct. Instruments used in many studies, such as the CRS (Wainwright 1996) and the CBCL (Vignoe *et al.* 1999), thereby have an advantage.

Concurrent validity concerns the associations (or correlations) between the scores on one instrument with those on other instruments designed to measure similar constructs. Why this should be carried out; if a good measure already exists, why

bother to test another one? It is usually performed because the instrument used as the criterion is too long or expensive. This may be the case when a brief and inexpensive rating scale is compared with a more time-consuming and expensive clinical interview. For example, the Youth Self-Report (YSR; Achenbach 1991d), an inexpensive and easy to administer self-report questionnaire, was correlated with the Semistructured Clinical Interview for Children and Adolescents (SCICA; McConaughy and Achenbach 1994), an interview that has to be given by a trained clinician (Kasius 1997). The intercorrelation between the two was 0.62, comparable to the mean correlation of 0.60 found for pairs of similar informants using the same scale (Achenbach *et al.* 1987).

Criterion-related validity refers to the relationship of a measure to another measure that is regarded as the 'gold standard'. For brief rating scales, this type of validity can be called *predictive validity*. The external reference criterion usually takes the form of a comprehensive definitive clinical diagnostic evaluation, but it is very dubious whether this should be viewed as a 'gold standard' in view of the uncertainties over the validity of such assessments. Questionnaire scores have been tested against DSM diagnoses derived from standardized interviews (e.g. Grayson & Carlson 1991; Kasius *et al.* 1997; Gadow & Sprafkin 1998), or with DSM diagnoses derived through unstandardized clinical procedures (Naglieri & Pfeiffer 1999).

Because of doubts about the superiority of one approach over others, these studies are really testing *concurrent validity*. This view is supported by Boyle *et al.* (1997) who compared the associations with external validators of a rating scale (the Ontario Child Health Study scales) and a psychiatric interview (the revised version of the Diagnostic Interview for Children and Adolescents; DICA). They concluded that validity differences between the two procedures were small and, where present, showed a somewhat better performance for the rating scales than the interview.

Referral status is used for many rating scales to test the criterion-related validity by testing the ability of an instrument to discriminate between children and adolescents who are referred for mental health services and those who are non-referred (ASEBA, CRS-R, RBPC, DSMD, Rutter, SDQ, CSI). Referral status is not an infallible morbidity criterion either, because some children and adolescents are referred for reasons other than being truly disordered. Equally, it is known that many disordered children and adolescents in the general population do not receive professional help for their problems. When an instrument is tested against referral status as the criterion, this may result in an underestimate of its ability to discriminate between disordered and normal children or adolescents.

Other validity issues

Measuring change

Because rating scales may be used to test changes over time, it is important that they are sensitive to such changes. Few tests of

this feature have been undertaken with most scales. The CRS-R and earlier versions of the CRS have been shown to be sensitive to the effects of drug treatment of hyperactive children, supporting the validity of the hyperactivity construct (Conners 1999). The CBCL was found to be sensitive to change and to be useful for evaluating the clinical significance of therapeutic intervention (Kendall *et al.* 1999). The manual of the CBCL and related instruments (Achenbach 1991a–d) and a number of studies with the CBCL (Crijnen *et al.* 1997, 1999; Stanger *et al.* 1997) showed that the CBCL captures age differences in scores in cross-sectional as well as in longitudinal studies. However, these usually span longer time periods than used in trials of interventions.

Drop in scores on re-administration

A well-known, but poorly understood, phenomenon is that re-administration of a rating scale usually results in a decrease in scores (see Fombonne, Chapter 4). By testing differences in mean scores over time in test–retest analyses, the magnitude of differences in mean scores on re-administration can be determined; however, such information is available for very few scales. For the original version, as well as for the Dutch translation of the CBCL, it was found that for some scales re-administration resulted in a small but significant decrease in scores across intervals of 1–2 weeks (Achenbach 1991a; Verhulst *et al.* 1996). In a separate study, a decrease in CBCL scores was found over a 2-year period but this was not maintained at a 4-year follow-up (Verhulst & Althaus 1988; Verhulst *et al.* 1990). This decrease in levels of problems has also been reported for standardized interviews, both for adult and child psychiatric disorders (Edelbrock *et al.* 1985; Helzer *et al.* 1985).

The reason for this decline in scores on re-assessment is not known, so it is not clear how it should be dealt with. Case-control intervention comparisons should be robust to this bias because the decline should affect both, provided measures are taken at the same time intervals. The bias is more problematic in simple group longitudinal studies. Although not done routinely, it may be advisable to ask each respondent who completes a rating scale to indicate whether the same rating scale had been completed earlier.

Short vs. long rating scales

Most rating scales take between 10 and 20 min to complete. For screening and early assessment procedures in which a global impression of the child's functioning is needed, to be followed by more extensive assessment in a later phase for those who have elevated problem scores, a very brief rating scale is sometimes desirable. Another situation in which there is often a need for a very brief rating scale is when one teacher has to complete rating scales for many children in one classroom.

A number of rating scales in their standard format are relatively brief, such as the Eyberg Child Behaviour Inventory (ECBI), PSC, Revised Rutter Scales, and the SDQ. The ECBI and

the PSC only provide an overall measure of dysfunctioning, whereas the other rating scales allow more differentiation and can be scored on syndrome scales.

The CRS-R has abbreviated versions in addition to the longer standard forms. The short parent form is approximately one-third of the length of the long form, and covers only four scales instead of the 14 scales in the long form. Although the correlations among the four scales of the short form and the corresponding scales of the long form are reported to be very high, there are no comparisons between the short and the long versions with respect to validation against external measures (Conners 1997). Also, it is clear that the short form gives a much less differentiated picture of the child's problems.

There are few studies that directly compare short vs. long rating scales. One study compared the short SDQ with the much longer CBCL (Goodman & Scott 1999). Scores from the SDQ and CBCL were equally able to discriminate psychiatric from non-psychiatric comparison children. As judged against a semistructured parent interview, the SDQ was better than the CBCL at detecting inattention and hyperactivity, and did equally well at detecting internalizing and externalizing problems.

For measuring psychopathology in adults, the General Health Questionnaire (GHQ; Goldberg & Williams 1988) is used with different numbers of items varying from the full 60 to 12. The shorter versions perform rather well in discriminating between psychiatric cases and normal individuals (Goldberg *et al.* 1997), and some even advocate the use of only four items of the GHQ to detect cases (Jacobsen *et al.* 1995).

The use of extremely brief rating scales with only a few items, questions the rationale for using a rating scale at all. Why not just pose two questions to parents: 'Do you think your child has a problem?', and 'Do you or other people have a problem with your child?' The fact that very short rating scales do not perform much worse than the longer versions in detecting psychiatric cases also reflects the lack of specificity of psychopathology, and casts doubt on the usefulness of mass screening if the initial screening is not followed by more extensive evaluation.

Measures of accuracy of a rating scale

Rating scales applied to populations not known to have psychiatric conditions can be regarded as *screening tests*, whereas the same rating scales applied to populations known to have symptoms can be termed *diagnostic tests* (Weiss 1998). The underlying rationale for the use of a test is identical for both screening and diagnostic tests. The rationale is that among individuals to whom the test is administered, the monetary, physical and psychological costs of the condition along with the cost of the test and the errors that arise when the test does not classify individuals accurately, will be exceeded by the costs of the condition had the test not been carried out.

Sensitivity, specificity and predictive value

The usefulness of a test depends on its accuracy. This can be assessed in several different ways: by sensitivity, specificity, positive and negative prediction. The meaning of these terms, and how to measure them is described by Fombonne (Chapter 4). As he points out, sensitivity and specificity do not reflect an intrinsic quality of a test; they will vary with the samples on which they were based and with the critical values chosen. Robins (1985) showed how the sensitivity of a test for the presence of a psychiatric disorder was higher in a patient sample than in a general population sample (such tests usually detect severe cases more readily than mild ones), but specificity will be higher in general population than in patient samples. Cutpoints are chosen by making compromises among several considerations. Any cutpoint chosen is a trade-off between sensitivity and specificity.

The relationship between sensitivity and specificity can also be expressed by a Receiver Operating Characteristic (ROC) curve. The ROC curve is constructed by plotting the sensitivity on the vertical axis, against the false positive rate (100-specificity) on the horizontal axis. The use of ROC curves has two advantages. The curve readily shows the trade-off between sensitivity and specificity, and so indicates the optimal scoring range for choosing the cutpoint that provides the best match with the aims of the user. The area under the curve (AUC) can be computed and used as an index for the criterion-related validity of a test. The AUC can be conceptualized as the probability of correctly identifying a randomly chosen pair of individuals (one who has the disorder, one who does not have the disorder). The AUC ranges between 0.5, which indicates that the test does not add to the chance probability of correctly classifying individuals, and 1.0 which would indicate a perfect test. The AUC enables us to compare the discriminative power of different rating scales (Kresanov *et al.* 1998).

We can also express the accuracy of a test as the extent to which being categorized as ‘test positive’ or ‘test negative’ actually predicts the presence of the disorder. This may be an important method by which to determine the probability that an individual has a certain disorder, given the results of a test.

Predictive value is much influenced by prevalence. In a sample with relatively few disordered individuals, the positive predictive value (PV+) of even a very specific test will be low, meaning that a ‘positive’ result will yield many false positives. If the same test was used in a sample with a much higher prevalence, the PV+ would be much higher. This makes screening for very rare disorders, such as autism, using rating scales in community settings unattractive. Although the problem of low base rates for predicting rare conditions, even with highly valid tests, was observed long ago (Meehl & Rosen 1955), Clark & Harrington (1999) showed that few child mental health professionals who regularly use questionnaires to screen for mental disorders were aware of this problem. A technique that can be used to overcome low base rates problems is *sequential screening* (Derogatis & Lynn 1999; see epidemiological applications below).

For some rating scales in Table 5.1, the authors specify the sensitivity and specificity (ASEBA, Rutter, SDQ, PSC, CSI); they are usually satisfactory and in the same range as rating scales for adult psychiatric disorders. However, the relative nature of these measures makes it imperative for the potential user to judge these values against the background of the specific purpose for which the rating scales is intended.

Scoring procedures and interpretation

The scoring procedures and the interpretation of the results of a rating scale should be easy to follow and understandable. Most rating scales have scoring forms or graphic displays that describe the scores relative to the norms. Computerized scoring and profile printouts in graphic form have many advantages. The majority of rating scales listed in Table 5.1 have the option of using computerized scoring, including the ASEBA, CRS-R, BASC, DSMD, CSI, MMPI-A and the MACI. Rating scales are developed to assist in determining the likelihood that the subject does or does not have the specific problem the instrument is designed to identify. Use for any other purpose (e.g. assigning a diagnosis based solely on the instrument’s results) only serves to undermine the integrity of the instrument (Maruish 1999, p. 16).

Translation

There is a growing need for translations of psychometrically sound rating scales, mostly from English into other languages. This comes from researchers and clinicians in various countries, but also from researchers and clinicians who work in major metropolitan areas with their multiethnic multilanguage character.

There are no generally accepted guidelines for gauging the adequacy of translation, although there is an increasing awareness of the many difficulties in the faithful translation of instruments (Weisz & Eastman 1995; Streiner & Norman 1998; Canino & Bravo 1999; see also Fombonne, Chapter 4). To ensure optimal accuracy in translations, some authors advise repetition of the translation-back-translation procedure (Weisz & Eastman 1995), whereas others emphasize the importance of field testing (Canino & Bravo 1999). However, even very accurate translations may result in linguistic nuances that need explicit reporting.

The CBCL (Achenbach 1991a), the CSI (Gadow & Sprafkin 1998), the CRS-R (Conners 1997), the DSMD (Naglieri *et al.* 1994) and the Revised Rutter Scales have all been translated into multiple languages.

Accurate translation is the first step towards using an existing instrument in different cultural settings. The second step is the testing of the instrument’s psychometric properties in these other contexts, including the reliability and validity. In particular, the determination of the factorial structure needs to be determined in case empirically derived syndromes are used. The third

step is the derivation of reference scores, both in representative normative and clinical samples. The last step is the testing of the generalizability of the results by comparing population norms (Crijnen *et al.* 1997, 1999), and by comparing the factor structure across different cultural settings.

Advantages and disadvantages of rating scales

One of the great advantages of rating scales over clinical interviews is that they can be applied in a flexible, easy to administer and economic way. Administration time is usually modest—some 10–20 min. Rating scales are also characterized by great flexibility in the way they can be administered: in person, by telephone or by mail. Administration can be facilitated by using computer-assisted client entry programs. Some rating scales, such as the ASEBA, CRS-R, and the BASC have a computer-assisted client entry program.

Rating scales need not be administered by expensive clinically trained professionals. This means that they can be routinely administered in (mental) health settings at intake, or can be used in large-scale epidemiological surveys. Thanks to their practicality, many rating scales also have good data on reliability and validity.

Rating scales also have a number of disadvantages, some of which are shared by other measurement procedures. They are limited to the informant's perspective. Characteristics of the informant and the tendency toward response biases are sources of variation in ratings (Briggs-Gowan *et al.* 1996; Fergusson 1997; Sawyer *et al.* 1998). Scales are limited to the structured scores for standardized items. Information that may be relevant but that is not covered by the items of the scale will be missed. It is not possible to explore the informant's responses and subjective experiences, nor is it possible to observe behaviour directly. Misunderstandings and ambiguous answers that may be clarified in a clinical interview are missed when using questionnaires. Slight changes in the wording of instructions, or the wording of the items themselves, may have large effects that limit comparability (Woodward *et al.* 1989). Despite these limitations, one study that directly compared the validity of a rating scale against a structured interview in the ability to predict external criteria did not find the rating scale to be less valid (Boyle *et al.* 1997). Many of these problems can be prevented by unambiguous wording of items and instructions. For instance, before having a respondent complete a screening questionnaire, we must have an indication of the respondent's reading skills.

Use of rating scales as screening instruments

Because rating scales are relatively inexpensive and easy to administer, they are often thought of as handy tools for screening large populations both for research and community health pur-

poses. The medical meaning of screening refers to the examination of asymptomatic or non-referred people in order to classify them as likely or unlikely to have the disease that is the object of screening (Morrison 1998). People who appear likely to have the disease are investigated further to arrive at a final diagnosis. Those people who are then found to have the disease are treated. When the application of early diagnosis and treatment is organized within large groups, this is described as mass screening or population screening. It is not readily evident that psychiatric conditions meet all the criteria for being subjected to screening programmes (Derogatis & Lynn 1998).

First, screening is a method originally developed for detecting highly specific medical target conditions that are either present or absent, such as phenylketonuria or breast cancer or HIV. Medical screening usually has a narrow focus, and is able to use a single test with a high degree of diagnostic precision. In contrast, psychiatric disorders lack specificity and do not have a highly accurate diagnostic test.

The second concern is that most child and adolescent psychiatric disorders are not characterized by an asymptomatic or benign period in which detection can be reliably and validly performed. Moreover, most conditions lack a clear-cut well-delineated onset (see Sandberg & Rutter, Chapter 17). If sub-threshold psychopathology is accepted as a risk factor for the persistence or recurrence of psychopathology, then the early detection of problems could be advantageous. The moderate to strong continuity of problem behaviour from childhood or adolescence into young adulthood supports this view (Ferdinand *et al.* 1995; Verhulst & Van der Ende 1995; Hofstra *et al.* 2000). It has been found that high levels of parent reported problem behaviours in non-referred children from the general population were not only predictive of referral for mental health services as recorded in a psychiatric case register in the year following the assessment, but they were almost equally strong predictors of referral for up to 5 years later (Laitinen-Krispijn *et al.* 1999). Earlier detection and subsequent treatment may improve the prognosis or reduce the period of suffering.

The third factor that makes it not readily evident that mass screening is helpful is that it has not been definitively demonstrated that treatment or prevention of child and adolescent disorders at the stage before disorder is manifest is beneficial (see Brent, Chapter 54).

We do not advocate the use of rating scales, or any other assessment procedure, in mass population screening to detect whether or not a certain psychiatric condition is present. However, if precision in individual diagnosis is not required, as in epidemiological studies in which the error can be taken into account, or if early assessment is just one component in decision making, then there is a place for the use of rating scales.

Application of rating scales in screening procedures and early assessment

Epidemiological application of screening procedures

Epidemiology, with its emphasis on large-scale measurements, has an evident need for assessment procedures that are accurate, practical and economical. When the first child psychiatric epidemiological studies were planned, the lack of such assessment procedures was the driving force for developing the first generation of brief rating scales. The first version of the Rutter scales proved their value in the Isle of Wight study (Rutter *et al.* 1970).

Multistage/multimethod sampling

Epidemiological measures for large-scale descriptive or aetiological studies need to be brief and inexpensive. Especially when investigating conditions with low base rates, it is problematic to assess many individuals who do not have a disorder with elaborate procedures. Therefore, it is advantageous to use a multistage sampling approach (Dohrenwend & Dohrenwend 1982; Verhulst & Koot 1992; Derogatis & Lynn 1998).

In stage 1, a rating scale is applied to the total sample in which the base rate of a disorder is relatively low. Individuals with high problem scores are designated cases or 'screen positives'. All others are designated non-cases or 'screen negatives'. The advantage here is that although a low base rate has a bad effect on positive predictions, its impact on negative predictions is far less.

In stage 2, all 'screen positives' (thereby an enriched sample with a higher prevalence rate, so avoiding the problematic effect of low base rates) and a random sample of the 'screen negatives' from stage 1, are assessed using more elaborate procedures, such as a clinical interview. The results of the interviews will confirm or disconfirm 'caseness' as determined in stage 1.

For some purposes this two-stage approach may be sufficient. However, if greater precision is desirable, a third assessment procedure can be introduced, preferably using other indices of malfunctioning. This may be a measure of social impairment or some alternative method, such as the use of records.

Either total problem scores or specific syndrome scale scores can be used in these ways. Some individuals who score above the cutpoint of a specific syndrome scale may score below the cutpoint for the total problem score and vice versa. Because selection of individuals based solely on one strategy may miss cases that would have been identified by the other strategy, it may be advantageous to combine both approaches. By doing so not only will the number of cases identified by the procedure be raised (a higher sensitivity), but the number of normal individuals misclassified as disordered will also be raised (lower specificity). This need not be a problem if a higher specificity in the stage 2 assessment is achieved.

Specific questionnaires, generic questionnaires, or both?

When information about only one disorder (such as depression) is sought, it is possible to use a brief questionnaire in stage 1 that is focused only on the condition of interest. However, if a specific selection strategy in stage 1 is chosen, it is important that the stage 2 assessments cover a much broader range of psychopathology otherwise problems that are associated with depression (such as conduct problems or substance abuse; see Rutter, Chapter 28) will be missed.

A question that may arise is whether it is better to use one generic rating scale or multiple specific rating scales at the initial stage of assessment. Most generic rating scales have the option of using the total problem score, the specific syndrome scales, or both, to score each individual. A disadvantage of using multiple instruments that only assess one area (such as depression, anxiety, or hyperactivity) is that each instrument has its own metric and norms, making comparisons difficult, and there may be considerable overlap in the items across the various instruments. Accordingly, we do not advocate the general use of multiple focused scales for screening purposes. An exception when this might be a preferred option is when it is important to detect disorders not well encompassed by syndrome scores and which might not be picked up by a high total score. This might apply, for example, to obsessive-compulsive disorders, Tourette syndrome and anorexia nervosa.

Combining information from multiple informants

For all the reasons discussed here and by Fombonne (Chapter 4) all stages of epidemiological assessment need to be based on multiple informants. The key issue is how best to combine this information. Each strategy for combining the results from multiple informants has its consequences for the sensitivity and specificity of the assessment procedure. If any positive result is accepted, the sensitivity of the procedure will be higher than when all tests need to be positive. The more restrictive the criterion, the lower the sensitivity will be, and the more disturbed the individuals who are selected (Verhulst *et al.* 1994).

There is another way to combine information from different informants by treating the data from rating scales as continuous scores. The problem that different scores will have different metrics can be overcome by transforming the scores for each version into standard scores (z-scores) with a mean of 0 and a standard deviation of 1. It is now possible to compute each individual's mean z-score across the different informant versions of rating scales. By applying a cutpoint to the frequency distribution of this mean score, we can determine the individuals who score above this cutpoint and who may be selected for further evaluation (Verhulst *et al.* 1997).

Clinical applications of rating scales

The application of rating scales need not to be confined to community samples, but can also be applied in routine clinical prac-

tice to assist in decision-making. Many countries have financial or other constraints on the services that can be provided to children and adolescents with mental health problems. Rating scales can help in ensuring that professionals' valuable time is used in the most efficient and productive way. At the time of referral, decisions are needed on whether assessment at this particular clinic is the most appropriate way of proceeding; if it is, what sort of diagnostic assessment should be undertaken, what type of treatment should be provided for how long, what type and degree of improvement should be expected with intervention, and what should be done after treatment?

Clinical practice can benefit from a standardized approach to these various decisions. When decisions are based on explicit rules and procedures, we may improve our ways of helping young people. The series of steps that need to be taken from first contact with the clinic to the time of case closure should be based on an adequate database, and at each point decisions need to be taken on what is needed for that purpose. Clearly, it would not be feasible for everyone to have the fullest evaluation from the most experienced clinicians at all stages. Rather, some sort of filter, or process of triage, is needed to decide which cases need the most extensive and specialized assessments and treatments.

Rating scales can have a useful role in this process. For example, they may be mailed to parents, teachers or the adolescents themselves before first attendance. Many clinicians combine this contact with a request to the family to outline their main concerns and questions that they want addressed. This combination of standardized measurement and open-ended enquiry can be useful in guiding the form of the initial (fuller) evaluation, and it may also assist decisions on which part of the clinical service should be involved.

Once a comprehensive formulation has been made (questionnaires can never provide that), rating scale data can aid in the selection of the key targets for intervention. It has been found that interventions that are effective under research conditions are often much less so under typical clinical conditions (Weisz *et al.* 1992). If standardized assessments are used systematically to identify the target problems that should be matched with the most appropriate treatment, it may be possible to improve the efficacy of interventions in routine practice. Similarly, by monitoring the effects of interventions, it should be possible to decide whether the treatment is being effective or whether a change needs to be considered. Rating scales can have a valuable role in this monitoring because they are quantified and provide measures that are comparable from case to case. The same advantages apply to the assessment of outcome.

How to select a rating scale

In our review of generic rating scales we were more impressed by the similarities among the various scales than we were with their differences. Most cover a roughly similar content, although their extensiveness varies, most have evidence of reliability and validity, most are user-friendly and most can be scored in a com-

prehensive way. However, there are some differences that may be relevant for some purposes. Answers to a series of questions may help in making a choice of which scale to use.

1 Do I need multiple informants? The ASEBA, CSI, CRS-R and the SDQ have versions for parents, teachers and self-report on problems.

2 Do I need a rating scale for early assessment/screening, or do I need one for more extensive evaluation, and will the instrument be completed for one individual or for many individuals by the same informant? Most scales take 10–20 min to complete. The ECBI, PSC, Revised Rutter Scales and the SDQ are much shorter. However, only the Revised Rutter Scales and the SDQ can be scored on specific syndrome scales and not only on a global index of malfunctioning. The CRS-R has both short and long forms.

3 Do I need to assess problems only, or do I need to assess competence as well? The ASEBA, BASC, the Revised Rutter Scales and the SDQ have scales for adaptive functioning.

4 Do I want to obtain ratings that can be scored on DSM-orientated scales, on empirically derived scales, or both? Five instruments have empirically derived scales (ASEBA, BASC, CRS-R, DSMD, RBPC), whereas the other seven have a priori derived scales. The new version of the ASEBA will have both options: the same rating scale can be scored on empirically derived scales as well as on DSM-orientated scales.

5 Are translations of the instrument available in the languages I need? The most widely used scales (ASEBA, CRS-R, Revised Rutter Scales) have the advantage that they are translated in different languages. This is not only an advantage for cross-cultural research but also for the assessment of children from different cultures living in our present day pluriform societies.

6 Are there local norms available for the instrument or not? The ASEBA is probably the instrument with the largest number of normative data from different countries.

7 Do I want to compare my findings with those from others? The most widely used instruments (ASEBA, CRS-R, Revised Rutter Scales) have the most well-documented and published findings with which new findings can be compared.

Challenges and prospects for the future

It is hard to imagine that any future rating scale would be much better than the ones that already exist, or that this new instrument would solve the problems that are probably inherent in the assessment of child psychopathology. Rather than designing new instruments, the challenge for the future lies in the improvement of the construction and, especially, the use of scales. This may come from the application of modern statistical techniques (such as structural equation modelling) and from genetic studies that aim at constructing phenotypes that are more genetically informative. Also, the development of parallel scoring of the same instrument on both empirical and DSM-orientated scales may be a step towards more informative diagnostic information.

There is an increasing need for more standardized assessment

of child psychiatric conditions and for evaluation of treatment. Rating scales can be valuable in clinical practice where research standards are increasingly adopted. Future directions then include the development of methodologies, including the use of rating scales, that will enhance clinical decision making.

Appendix 1

Description of generic screening questionnaires

Achenbach System of Empirically Based Assessment (ASEBA)

The ASEBA (Achenbach 1991a–d, 1992, 1999; McConaughy & Achenbach 1994; Achenbach & Rescorla 1999) are rating scales for assessing psychopathology, social competence and adaptive behaviours. There are separate forms for different ages and for parents, teachers and self-reports. The forms for parents are: the Child Behavior Checklist/2–3 (CBCL/2–3) for ages 2–3 years; and the Child Behavior Checklist/4–18 (CBCL/4–18) for ages 4–18 years. The forms for teachers are: the Caregiver–Teacher Report Form (C-TRF) for ages 2–5 years; and the Teacher’s Report Form (TRF) for ages 5–18 years. The self-report form, the Youth Self-Report (YSR), is for ages 11–18 years. The items for assessing psychopathology are rated on a 3-point scale ranging from ‘Not true’ to ‘Very true or often true’. The items of the CBCL/4–18, TRF and YSR are scored on the eight scales listed in Table 5.1 for ages 4–11 and 12–18 years, although the number of items per scale varies slightly across informants. The items of the CBCL/2–3 and C-TRF are scored on separate scales. For the CBCL/2–3 these scales are Anxious/Depressed, Withdrawn, Sleep Problems, Somatic Complaints, Aggressive Behaviour and Destructive Behaviour. For the C-TRF these scales are Anxious/Obsessive, Depressed/Withdrawn, Fears, Somatic Problems, Immature, Aggressive Behaviour, and Attention Problems. The CBCL/4–18, TRF, YSR, CBCL/2–3 and C-TRF can be scored on the composite scales of Internalizing, Externalizing and Total Problems. CBCL/4–18, TRF and YSR norms for different gender and age groups 4–11 and 12–18 years are based on a representative sample of children who were not referred for mental health services or did not attend special classes in the year prior to data collection. Rating scales can be scored using hand scoring profiles or computer scoring profiles. The computer scoring profiles also gives the level of agreement between informants. Computer software for administering the rating scales is available. The CBCL is translated into nearly 60 languages. The bibliography of published studies using ASEBA (Vignoe *et al.* 1999) lists over 3000 studies.

Behavioral Assessment System for Children (BASC)

The BASC (Reynolds & Kamphaus 1992; Kamphaus *et al.* 1997; Kamphaus *et al.* 1999) are rating scales for assessing psy-

chopathology, self-perceptions and personality. There are separate forms for different ages and for parents, teachers and self-reports (only for perceptions and personality). The Parent Rating Scale (PRS) forms are for ages 2½–5, 6–11 and 12–18 years. The Teacher Rating Scale (TRS) forms are for ages 2½–5, 6–11 and 12–18 years. The self-report forms, the Self-Report of Personality (SRP), are for ages 8–11 and 12–18 years (not listed in Table 5.1). The items of the PRS and TRS are rated on a 4-point scale ranging from ‘Never’ to ‘Almost always’. The items are scored on the scales listed in Table 5.1, with scales and number of items per scale varying slightly across ages and informants. The PRS cannot be scored on the scales Learning Problems, Study Skills, and on the composite scale School Problems. The SRP assesses personality traits; therefore they are not listed here (Reynolds & Kamphaus 1992). Norms for different gender and age groups are based on a representative sample, except for the SRP which was based on convenience samples. Rating scales can be scored using hand scoring profiles or computer scoring profiles. Computer software for administering the rating scales is available.

Child Symptom Inventories (CSI)

The CSI (Gadow & Sprafkin 1996, 1997a,b, 1998, 1999) are rating scales for assessing psychopathology. There are separate forms for different ages and for parents, teachers and self-reports. The forms for parents and teachers are: the Early Childhood Inventory-4 (ECI) for ages 3–5 years, the Child Symptom Inventory-4 (CSI) for ages 6–11 years, the Adolescent Symptom Inventory-4 (ASI) for ages 12–18 years. The self-report form is the Youth’s Inventory-4 (YI) for ages 12–18 years. Most items are rated on a 4-point scale ranging from ‘Never’ to ‘Very often’. Some items are rated with only ‘No’ or ‘Yes’. The items of the CSI are scored on scales representing DSM-IV categories (see Table 5.1). Scales and number of items per scale vary slightly across ages and informants. Norms for different gender and age groups 3–5, 6–11 and 12–18 years are based on samples of children who did not receive special education services. Rating scales can be scored using hand scoring profiles or computer scoring profiles.

Conners’ Rating Scales–Revised (CRS-R)

The CRS-R (Conners 1997; Conners *et al.* 1997, 1998a,b) are rating scales for assessing psychopathology. There are separate forms for different ages and for parents, teachers and self-reports. The form for parents is the Conners’ Parent Rating Scale (CPRS-R:L) for ages 3–17 years. The form for teachers is the Conners’ Teacher Rating Scale (CTRS-R:L) for ages 3–17 years. The self-report form is the Conners/Wells Adolescent Self-Report of Symptoms (CASS:L) for ages 12–17 years. These forms also exist in short versions for parents (CPRS-R:S), teachers (CTRS-R:S) and self-report (CASS:S). The items are rated on a 4-point scale ranging from ‘Not true at all’ to ‘Very much true’. The items of the CRS-R are scored on the scales in Table 5.1,

although scales and number of items per scale vary slightly across ages and informants. The CTRS-R:L does not have a Psychosomatic scale. The items of the CASS:L are scored on different scales than the scales of the CPRS-R:L and the CTRS-R:L. The items of the CASS:L are scored on Family Problems, Emotional Problems, Conduct Problems, Cognitive Problems/Inattention, Anger Control Problems, Hyperactivity, ADHD Index, DSM-IV Symptoms, DSM-IV Inattentive, and DSM-IV Hyperactive-Impulsive. Norms for different gender and age groups 3–5, 6–8, 9–11, 12–14 and 15–17 years are based on representative samples. Rating scales can be scored using hand scoring profiles or computer scoring profiles. Computer software for administering the CRS-R is available. An annotated bibliography (Wainwright 1996) lists over 450 studies.

Devereux Scales of Mental Disorders (DSMD)

The DSMD (Naglieri *et al.* 1994) are rating scales for assessing psychopathology. There are separate versions for different ages and for parent and teachers. The parent and teacher forms are for ages 5–12 and 13–18 years. The items are rated on a 5-point scale ranging from ‘Never’ to ‘Very frequently’. The rating scales are scored on the scales in Table 5.1, although scales and number of items per scale vary slightly across ages and informants. The scale Attention is for ages 5–12 years only, and the scale Delinquency is for ages 13–18 years only. Norms for different gender and age groups 5–11 and 12–18 years are based on a representative sample of children who did not receive special education services. Rating scales can be scored using hand scoring profiles and computer scoring profiles.

Eyberg Child Behaviour Inventory (ECBI) and Sutter–Eyberg Student Behaviour Inventory–Revised (SESBI-R)

The ECBI and SESBI-R (Eyberg & Pincus 1999) are rating scales for assessing disruptive behaviours. There are separate forms for different informants. The form for parents is the ECBI for ages 2–16 years. The form for teachers is the SESBI-R for ages 2–16 years. The items are rated on a 7-point Intensity scale, and on a Problem scale with ‘True’ or ‘False’ answering categories. Norms for different gender groups are based on a representative sample. The rating scale is hand scored.

Millon Adolescent Clinical Inventory (MACI)

The MACI (Millon 1993) is a rating scale for assessing personality and psychopathology. There is only a self-report for ages 13–19 years. The items are rated with ‘True’ or ‘False’ answering categories. The items of the MACI are scored on scales indicating personality traits and scales indicating psychopathology. Only the psychopathology scales are listed in Table 5.1. Norms for different gender and age groups 13–15 and 16–19 years are based on a representative sample. Rating scales can be scored using hand scoring profiles.

Minnesota Multiphasic Personality Inventory–Adolescent (MMPI-A)

The MMPI-A (Butcher *et al.* 1992) is a rating scale for assessing personality and psychopathology. There is only a self-report for ages 14–18 years. The items are rated on ‘True’ or ‘False’ answering categories. The items of the MMPI-A are scored on scales indicating personality traits and scales indicating psychopathology. Only the psychopathology scales are listed in Table 5.1. Norms for different gender groups are based on a representative sample. Rating scales can be scored using hand scoring profiles.

Paediatric Symptom Checklist (PSC)

The PSC (Jellinek *et al.* 1979, 1986; Jellinek & Murphy 1988; Pagano *et al.*, 2000) are rating scales for assessing psychopathology. There are separate versions for different parents and self-reports. The form for parents is for ages 2–16 years. The self-report form is for ages 11–16 years. The items are rated on a 3-point scale ranging from ‘Never’ to ‘Often’. The items of the PSC can only be scored on a Total Problem scale. The rating scale is hand scored. A form for teachers is currently being tested.

Revised Behaviour Problem Checklist (RBPC)

The RBPC (Quay & Peterson 1996) is a rating scale for assessing psychopathology. There is a single form for both parents and teachers for ages 5–18 years. The items are rated on a 3-point scale ranging from ‘Not a problem’ to ‘Severe problem’. The items of the RBPC are scored on the scales in Table 5.1. Norms for different gender and age groups 5–8, 9–11 and 12–13 years are based on samples of children who did not receive special education services. Rating scales can be scored using hand scoring profiles.

Revised Rutter Scales (Rutter)

The Revised Rutter Scales (Rutter *et al.* 1970; Rutter 1976; Elander & Rutter 1996a,b; Hogg *et al.* 1998) are rating scales for assessing psychopathology and prosocial behaviour. There are separate versions for ages 3–5 and 6–16 years, and for parents and teachers. The items are rated on a 3-point scale ranging from ‘Does not apply’ to ‘Certainly applies’. The items of the Revised Rutter Scales are scored on the scales in Table 5.1. Rating scales can be scored using hand scoring sheets.

Strengths and Difficulties Questionnaire (SDQ)

The SDQ (Goodman 1997; Goodman *et al.* 1998; Goodman & Scott 1999) are rating scales for assessing psychopathology and prosocial behaviour. There are separate forms for parents and teachers for ages 4–16 years. The self-report form is for ages 11–16 years. The items are rated on a 3-point scale ranging from

'Not true' to 'Certainly true'. The items of the SDQ are scored on the scales in Table 5.1. Cutpoints for discriminating between normal and clinical cases based on community and clinical samples are available. Rating scales can be scored using hand scoring sheets.

Psychological Testing and Observation

Joseph Sergeant and Eric Taylor

Introduction

The approach of a psychologist to assessing a case is that of an investigator. The first step is to understand and clarify the problem being presented, and from then on the process of assessment is a succession of formulating hypotheses about the nature of the problem, testing them, and modifying the formulation and the intervention plan accordingly. From this perspective, a ‘test’ is any systematic and quantified way of describing behaviour. It may be as highly standardized as an IQ test, or it may be developed and used for the unique problems of an individual case. The rating scale and interview approaches described by Verhulst & Van der Ende (see Chapter 5) and Angold (see Chapter 3) are tests in this sense; so are psychophysiological measures and naturalistic observations. It is important for the assessor to think broadly and creatively about the process of assessment, and to bring together different sources of evidence (see Rutter & Yule, Chapter 7).

The more narrow and traditional definitions of psychological tests concentrate on those procedures and instruments that have been standardized through psychometric refinement, have demonstrated satisfactory reliability, and are known to be valid in giving descriptions of an individual child in relation to the rest of the population or in predicting a specified criterion. Such tests can bring power to clinical inferences, because they allow one to know the accuracy with which a test can be generalized to other circumstances—whether, for instance, it will give the same result if administered again. Some clinical problems lend themselves very well to the use of such batteries: for example, whether a child who is failing to make school progress has an impairment of intellectual function. IQ scales then include a good (but not complete) description of a range of functions. Even then, the essential rationale remains that of testing a falsifiable hypothesis. However, many clinical problems require one to go beyond the boundaries of standardized tests. The assessor will then consult the research literature for suitable measures as well as compendia of established tests (Sattler 2001).

This volume describes many clinical uses of psychological tests and systematic observational schemes. They include contributing to psychiatric diagnosis, as of disorders in the autism spectrum (see Lord & Bailey, Chapter 38); to neurological diagnosis, as in the early stages of dementing disorders (see Goodman, Chapter 14); resolving differences when there are discrepant accounts of a child’s competence or problems, as in the case of hyperactivity (see Schachar & Tannock, Chapter 25);

and differentiating between the various possible causes of a clinical problem, such as reading (see Snowling, Chapter 40). They contribute strongly to decisions outside the mental health services, for instance in helping to determine special needs in education (see Howlin, Chapter 68). Most of them give rise to one or more of a key set of objectives for the assessment process: describing a child’s behaviour or cognitive performance relative to that of other children; predicting the future; determining profiles of performance to indicate whether one ability is out of keeping with others; analysing the reasons for discrepancy between different reports; explaining a behaviour change or cognitive alteration by reference to another level of description; and tracking changes over time.

The development of psychological testing and observation has been a process of making mental assessments more reliable and closer to what they seek to measure. Test developers start from concepts of the mental function they wish to assess. They seek to make the assessments *quantitative*, so that individuals can be ordered according to level of function they show; *standard*, so that the ways assessments are made are constant; *referenced*, so that children can be ordered with respect to the population they come from; and *explicit*—for example, in inter-rater reliability and stability—so that the strengths and limitations of inferences based upon them can be known.

All these are aspirations of other types of assessment too. Investigators developing rating scales (see Verhulst & Van der Ende, Chapter 5) and standardized interviews (see Angold, Chapter 3) have also made explicit their reliability and validity and established normative values. The characteristic quality of tests is that they are also *operational*. That is to say, they seek to obtain more objective data than can be obtained through the filter of descriptions made by people who are already in a relationship with the child. They specify what procedures are to be carried out—for example, what task the child is asked to do—and provide explicit ways of scoring the child’s responses.

Observational methods are not usually so well operationalized (although they can be) and they may be conducted in naturalistic as well as in controlled settings. However, they do provide either control or careful description of the stimulus setting, they substitute a professional observer of known reliability for the involved parent or teacher, and correspondingly they are able to record behaviour more accurately and more precisely. Further, they may be necessary to interpret the validity of test results.

Tests of cognition

Descriptions of individual differences

The key concept in the minds of early developers of cognitive tests was ‘intelligence’ (Binet 1905). There were already many and varying definitions even by that time; but the main notions were the capacity to learn from experience and the ability to adapt successfully to changing environmental demands. More recently, Gregory (1981) has succinctly described intelligence as the creation and understanding of successful novelty.

The tests that were developed therefore used problems that would be novel to a child being tested. They were intended at first for educational purposes. If one knows only that a child is failing in school, there is no way of distinguishing ability from motivation or previous learning experiences. The use of an IQ scale aims to control for previous learning by giving quite unfamiliar and culture-fair problems, and for motivation by providing a standard setting with distractions minimized. If this is successful—and the extent to which it is successful is an empirical question—then a poor score suggests low aptitude.

The study of individual differences in test scores proved to be very productive. Scores were stable over time (see below) and predicted quite well to real-world measures such as examination grades. In turn, the technology of IQ testing altered concepts of intelligence. Long familiarity with IQ scores has led most clinicians tacitly to accept that intelligence is what an IQ score measures, and that it is an important aspect of mental function. This is in some contrast to developing theories of cognitive functioning, which largely reject a unified intellectual capacity, and propose a variety of independent (but cooperating) systems for processing information, or a hierarchy of competencies (Sternberg & Kaufman 1988). Furthermore, the advent of cognitive paradigms in experimental psychology in the 1960s generated a different approach to information processing. This work was theory driven (Broadbent 1971) and could predict human performance in relation to task demands, stimuli, temporal characteristics and the effect of higher order control systems (Sanders 1983). In contrast to the psychometric approach in IQ development (where norms and standardization are key issues), cognitive psychologists showed that task performance on tests and paradigms depended upon whether the task demands were continuously varying or held constant (Shriffrin & Schneider 1977). From this emerged the concept of *controlled* and *automatic* processing, whereby attentional allocation and resource deployment depended upon whether the task was new or old. Later work showed that cognitive resources not only depended upon this distinction but also upon whether in a double task, the child was required to perform attentional switches (Allport & Styles 1997).

The tension between ‘cognitive’ and ‘IQ’ approaches is pervasive. It is one of the reasons that some practitioners have abandoned intellectual testing in their work with children. Yet the practical value of tests is substantial. IQ tests have evolved

through several generations since the original work of Binet and Simon to the modern test batteries described below. The most influential consist of a range of different, short puzzles that require a variety of intellectual operations to solve them. They are given on a one-to-one basis, the child sitting with the examiner in a quiet and distraction-free room. The examiner takes care to establish a rapport with the child, explains what will happen and allays worries about the situation. This usually entails going through the same process with the parent, and explaining why the child is being seen separately from them. General encouragement to performance is given, but not feedback about whether individual answers are correct.

Standardized scores for each subtest are calculated on the basis of the child’s performance and age. The scores show a Gaussian distribution in the population, not because this reflects a fundamental truth about the population but because the tests have been developed in order to give such a distribution. Statistical methods of taxonomy—especially, factor analysis—have been applied to them so that the results from the variety of items can be reduced to a small number of factor scores, and ultimately to a single score, the IQ. The standardization of the tests ensures that these scaled scores will have a mean of 100 and a standard deviation of 15. The IQ score therefore gives an estimate of the individual’s deviation from the population mean. The main such test ‘batteries’ are described below. It is also possible to use the individual subtests as measures of more specific processes, though caution is needed in this. The reliability of an individual subtest is considerably less than that of the scales based on several subtests. Correspondingly, there needs to be a large difference between one subtest score and what is expected from other scores before one can conclude that poor performance on what that subtest measures is a robust description of the child’s ability. Even scale scores can be influenced by many factors, and a trained psychologist’s judgement is needed to interpret them.

Stability of individual differences

Early in the development of IQ tests, longitudinal studies followed individuals with regular testing from infancy into adult life: after the age of about 6 years there were high correlations between test scores at different times, typically of the order 0.8 over 5-year periods (Bayley 1949). The prediction is substantial but incomplete, and individuals can show considerable difference between successive administrations. Nevertheless, Moffitt *et al.* (1993) have analysed trajectories of intellectual development in a longitudinal study of a birth cohort, and have stressed that continuity of individual differences is the rule. When a child has departed from the previous trajectory at a testing point, then he or she is likely to return to the previous level at subsequent testing points. Most change over time is unpredictable and seldom shows evidence of systematic increase or decline.

At the individual level, it is not possible to regard IQ as a fixed capacity. As most change is random, then a child who is far removed from the mean when first tested is likely to be closer to

the mean on subsequent testing. This can be quantified for the group—for instance, if the correlation between two age points is 0.7, then children will regress almost half the distance towards the mean at subsequent testing. This cannot be taken to the individual level, and clinicians should remember that there is change as well as continuity in test scores. When decisions have to be based upon IQ tests (e.g. recommendations about suitable schools) the psychologist should retest and not base judgements on outdated information.

Test scores also predict other qualities of children. Some of these are important only at the extremes of the range. An IQ less than 50, for example, predicts quite strongly that there will be structural abnormalities of the brain, that there will be a much higher prevalence than normal of known medical causes of intellectual retardation, that independent life will not be reached in adulthood, that fertility will be reduced, and so on. For reasons such as these, the categories of intellectual handicap are an important classification of clinical cases and constitute one of the axes of the ICD-10 diagnostic scheme.

Profile analysis

It can be of great help in assessing a case to know that different abilities are out of keeping with one another. For instance, for a child who is failing in school and scoring poorly on IQ tests, it may be very illuminating to know that all the depression of the scores can be accounted for by one factor, such as processing speed. A specific rather than a global impairment is suggested. It helps the child and family to understand the problem, and it suggests strategies to teachers: in this instance, perhaps to relax time pressure.

The distinction of global and specific delays is not exclusive. A child with global delay may still have an extra problem in one type of function, such as language (see Bishop, Chapter 39). Detecting a specific problem in the presence of a global one would be very difficult in the absence of quantified tests for a range of functions.

It is important to remember that this practical value does not depend on acceptance of any one theory. Even those who reject the idea of a unified concept of intelligence, and prefer to think of a number of specific intelligences, will find it valuable to describe children in terms of their strengths and weaknesses. An investigator who is trying to establish whether a particular function is impaired will need to establish whether it is impaired by comparison with other functions. IQ is convenient as a summary description of some of those functions. Its value therefore does not depend upon supposing that it indexes an underlying entity. Indeed, judgement is often needed in deciding exactly what one is controlling for, and therefore on the exact tests to be used. If the aim is to measure short-term memory, then one would want to say that it is (or is not) disproportionate to scores on IQ tests that do not place much load on memory. One is controlling for other aspects of test performance. If memory tests were included in the IQ measure that is used as a control, one would be in danger of controlling out the main subject of study.

Analysis of impaired function

Psychological testing is also used in a more explanatory way. The aim then is to clarify a known problem by reference to a more fundamental level of description. An example would be the testing of a child with poor reading. Not only can the severity of the reading problem be quantified and its severity be shown to be out of proportion to general cognitive development, but it can also be shown to be associated with a finding of specific problems in phonological processing or word recognition (see Snowling, Chapter 40).

The process of understanding a dysfunction often takes the investigator to the research literature, selecting tests from experimental psychology that may not have much normative data. Caution is needed when applying tests, whose validity is known only at the group level, to individuals. This is all the more true when a test is given repeatedly with systematic variation in the way it is given. Experimental control of one aspect of a test is, in theory, a powerful way of analysing a deficit. For example, it might be highly relevant to know that a child had poor performance on a continuous performance test (CPT) of attention when given without incentives, yet a normal performance when correct responses were rapidly rewarded. Experimental tests are often set up in this way for comparing groups. For assessing individuals, the reliability between two administrations of the test should ideally be known. Without this knowledge, test results should be seen as aids to making a clinical formulation, not as direct providers of diagnostic information. Nevertheless, the suggestions made from analysing problems in this way are often illuminating, and can be tested by the consequences of actions based on them.

Descriptions of outcome

Clinicians often wish to quantify change over time—both the natural course of disorder and the response to treatment. Accurate quantification helps not only in detecting subtle differences (e.g. whether attention has improved during a course of stimulant medication) but also in allowing for the fact that the child is maturing over the period of observation. Cognitive tests standardized for different ages are therefore very valuable. They can, however, be confounded by the effects on test scores of repeating the test. ‘Practice’ effects are of various kinds. First, and simplest, the child may remember from one administration to another what the answers were, so that memory rather than problem-solving is being tested on the second occasion. This kind of practice effect is perhaps the easiest for the clinician to manage. Some tests have alternative forms available, so that the second presentation can be of different material but of comparable difficulty. For a well-standardized scale, such as the Wechsler, the effects of repeated testing are known and can be allowed for, both by specifying the minimum time between administrations for them to be valid and by providing tables for the probable limits of practice effects. For less well-standardized tests, even the simple effects of practice may be unknown.

A second kind of practice effect is more fundamental: the child has acquired an insight into how to do tests of this type. For instance, an effective strategy for coding one set of symbols into another may only have been worked out by the end of the first test administration, but is available right from the start of a second. This is best detected by the observation of the alert examiner, who will be noting the way that the child is carrying out the test as well as recording the score.

A third kind of practice effect, particularly affecting attentional performance, is a shift from automatic to controlled processing in the same test. Some tests evoke both automatic and controlled processing, so that the effects of repetition are complex. For example, the Stroop test (see Executive Function, below) is based upon an interference effect between an overlearned and automatic process—reading words such as red, blue, green and yellow—and the controlled process of inhibiting the reading and naming the colour in which they are printed. With repetition the inhibition may become automatic. The converse of the Stroop effect is the phenomenon that controlled attention is independent of past learning and depends upon the child being able to meet changing relations within the task. For example, in one version of the CPT, the letter that has to be identified as a target changes from trial to trial. This places demands upon the child that are different from the version of the CPT in which the target remains constant over the entire series of trials. In the first case there is clearly demanded controlled attention. In the second case the child may learn the target–non-target relations and become swifter in performance as the task progresses. If sufficient trials are given in the constant target condition, a relatively automatic process of detection will develop, which is called an automatic attention response. Thus analysis of the task demands of what is apparently the same test, the CPT, can involve quite different attentional processes, each of which are of interest in themselves. These subtle differences may point to quite different types of deficits in attention, and may vary in different ways over time.

For all these reasons, one should record in detail the previous testing history of the child. Even when carrying out an initial assessment, it is important to find out whether the child has had any previous exposure to the test so that possible practice effects can be allowed for.

Cognitive tests and test batteries

Tests differ in the psychological functions measured and the cognitive theories that underlie them. For example, the Wechsler scales (see below) derive from a psychometric approach. Subscales are derived from factor analysis, and items are chosen partly for the strength of their loadings on specific factors. The aim is to give an economical description of a range of performance scores, and the scales are not necessarily to be reified into specific mental modules. By contrast, more recent scales such as the Kaufman (see below) were developed to reflect more explicitly the theoretical distinctions between different types of cogni-

tive function that have come from experimental psychology. Many cognitive tests are available, and we mention only a few: they are chosen to indicate the range of purposes and methods, and the considerations that enter into the choice of test. To go more deeply into the existing tests, the reader may consult a recent review (e.g. Sparrow & Davis 2000) or text book (e.g. Sattler 2001).

Intellectual functions

The Wechsler Intelligence Scales are the most popular of all the comprehensive and general-purpose test batteries. The Wechsler Preschool and Primary Scale of Intelligence-Revised (WPPSI-R) (Wechsler 1989) is standardized for ages 3–7 years; the Wechsler Intelligence Scale for Children–Third Edition (WISC-III) (Wechsler 1991) for ages 6–16 years; and the Wechsler Adult Intelligence Scale–Third Edition (WAIS-III) (Wechsler 1997) for ages 16–74 years. The extensive data available about them, their translation into a number of languages, and the existence of norms for some countries outside the USA (e.g. for Wechsler 1992a) are all substantial advantages. Each subtest is standardized to a mean of 10 and standard deviation of 3 and has a range of 3 standard deviations on either side of the mean. The two subscales—verbal and performance IQ—and the full scale IQ have means of 100 and standard deviations of 15. The standardization allows quantitative inferences to be made about the significance of discrepancies between the scales and the reliability of differences between two administrations. Figures for judging the reliability of subtest scores on items such as memory have also been published (Ryan *et al.* 2000).

These are, of course, statistical considerations. A ‘significant’ discrepancy means that it is likely to be a reliable description of that child’s performance but it does not in itself imply a pathological cause. Further, a ‘verbal-performance’ distinction is about the type of information that is being presented, not the way it is being handled. Many practitioners prefer to base their interpretations on a four-factor solution: verbal comprehension, perceptual organization, freedom from distractibility and processing speed. These roughly correspond to some clinical distinctions, e.g. groups of children with attention deficit hyperactivity disorder (ADHD) tend to have low scores on ‘freedom from distractibility’, and children with language disabilities tend to score poorly on ‘verbal comprehension’ (Wechsler 1991). However, the match cannot be pushed too far; there is considerable overlap between groups, and individual diagnosis on this basis should not be attempted.

The Wechsler scales have been criticized on various grounds—most pervasively, for lacking a clear theoretical rationale (some perceive this as a strength). Individual items have been criticized for including emotionally laden material, information derived from education, and language-driven instructions. These could reduce its fairness to children from adverse backgrounds or whose native language is different from that of the tester. The corresponding advantage is that it does include important aspects of linguistic and social intelligence for use in groups to

whom they are appropriate. The 3-standard deviation range (either side of the mean) makes it somewhat insensitive to differences at the extremes of the range.

Other tests are also available, some of which avoid some of the disadvantages and are preferred in some situations. The Stanford–Binet Test, Fourth Edition (SB-IV) (Thorndike *et al.* 1986) has the longest pedigree of any test. The norms are good, and extend from age 2 years to adulthood. It shares many of the limitations of the Wechsler, and the linguistic demands of test presentation are considerable. It does have a potential advantage in assessing differences at the top end of the IQ range, and is sometimes used by those assessing gifted children. A version has also been developed for children with visual impairment (Perkins–Binet Test of Intelligence for the Blind; Davis 1980).

The Leiter International Performance Scale–Revised (Roid & Miller 1997) avoids much of the dependence upon language to understand tests—which are presented with pantomime and simple practice items. Its norms extend from age 2 to 20 years and it yields standard scores on scales of reasoning, visualization, attention and memory. It is therefore popular in assessing children with communication problems. Raven’s Progressive Matrices (PM) (Court & Raven 1995) are suitable from age 5 years to adult life. Like the Leiter, the tests can be presented with virtually no spoken language; like the Leiter, they are untimed. PM testing is quicker, but less comprehensive, than most other tests of intellectual function. Both these tests are useful in assessing children with hearing impairment. The Hiskey–Nebraska Test of Learning Aptitude (Hiskey 1966) is particularly intended for hearing-impaired children and has been standardized for them (ages 3–17 years).

The Kaufman Assessment Battery for Children (Kaufman & Kaufman 1983) is firmly based on cognitive theory, and especially on the distinction between sequential processing (involved in processing information that is ordered in time or space) and simultaneous processing (in which several pieces of information are integrated and processed as a whole) (Luria 1980). In practice most ‘simultaneous’ tasks are visuoperceptual, and most ‘sequential’ tasks are verbal or motor; so the theoretical distinctions may be confounded in practice. Other items are derived from Piagetian theory and from Luria’s notions of high-level planning ability (especially decision-making and hypothesis evaluation). The test was standardized on 2000 children in the USA. It covers ages 2–12 years (and the Kaufman Adult and Adolescent Intelligence Test extends the range to adult life). It has been translated into several languages, though not yet standardized for other cultures. Its exclusion of verbal abilities and specific knowledge has made it of particular interest to those working with children with communication disorders. It gives not only Sequential Processing and Simultaneous Processing scales but also a Mental Processing Composite that is equivalent to an IQ score.

The Cognitive Assessment Scale (Naglieri & Das 1997) is another attempt to combine psychometric credibility with satisfying psychological theory, and yields subscales of planning, attention, simultaneous and successive processes, as well as

a Full Scale. It was standardized on 2200 children in the USA, and its validity was tested in several criterion groups. It is too early to assess its full value, and especially the extent to which it will prove culture-fair.

The British Ability Scales (Cook 1988) also include items that are based on current cognitive theories of attention, information processing and memory. The test battery was standardized on 1700 children in the UK, which has made it popular in this country. It covers ages 2–6 years in one form, and 6–18 years in another. It yields scales of verbal (often interpreted as ‘crystallized’) and non-verbal (often interpreted as ‘fluid’) reasoning and spatial ability; there is a general conceptual ability scale (corresponding to IQ) and another general measure from which verbal test scores have been excluded (‘special non-verbal composite’).

Neuropsychological tests

Neuropsychological test batteries base their component tests on theories rather different from those informing IQ tests—those of brain–behaviour relationships (Korkman 1999). Their emphasis in the past has been on those tests that are similar to the adult neuropsychological tests that have shown themselves sensitive to localized neurological disorders, e.g. the Halstead–Reitan battery (Reitan & Wolfson 1993) and Luria Nebraska (Golden 1987). Scepticism has often been expressed about the extent to which this localization is relevant to the problems shown by children with brain abnormalities, for whom the psychological consequences are characterized by plasticity and compensation and by global rather than specific outcomes (Taylor 1991). More recent development of neuropsychological batteries aim to give a broader description of the strengths and weaknesses of cognitive function. The NEPSY (Korkman *et al.* 1997), for example, includes scores for language and communication, sensorimotor functions, visuospatial abilities, learning and memory, and executive functions such as attention and planning. It therefore represents something of a compromise between the psychometrically based tests such as the Wechsler (with their advantage of comprehensiveness) and the more experimental neuropsychological tests (with their advantage of close and detailed analysis of a specific function).

The study of brain–behaviour relationships in cognition is currently undergoing a rapid and exciting change. The correlation of psychological test performance with underlying alterations of the brain has been thrown into revolution by the advent of modern neuroimaging (see Bailey, Chapter 10). Some tests have shown surprisingly strong associations, e.g. tests of attention with size of frontal structures and basal ganglia (Castellanos 1997). It is too soon to know how far this process will go, but it seems to give promise of understanding which functions are carried out in a modular way by particular brain structures, and which (and how) are served by the cooperative working of several brain structures. Such tests are likely to play

an increasingly large part in the future of assessing children psychologically.

The most common neuropsychological functions assessed are the following.

Language

The verbal IQ of the Wechsler can give a general guide. More detailed analyses of language function are available, such as the Clinical Evaluation of Language Fundamentals—Third Edition (CELF-3; Semel *et al.* 1995). Language assessments can make distinctions about types of language impairment, e.g. comprehension, expression and pragmatic use, and quantify the degree of any impairment (see Bishop, Chapter 39).

Memory

Brief tests stressing memory are found in the Wechsler Memory Scales, Binet Short-Term Memory, and the Kaufman tests. More detailed assessment, with some normative data, are provided by the Rivermead Behavioural Memory Test (Wilson *et al.* 1985) which includes useful tests of new learning with non-verbal and motor as well as verbal components; the California Verbal Learning Test—Children’s Version (Delis *et al.* 1993; Elwood 1995) and the Wide Range Attention and Memory and Learning Test (Sheslow & Adams 1990).

Visuospatial skills

Visuospatial processing is included in all the main test batteries. Specific tests are available, but usually add rather little by way of superior standardization or making finer distinctions. However, a motor-free visual perception test may be useful in assessing perceptual processes more specifically (Aliotti & Rajabiun 1991) and the Bender—Gestalt Test (Piotrowski 1995) offers a complementary emphasis on visuomotor integration—though its initial purpose of detecting brain damage would no longer be seen as a valid rationale.

Attention

A large experimental literature has not yet translated itself into well-standardized tests (Sergeant *et al.* 1999). It has been conceptually and practically difficult to distinguish between attention on a test and ability at the test when the only measure available is test performance. Experimental tests are usually presented under strict timing control (usually with a computer) and with manipulation of experimental parameters. Standard automated versions of the CPT are available with age norms (Conners 2000). Simple counts of number of errors will reflect processes other than attention, but analysis of different patterns of error is feasible and may give clues to the presence of such ‘attentional’ problems as overrapid and impulsive responding (see Schachar & Tannock, Chapter 25). Computer batteries exist for tests of attention (de

Sonneville *et al.* 1999) and executive functioning (Robbins *et al.* 1998).

Attention is a behavioural as well as a cognitive construct. Observation of children’s behaviour during testing (see below) is probably the main source of evidence on which judgements about attention are based.

Executive functioning

Since the 1970s, cognitive neuroscientists have stressed study of the active, planning and evaluative systems of cognitive performance (Broadbent 1971; Posner 1978; Shallice 1982; Sanders 1983). Various tests are intended to measure the high-level functions of planning, inhibiting immediate or inappropriate reactions, decision-making and organization. For the most part their standardization is weak. They include the Stroop Colour—Word Test (Stroop 1935), in which a conflict of information is set up (e.g. the word ‘blue’ being printed in red colours), so that successful completion of the test requires one to suppress an ‘obvious’ but wrong response. Like many neuropsychological tests, it is dependent upon a wide variety of processes. Colour perception and reading ability influence performance (Semrud-Clickeman *et al.* 2000; Tannock *et al.* 2000). The interference score derived from the Stroop may not simply reflect a sole process, such as inhibition. Unlike many neuropsychological tests, the Stroop controls for some of the processes: it contains separate information on colour naming and reading.

Other ‘executive function’ tests are intended to test aspects of problem-solving, e.g. the Trail Making and Wisconsin Card Sort Tests (WCST; Berg 1948), especially when an abstract element of thinking before response is required, e.g. Tower of London (TOL; Shallice 1982). A set of tests of this type is available as the CANTAB (Cambridge Neuropsychological Test Automated Battery; Lowe & Rabbitt 1998; Robbins *et al.* 1998; Luciana & Nelson 2000). These computerized tests include set-shifting, working memory, pattern recognition, inhibition and planning. There are developmental trends on these tasks, which have been followed (for example) from age 4–8 years by Luciano & Nelson (1998), but they do not yet have the kind of standardization that would allow for secure inferences about individual children. Tests of planning and organization are embodied in tests such as the Behavioural Assessment of Dysexecutive Syndrome (BADS; Wilson *et al.* 1996), which have been applied essentially to adults with disorders such as schizophrenia but have a face validity for neurodevelopmental disturbances in childhood. (Evans *et al.* 1997; Krabbendam *et al.* 1999). Tests of inhibition are operationalized as ‘stop’ tests, in which a response to a stimulus has to be interrupted after another stimulus has indicated that one should not respond; ‘go–no go’ tests, in which standard signals call for a response but others require the response to be withheld; and ‘delay’ tests, in which a stimulus calls for a response to be emitted only after a period of a few seconds has elapsed (Rubia *et al.* 1999).

Some of these tests are very prone to the practice effect mentioned above. For instance, a child’s performance on the

TOL requires careful clinical observation. In the beginning of such a task, the child has to ‘catch on’ to the sort of planning that is required, so thoughtful reflection is needed before carrying out a sequence of permissible moves. As time passes, the child learns which moves are required or, in the WCST, learns when hearing ‘no’ that the principle for sorting cards has been changed. Once the child has caught on to what ‘the trick’ is, the test no longer measures planning or control over perseveration in the same way. If one repeats the TOL or WCST with the same child, reliability will be found to be low, because the child is often able to recall ‘the trick’. Hence in clinical practice, careful inspection of the performance of the child over time is required to assess at what point planning may have been measured and at what point the trick has been applied. Scores on such tests may over- or underestimate the child’s planning ability.

Executive function tasks are sometimes supposed to draw on a common working memory (Baddeley & Hitch 1974). This assumption has been modified: there may be specific and distinguishable working memory domains (Baddeley 1990). Indeed, Kimberg & Farrach (1993) have argued that performance on the TOL, Stroop and WCST may be managed by separate working memory systems. If this proves to be correct, it would emphasize that the terms ‘executive functioning’ and ‘working memory’ are not homogeneous. This being the case, practical neuropsychological assessment must examine different features of these concepts (Pennington & Ozonoff 1996). A flexible rather than a fixed test battery approach would seem more appropriate to answer issues such as which type of working memory is deficient in children with learning disabilities. If one does not apply sufficiently comprehensive testing with sufficient flexibility to meet the case at hand, one may be replacing one ‘wastepaper basket’ term with another. In summary, choosing a ‘working memory’ task may result in greater heterogeneity than one might expect, but may still validly reflect cognitive-neuropsychological processing. Clinicians should not be surprised when the apparent cross-reliability between tests is not found to be high.

Motor abilities and adaptive function

The organization and coordination of motor tasks is a difficulty for children referred with problems related to dyspraxia. Clinical neurological examination is usually the key tool for assessment. It aims to uncover patterns of incoordination (such as cerebellar ataxia, motor overflow or ideomotor apraxia) as well as underlying causes (such as mild cerebral palsy). Standardized tests of various kinds are available, and are used when the level of incoordination needs to be quantified more precisely (when a test battery of a wide range of fine and gross motor coordination, such as the Henderson & Sugden (1992) Movement ABC, based on the Lincoln Oseretsky, is suitable); or when a specific problem is detected (as by the Fogs tests; Szatmari & Taylor 1984, concentrating on the observation of associated and redundant movements during specified effortful motor tasks).

Quantified motor tests have a particular place in the assessment of the development of younger children, for whom tasks involving complex communication and symbolic understanding are not appropriate. The Griffiths Scales of Mental Development (Griffiths 1970) contain a range of tasks requiring motor skills, and locomotor development constitutes some of the scales of the Revised Denver Developmental Screening Test (Frankenburg & Dodds 1967; Frankenburg *et al.* 1986)

Griffiths and Denver scales also include items that relate to self-care and independence skills. Quantifying these kinds of ‘adaptive function’ are important in assessing the needs of children with global learning disabilities (see Bernard, Chapter 67). The Vineland Adaptive Behaviour Scales (Sparrow *et al.* 1984) are widely used for this purpose, and have a practical advantage in that information can be acquired by parental report as well as by direct examination of the child’s abilities.

Achievement tests

It is often useful to quantify the level of academic achievement—for instance, in reading or mathematics—that a child has attained. Schools do so for many purposes—to assess pupils, teachers and whole school systems—and the methods vary with the aims.

The most common aim in clinical practice is diagnostic—to determine whether the degree of difficulty in (say) reading is above and beyond that which can be attributed to any global cognitive impairment. If there is a specific problem, then detecting it helps in giving advice to young people and their families, and (in many school systems) leads to administrative decisions about provision of special help and placement in special units. For this purpose, the tester is seeking evidence of a discrepancy between achieved scores and those predicted from the age and IQ of the child. In order to do this, one should not rely on impressionistic statements that the child is below expectation, or that the child is so many years behind his or her peers (because the significance of, say, a 2-year discrepancy will be very different at the age of 8 to that of 14 years), or arbitrary statistics such as the ratio of reading age to mental age. These fail to achieve the precision that is the point of quantifying. Regression formulae or expectancy tables should be used to predict the expected level of attainment from age and IQ (Yule 1967) and identify those with an extreme difference between that and the observed level, such as 2 standard errors of prediction below expectation (see Snowling, Chapter 40). The best scales to use for this purpose will be those that have been developed and standardized alongside IQ scales. A tester using the Wechsler Intelligence Scales will usually choose the Wechsler Objective Reading and Numerical Dimensions (Wechsler 1992b, 1996); one using the Kaufman will opt for the Kaufman Test of Educational Achievement (Kaufman & Kaufman 1985).

In educational practice, simple achievement tests are helpful in screening to detect children whose progress is untypical. This is a part of routine good practice in schools, but nationally standardized tests are also valuable as reference points. For this

purpose, the prime consideration will be to choose a test with the best national standardization. The Wide Range Achievement Test (Jastak & Wilkinson 1984) is extensively used and provides both a brief screen and a more comprehensive version analysing types of errors in reading decoding, reading comprehension, mathematics applications, mathematics computation, and spelling. The Neale tests of reading (Neale 1997) are reasonably quick to administer and widely used.

Teachers are often disappointed with the results of psychological testing because they are hoping for a prescriptive approach to guide curriculum and classroom practice for the individual child. There is still a considerable gap between the description of abilities that comes from testing and the decisions about the most helpful remedial approaches. For this reason, many educationists emphasize the approach of curriculum-based assessment (Tucker 1985). This is criterion-based rather than based on what is average for the population; the aim is simply to describe whether or not a young person has mastered what they are expected to learn. The test items should be drawn directly from the curriculum, and assessment is closely bound up with teaching. Such tests are indicative of the level reached rather than diagnostic of the reasons for any impairment.

Social and emotional understanding

Standardized self-reports are valuable tools in an assessment of social and emotional function (see Angold, Chapter 3). Further questions often arise as to how far an abnormality of social behaviour is based on a failure to understand social situations and the expectations of others. Research approaches to this issue can be adapted to the assessment of individuals. ‘Theory of mind’ tests describe the extent to which individuals can understand situations involving the motives and understanding of other people—the extent, for instance, to which they appreciate what will embarrass other people or how they will understand deception. Carefully constructed false-belief tasks have been found to show good test–retest reliability and internal consistency (Hughes *et al.* 2000). They are therefore suitable for individual assessment. The recognition of faux pas has also been assessed with a test showing predictive validity in distinguishing groups of people with and without Asperger disorder (Baron-Cohen *et al.* 1999). Heavey *et al.* (2000) have presented an Awkward Moments Test: an advanced theory of mind task, developed to approximate the demands of real-life mentalizing in able individuals with autism. Excerpts of films showing characters in social situations are presented, with participants required to answer questions on characters’ mental states and on control, non-social questions.

Projective tests are still widely used, in spite of having fared poorly against empirical tests of reliability and validity. The lack of structure, and the difficulty of making quantitative sense out of the enormous number of possible responses, has worked against their utility. When clear and explicit rules for administration and scoring have been applied, then progress can be made. The presentation of projective test materials has been

used as the key operational manipulation in several experimental means of eliciting responses. For example, ‘communication deviance’ can be scored from responses to Thematic Apperception Test material, and was predictive of breakdown in young people at risk for schizophrenia (Doane *et al.* 1981). A specified scoring system for the Rorschach has been introduced (Exner & Weiner 1994), although even the most recent evaluations (Jorgensen *et al.* 2000; Wood *et al.* 2000) have had to conclude that the test is unsuitable for scientifically based assessment. However, the principle that has survived the individual tests is that of providing a standard set of stimuli to elicit the behaviours for professional observation—a principle taken up under ‘Observational approaches’, below.

Cognitive testing in very young children

Several test batteries describe the cognitive abilities of very young and preverbal children: the most commonly used are probably the Bayley Scales of Infant Development, now in their second edition (Bayley 1993). Other tests, such as the Merrill Palmer (Stutsman 1931), are sometimes used but have less satisfactory normative data. The same tests are used to describe the competencies of older children with severe mental retardation. The two uses, however, raise rather different issues.

There are at present serious limitations to the predictive value of cognitive testing when one tries to predict from infancy to later childhood. This can be a pressing clinical issue, because it would often be very useful to know whether a baby with a risk factor for later cognitive development (such as a very low birth weight) is in fact specifically vulnerable. Remedial education could then be started very early for the high-risk group in the hope of preventing the later sequelae. The hope has not yet been translated into reality, partly because of a lack of strong predictors from infancy to cognitive abilities in later childhood. The difficulty does not arise from lack of measures for infant development, nor from lack of reliability in those tests (Bayley 1993). Indeed, there is a respectable measure of agreement between different types of developmental assessment when carried out in children aged 1 year (Raggio *et al.* 1994). Rather, the problem seems to be that the abilities that are assessed in early development (such as sensorimotor coordination) have rather little to do with the symbolic cognitive operations that are assessed in later childhood.

The situation is improving with further research. More recently developed measures for infants, such as those of visual information processing and means–ends problem-solving show significant correlations with IQ in later childhood (Slater 1995). They have clarified some of the reason for poor predictiveness of traditional tests. For example, habituation to sensory stimuli at the age of 4–8 months is not a stable trait. It does not predict similar measures taken at the age of 3 years. It does, however, predict developmental quotients at the age of 3 years quite well (McCall & Carriger 1993). The apparent paradox—that an unstable test can have predictive validity—emphasizes that a test

such as habituation indexes different psychological functions at different ages.

The new generation of tests in infancy may well come to be applicable on a routine clinical basis, though at present it is difficult to achieve robust and reliable descriptions of individuals because of marked fluctuations in scores depending on the state of the infant. Nevertheless, the prediction of later impairment is still rather too weak to be a basis for selecting children for intervention. Practically, the best predictors of cognitive outcome in very high-risk groups remain neurological signs, or neuroimaging tests of the extent to which the physical structure of the brain has been altered by perinatal hazards (Stewart *et al.* 1999).

The assessment of older children at very low levels of function raises different issues. Nearly all such children have diffuse structural abnormalities of the brain, and the cognitive consequences are complex. The tests are highly predictive of later cognitive functioning at this extreme of the range. However, individual tests have rather little in common. Gould (1977), for example, found very little association between measures of social maturity, visuospatial skills not involving symbolic concepts, and level of language comprehension in an epidemiological study of young people with severe disability. The discrepancies probably reflect the true situation of the children, and underline the importance of understanding the range of strengths and weaknesses that they present.

Special testing situations

Every child needs individual consideration; the tests and observations to be used will need to reflect not only the presenting problems, but the effect that testing is having on the children, their developmental level and ability to understand test expectations, and their willingness to comply with them. The length and difficulty of tests need to be taken into account: if difficult items are presented too early in the course of an assessment, or if children are asked to persist for too long at test items that are too hard for them, then they may become demotivated. The extent to which tests are giving a valid description of the individual needs always to be considered; the issues involved in doing so are described by Rutter & Yule (Chapter 7).

The clinician is often confronted with situations where for one reason or another the standard approach to testing needs to be modified considerably. For example, sensory or motor impairments can have their own influence on cognitive tests. At the simplest, the professional making the assessment needs to check that children do indeed have the spectacles or hearing aids that they may need for adequate performance; and to be alert throughout the assessment for signs that a superficially cognitive difficulty (for example, of detecting fine differences between pictures) may be caused by a sensory impairment (in this instance, diminished visual acuity). Sometimes, more meaningful scores may be obtained by special procedures. For example, inability to follow spoken instructions may be bypassed by the choice of a test (such as Raven's Progressive Matrices) where very little such instruction is needed, or by a test battery (such as the Leiter) that

is designed to be fair to children with sensory impairments—and therefore covers a narrower range of intellectual skills. Children with severe motor disability may need to be helped to a signalling system before their cognitive strengths and weaknesses can be fairly assessed, and reliance may have to be placed on tests (such as Raven's Matrices) where the answer is a choice from a limited range of alternatives and can be indicated through many different kinds of motor response. Clumsy children may obtain low scores on tests where speed of reaction is being assessed, merely because their motor responses take longer, and it may be wise to discount such tests in making the overall cognitive assessment. Very shy children, or those with selective mutism, may need to write down their responses or whisper them without eye contact with the tester. Care must be taken to indicate the limits of confidence that there may be in non-standard testing; but creative use of cognitive test materials has sometimes been able to show the presence of high ability in children whose sensory or motor impairments have previously prevented the abilities from being shown, and this rightly guides formulation of their special needs in education.

Observational approaches

As already indicated, observation of behaviour is always an important part of psychological testing. Observation can also be applied in many situations where testing is not feasible, and its reliability and validity need be no less.

The most explicit schemes of observation provide an experimental control of the environment and give standard stimuli to evoke informative behaviour. In a clinic or laboratory setting, specific tasks are imposed on the child and defined types of response are elicited. For example, Ainsworth's Strange Situation Test (see O'Connor, Chapter 46) has been the foundation of attachment research. In clinics it is seldom appropriate for it to be used in its exact experimental form, but observations of children reacting to a contrived separation and reunion are used extensively to inform judgements about the nature of the children's attachment to their parents.

The Autism Diagnostic Observational Schedule (ADOS; Lord *et al.* 2000; see Lord & Bailey, Chapter 38) is a good example of an observational scheme that is based on specified operations by the examiner (for example, providing a variety of standard stimuli and social presses) and explicit descriptions of the behavioural responses that are to be made. It was originally introduced for research purposes, and its high interrater and test-retest reliability, and its ability to discriminate well between autistic people and people with different diagnoses, have led to its adoption in clinical practice.

Kagan (1997) has reviewed an extensive series of studies based on the direct observation of young children's behavioural reaction to the standardized presentation of unfamiliar stimuli. Four-month-old infants who show a low threshold for becoming distressed and motorically aroused to unfamiliar stimuli are more likely than others to become fearful and subdued during

early childhood; whereas infants who show a high arousal threshold are more likely to become bold and sociable. Observed inhibition in this method has made predictions to later anxiety, even though only a small proportion of children maintain a consistently inhibited or uninhibited phenotype through their childhood (Kagan *et al.* 1998). Clinical application so far has been limited by the variability that individual children show over time on the measure.

Several observational schemes for inattentive and overactive behaviours have been presented; they have been reviewed by Luk (1985). In general, they have made rather less use of careful control of what social presses are imposed by the examiner, but specify the expectations that are on the child (e.g. by observation during psychological testing). The schemes have mostly been used in research, e.g. to describe the alteration in spontaneous activities of children in classrooms (Schachar *et al.* 1986), playroom and testing situations (Luk *et al.* 1987), controlled settings with parents (Kalverboer 1971) and interview with a psychiatrist (Dienske *et al.* 1985). In these studies they discriminate well between children with ADHD and healthy controls, and predict to questionnaire and interview measures. They gain something in ‘ecological validity’ by being based on naturally occurring events, but correspondingly lose the clarity of interpretation that comes from experiment.

Attempts to combine both sets of virtues have involved the careful description of a limited set of frequently occurring events (e.g. mother giving an instruction to child) so that the child’s reactions to those events can be clearly specified (Dunn & Kendrick 1980; Bates *et al.* 1985). Very large amounts of data are sometimes generated, so that analysis may become very complex. The techniques have therefore been limited to research applications, but the conclusions about process may well give good ideas to clinicians about what to look for; e.g. when interviewing and observing families, to note especially sequences in which the child has been asked to do something and has in fact done it, so as to record the consequence of compliance.

Most of these clinical applications of observational techniques are based on ratings that take into account the function and purpose of the behaviour. These qualitative ratings can be very reliable, but usually require training of the raters to make them so. They are needed because molecular descriptions of acts are usually rather unilluminating without their context. It is not only the speed of an action that determines whether it is impulsive, but whether it is too rapid to allow appraisal of the situation; therefore it depends on the amount of uncertainty in what response should be made. It is not just whether a child points at an object that is important in his or her appraisal of it; it is also whether that pointing includes the social function of indicating it to somebody else.

In some situations, however, systematic observation is trying to quantify a rather simple act. The frequency of tics may be important to note, so as to gauge the impact of a treatment; or the number of times a child strikes him- or herself may be an important dependent variable for understanding how different contingencies affect the self-injury. There is then a choice of

techniques: recording during a set interval how often the behaviour has happened, or sampling brief periods over a session to record whether or not it has occurred at each point. The decision will depend on the properties of the behaviour. If it fluctuates considerably over time (as tics may) then the counting of events during one time period may be seriously unrepresentative, and short intervals scattered throughout a longer period may be substantially more reliable. If the behaviour is infrequent then a succession of very short samples may not elicit enough events for a reliable estimate.

Clinical applications of observational analysis

Clarifying rater and source effects

In clinical practice, observation is sometimes used as the gold standard when there is discrepancy between sources of information. For example, a parent may say that a child is well-behaved but cannot concentrate, while a teacher says that the same child is able to concentrate but chooses not to; so the clinician decides to go to the classroom to decide for him- or herself. The simple question of ‘who is correct?’ often underestimates the complexity of what the professional observer strives to do. In the first place, the method has important limitations as well as strengths. It may be based on a very atypical period of observation; the observer may alter the behaviour unknowingly, and allowance needs to be made for this.

In the second place, the observer is not only trying to establish who is right but the reasons for the discrepancy. It will probably be very useful for the observer to check with the real life rater whether they are giving different meanings to the same behaviour, or referring to different behaviours shown on different occasions by the same child. In the above example, both parent and teacher may be observing the same thing—a high level of off-task activity; whether it is construed as disability or choice may stem from the significance attached to the observations. The raters’ accounts might be strongly coloured by their own personal circumstances or their relationship with the child. It may then be useful to explore what different actions would result from the theoretical expectations—how, for example, parents might provide incentives to test the idea that motivation would alter performance; or how the teacher might test the idea of a disability by presenting materials to be learned in a simplified and clearer way.

The third and most fundamental reason for regarding ‘who is correct?’ as an oversimplified question is that different accounts by different observers can reflect important situational influences. The reasons underlying situational differences in behaviour can be crucial clues to the nature of a child’s problems. For example, a child may be referred because of a massive recent deterioration in school performance; no emotional problems are apparent, and the first working hypothesis, of cognitive impairment, is provisionally disconfirmed by good performance at

the clinic on tests of intellectual aptitude and executive dysfunction. This does not mean that there is 'no real problem'. The next set of hypotheses should then relate to the reasons for the discrepancy: is it associated with the kind of test that is performed, the place it is carried out in, or the contingencies attending the way it is carried out? In one such example, the next step was to arrange for academic tasks (solving mathematics problems) and an attentional task (deleting the 'e's from a prose passage) to be performed in three settings: the clinic; the regular classroom; and the same classroom during a visit from the clinic psychologist. Both tasks were performed much less well in the classroom than the clinic, but the performance at school was as good as in the clinic when the psychologist was seen to be present. The discrepancy between school and clinic appeared not to lie in the precise nature of the tests used in the different settings, nor in the generic qualities of the settings, but in the degree to which the child received the attention of an adult. The provisional recommendation was therefore for enhanced monitoring in the classroom, and indeed intermittent individual attention from an aide quickly led to a resumption of good academic progress. The finding also led to another set of hypotheses about why performance should have been selectively affected—whether adult attention was providing monitoring or safety or warmth of interest—and therefore to reinvestigation of psychosocial stresses (in this case, a neighbourhood feud had spilled into the school setting). The general point is that the interactions between child traits and environments can often be understood from the effects of contrasting environmental circumstances. A functional analysis of a behaviour problem—which is often the purpose of making observations in natural settings—requires specification of the antecedents and consequences of the behaviour in the environment (see Herbert, Chapter 53).

It follows that the observations carried out at a school or home visit should not only focus on the child but also on the qualities of the environment. At school, one should note not only the child's scholastic behaviour and relationships with peers and teacher but also the organization of the classroom. In elementary class, can the child see a record of their achievement (such as a points system), and are examples of their good work on display? Do they know the activity to engage in, and are they in a position where their activity can readily be monitored by the teacher? Is the atmosphere of class and school one of safety and constructive activity? At home, is there a cognitively stimulating environment with toys or books? Are there rules for conduct and can caregivers tell what children are doing? What is the affective tone in exchanges between parents and children and between siblings?

Naturalistic observations can be distorted by the accidents of what salient events happen to take place during the visit, and it can be hard to be sure of the sequence of events in an escalating situation: did the child protest at an instruction about behaviour or was the instruction in response to the beginning of rebellion? It is therefore helpful, when possible, to give particular notice to how the child reacts to contrived or independent events. For

example, transitions between activities in the classroom are a high-risk point for disruptive behaviour, so in investigating this problem the teacher can be asked to introduce an activity change. Similarly, at home, the parent would be asked to introduce a press for an unwelcome activity (such as 'tidy up your toys now') so that the nature and consequences of compliance can be seen. As ever, it is necessary to check whether the sequence of behaviours that has been observed has been typical of what would normally occur in that situation.

Observational analyses of some clinical problems extend to a quasi-experimental use of specified procedures. A closely specified challenge can be inserted into a period of naturalistic observation. For example, intellectually impaired children who show challenging behaviours may have learned them in diverse ways (see Volkmar & Dykens, Chapter 41). Some may have learned to continue injuring themselves because the behaviour has been rewarded by the attention of others, some because self-injury serves to help them escape from unwelcome tasks, and some because the self-stimulation involved is inherently rewarding to them. It may not be obvious which of these apply in a particular situation, and the consequences matter a good deal. If a behavioural programme involves withdrawing contingent attention through a time-out procedure (see Herbert, Chapter 53) and if the true rewarder in the situation is escaping from school work, then the time-out may be a strong reward and perpetuate the problem. Accordingly, it is possible to introduce escape or contingent attention as consequences of self-injury during an extended period of observation and examine the effects (Sturme *et al.* 1988). The method is laborious because of the need for repetition of observations, and it is not always possible to be certain that these 'analogue observations' are representative of real life; but it can be a helpful guide to practice in difficult and refractory situations.

Clarifying discrepancies between test scores

Discrepancies between performance scores on tests may be illuminating in clarifying the nature of a problem—for instance, in detecting specific learning disorders. However, interpretation is often uncertain because of the imperfect reliability in test scores and the corresponding uncertainties about how far apparent differences are clinically meaningful. Observation is then a useful means of helping to determine the validity of test scores. For example, it may be apparent that a poor score on one subtest was associated with an uninterested and uncooperative attitude towards it. The tester may then do much more than usual by way of coaxing a good performance, or repeating it on another occasion—with, of course, the note that it was obtained in non-standard ways; and may interpret the difference as secondary to motivational factors.

Observation may suggest new functions to be tested. For example, a boy was referred for assessment some years after an episode of severe encephalitis. Even after apparent neurological recovery, he was quite unable to cope with the classwork in his academically orientated school. Extensive testing of intellectual

function showed no deficit: although premorbid testing was not available, he tested in the superior or very superior range on all tests given. The possibility of a breakdown in his confidence was entertained, but incidental observation and the description of his family both emphasized how muddled and disorganized he could be in simple everyday tasks, such as getting his outdoor clothes to go home—even though all tests relating to dyspraxia, attention and memory had shown better than average scores. He was therefore observed while carrying out several simple tasks simultaneously; and there was a marked disability in doing this that was not present when he was asked to carry them out successively. It appeared that he had an executive type of dysfunction in which the allocation of effort to tasks was uncontrolled. Statistical significance on this would have been hard to obtain, in that it would have required larger number of observations than could be obtained feasibly. Accordingly, the testing of the hypothesis was by the response to intervention. The result was in a sense encouraging, because careful breaking down of academic tasks into components helped performance of them substantially. But the disability remained, the burden of the intervention on teachers in a mainstream school was unsustainable, and specialist education was sought.

Examining relationships between functions

Systematic observation may assist in disentangling the relationships between different psychological processes, especially when they are hard to detect by rating scales and interviews. For example, an adolescent with Tourette disorder was referred because of recurrent transient episodes of great distress, but found it hard to describe the changes of his mood and the reasons for them, and the relationship between them and his tics was correspondingly difficult to formulate. Psychophysiological recordings of skin conductance and heart rate were carried out simultaneously with event recording of tics, and showed consistent marked increases immediately after bouts of tics—interpreted (in discussion with him) as indicating increased emotionality (associated with a distressed feeling that he had failed to control them and would be in trouble). This is not a usual pattern; more commonly, in our experience, children report a sense of tension as they strive to suppress the tics and even a sense of relief after a bout is finished. For him, it suggested an approach to treatment in which he practised coping skills while watching videos of himself during tics and was praised by parents for his courage in ignoring adverse comments by others. Although the tics continued a poorly controlled and fluctuating course, he described himself as less distressed and better able to cope with perceived teasing.

Description of outcome

Observed behaviour is often less vulnerable than cognitive tests to repeated administration. A lack of standardization may not be a serious problem for this purpose, because children act as

their own controls. Observation is particularly helpful when rating scales do not give the fineness of discrimination that is sometimes required. For example, rating scales made by teachers and parents for a boy of 6 years who had started on stimulant medication indicated that he was quieter and possibly more withdrawn in social situations. The question therefore arose of whether this was an adverse effect or an acceptable part of the package of drug action. It was possible that the behavioural descriptions described a more clinging and dependent style of interaction, or a lack of spontaneous interactions. Attachment behaviour was therefore observed by ratings during separation and reunion, analogous to the Strange Situation Test, and peer behaviour in a playroom situation with neighbourhood friends; both were recorded on and off medication by a clinical student who was blind to the treatment condition. Attachment measures did not show a change. Observations of approaches to peers and shared play with peers indicated that they were actually higher during medication. The description of quietness was confirmed, but it related to a diminution of loudness of speech and disinhibited behaviour, rather than to a lack of spontaneity. The conclusion was that the social change was unlikely to be harmful and did not constitute an indication for stopping medication. Conversely, clinical observation that a medicated child is socially unspontaneous, or perseverative in attention, may be crucial in detecting an adverse effect that is not apparent in everyday monitoring at school, where perseverativeness may be confused with enhanced attention.

Inferences from tests and observations

In the course of this chapter we have described tests and observational methods that can provide incremental knowledge by which a clinician can conclude that working hypotheses about the nature of children's problems are supported or rejected. This is an approach, not a diagnostic protocol. The way in which a clinician should organize tests to come to evidence-based decisions is guided by judgement and a clear sense of the questions that need to be answered. In other areas of medicine, there has been a considerable body of research on how clinicians gather and evaluate information. This knowledge base has not been applied systematically to child mental health issues, so this section briefly mentions some of the cognitive heuristics that are useful to bear in mind.

One common cognitive heuristic is *representativeness*. By this is meant that incoming information is processed primarily on the similarity it has with a particular class of information. For example, the clinician seeks to place incoming data (such as symptoms and signs) into a limited number of classes (syndromes). Psychiatrists and clinical psychologists are trained to detect symptoms that could be part of a prototype (Genero & Cantor 1987). A bias can arise if symptom variance is underestimated. Clinicians may overestimate the extent to which the symptoms agree with the prototype or syndrome, seeking confirmatory instances and not disproof. For training purposes, the

use of distinctive prototypes is a good starting point, but needs to be varied to show the full range of cases involved in the syndrome (Horowitz *et al.* 1979). The clinician then learns to make sure that the assessment is comprehensive, and has not stopped at the recognition of a prototype but has gone on to understand what is out of keeping with the prototype and what further problems are present.

Once a first impression has been formed, it can be hard to change it. ‘Anchoring’ refers to the potential problem that perceptions can become rigid as a result of the initial impression that one has made of a client. Friedlander & Stockman (1983) found that pathology that appeared late in a series of interviews had much less impact on diagnostic decisions than when it appeared early in the series. In short, we need to stay alert to new information that should force us to revise and review the case.

Prior conceptions have been shown to influence the interpretation which diagnosticians place on test results. An illusory association is constructed between a test result and a diagnosis, which can be hard to change. A study that neatly illustrates the problem of erroneous diagnostic observation was conducted over 30 years ago by Chapman & Chapman (1967). Novices tried to match responses on a projective test (Draw-a-Person) with a set of contrived symptoms. In one sense, they were successful, in that they produced the same associations between responses and symptoms as the experts, but in the experimental design the symptoms had been contrived so as to have no actual association with the responses at all. Apparent reliability between raters was achieved, but the validity of their ratings was zero.

Similarly, Golding & Rorer (1972) repeatedly presented to subjects an individual Rorschach response and asked them to predict what symptom was associated with the response. They were given immediate feedback on their decision and informed of the actual symptoms of the patient—which of course did not necessarily correspond. Despite this there persisted a strong illusion of an association between the Rorschach response and the actual symptoms of the patient. The remedy for the clinician is to remain open to the empirical reality of the case in spite of the temptations to theoretical overconfidence.

Fischhoff & Lichtenstein (1978) discussed how prediction of events was influenced by the knowledge that the event had occurred. This effect has been confirmed by Arkes *et al.* (1981). They showed that trained physicians, when required to diagnose one of four possible illnesses, were just as susceptible to hindsight bias as had been found by Fischhoff when using students. Those who knew the actual diagnosis overestimated the likelihood that they would have been able to predict the correct diagnosis had they been asked to do so beforehand. Even experienced clinicians have also been shown to suffer from this bias when dealing with patients who later commit suicide (Goggin & Range 1985). Systematic evaluation of one’s practice is an essential way of counteracting misleading subjective impressions.

Another important consideration in the interpretation of tests

is the application of understanding about base rates (see Rutter & Yule, Chapter 7). The significance that clinicians attach to an abnormal test result can be influenced by a variety of factors, one being the frequency with which they encounter it. Most clinicians work on the basis of the frequency with which they see the combination of a clinical problem and an abnormal test result, rather than the *relative* frequencies of an abnormal test in the presence or absence of the problem. For example, if clinicians are asked to judge the likelihood of pneumonia from an X-ray, a preliminary diagnosis can be given. When they are further provided with information on the sensitivity and specificity of the test and the prevalence of the disease and asked to estimate the predictive value (positive and negative), the prevalence tends to be ignored in their estimations (Casscells *et al.* 1978). Clinicians generally use frequency as a major principle guiding retrieval of information, so it is important that they school themselves to base their judgements about the significance of a test on the relative frequency.

Another important cognitive heuristic is *comprehensiveness*. This is intended to overcome one of the common errors in judgement—to focus too narrowly on one aspect of a complex case. Problem behaviour does not come packed in neat parcels. Comorbidity, correlated dimensions, and associated features have become much better recognized over the last 15 years and are dealt with by Fombonne (see Chapter 4), Verhulst & Van der Ende (see Chapter 5), Rutter (see Chapter 19) and Taylor & Rutter (see Chapter 1). This development implies that the assessment procedure must be sufficiently comprehensive in order to detect correlated dimensional problems, at the least, and to be aware that exceptions can occur that require probing for non-correlated conditions. For example, the clinician can use a standardized diagnostic interview that covers at least the most common presenting problems.

Comprehensive problem definition implies that the clinical problem as presented needs to be assessed at a variety of levels, including clinical syndrome; severity of impairment; somatic condition; personality; cognitive performance; social skills; and emotional processing (to name but a few). The problem then arises of how to square comprehensiveness with the costs of assessment? It is obvious that choices will have to be made. One policy (not recommended here) is to assess only that which is necessary for a particular treatment. One confirms a hypothesis, but rejects none of the alternatives and misses fundamental explanatory factors. Part of this issue can be solved by using ‘screeners’ for covering a wide range of pathology and psychological dysfunctioning.

The cognitive heuristics discussed above clearly spell out the message that empirical support for one’s hunches is required. They also have a second message: searching only to confirm a hunch exposes one to finding only what one expects. For most of the possible biases mentioned above, the remedy is the adoption of an investigative and hypothesis-testing approach, with a critical willingness to revise hypotheses about the nature of a problem that do not fit the data (see Rutter & Yule, Chapter 7).

Conclusions

In this chapter we have attempted to indicate the use of tests, tasks and observation in the diagnostic process. Further, we have touched on the cognitive biases which operate in the interpretation of the psychological assessment. We note that one of the major differences between classical psychometric tests and cognitive tasks is that the latter are theory driven. From the neuropsychological perspective, cognitive tests are linked to complex brain networks and not specific brain loci.

While cognitive heuristics have their dangers, when conditions are met and they are applied, these heuristics can be effective tools in clinical work. It seems likely that the future will bring an increase in their clinical use, especially as neurodevelopmental disorders are seen to depend strongly upon alterations of cognitive processing. However, their very strength can lead to their application in inappropriate conditions. It is this last point where the expert can excel the novice in detecting whether the cognitive heuristics are producing answers that are acceptable. This in turn is determined by the theoretical position, model or hypotheses being generated. Tests and observations are simply means to assess whether the assumptions and hypotheses about a case are being met. This requires insight into when or when not to use a test or task for a particular purpose and under which state they may or may not be applied. Consequently, child psychiatrist and psychologist need to work hand in hand in developing the rules and criteria for which tests can be applied to test specific aims. Standardized batteries depend for their application not on a slavish philosophy of assessment but on a critical definition of purpose, conditions, intervening variables and criteria. This places clinical diagnostics into the realm where it belongs: of critical cognitive processing.

Applied Scientific Thinking in Clinical Assessment

Michael Rutter and William Yule

Concepts of applied science

Both clinical psychology and clinical psychiatry (together with the rest of medicine) aspire to being applied sciences (Shapiro 1957; Kennedy & Llewelyn 2001; Rutter 1975; Yule 1989; see also Taylor & Rutter, Chapter 1). This does not mean that clinical practice only involves the use of scientific methods and scientific knowledge; interpersonal skills, and social sensitivity, are also crucially important. Intuition and experience constitute key elements in assessment, as well as in the planning and undertaking of treatment. Moreover, there are many points during the clinical process when either ethical considerations or value judgements have to be made. The current debate on whether tricyclic medication or selective serotonin uptake inhibitors should be the drug of first choice in treating depression in adults well illustrates the considerations that have to go into the interpretation of empirical findings (Barbui & Hotopf 2001; Thompson 2001). Findings on efficacy are fundamental but the choice of drug needs to be influenced also by side-effects, patient acceptability, and cost.

The concept of an applied science does not mean that practice has to be based just on 'facts'. It is a common misunderstanding that science is an enterprise defined by its production of factual knowledge. Rather, science constitutes a way of thinking and a set of approaches that is concerned with solving problems—with formulating hypotheses, putting these together in an integrated and cohesive notion of how nature might operate (a theory) and in finding ways of putting those ideas to the test. Scientific study does provide immensely useful findings but knowledge is always partial. It has been said that of the 'facts' learned during training, a third will prove to be true, a third will subsequently be shown to be wrong, and a further third will be found to be irrelevant. More importantly, scientific advances mean that during the course of a professional lifetime, clinical practice will change, and will need to change, as a result of the understanding and clinical opportunities that derive from research (Rutter 1998, 1999, 2000).

First and foremost, clinical training has to involve the acquisition of a large amount of factual knowledge because of the basic requirement that clinicians must function in ways that are both safe and effective. However, there are two other needs that are almost as important. First, training involves a considerable focus on experimental psychology, neurophysiology, neuroscience and biology. In addition, psychiatric training includes

systematic learning about pharmacology, neurology and internal medicine as they impinge on the workings of the brain and the functioning of the mind. This is not primarily because such knowledge is of immediate clinical importance: indeed, rather little is. Rather, it is because it provides a rich source of ideas about the ways in which nature operates and which might apply to clinical problems. It is likely, if not actually certain, that much of this knowledge will lead to clinical advances during the course of people's working years.

Secondly, in the course of their clinical lifetime, people will need to practise on the basis of new knowledge derived from research since they completed their formal training. They will have to cope with a flood of claims and counterclaims and an essential part of training is to enable people to understand enough about research for them to evaluate research evidence and its clinical implications—not just on the basis of the hyperbole of the evangelists, but on the basis of their own assessment of the quality of the evidence and of how it might, or should, alter what they do clinically. This applies, not just to psychologists and psychiatrists, but to nurses, social workers and psychotherapists; indeed to all clinicians.

These broad issues pervade the whole of this book. In this chapter, we concentrate on the narrower issue of how the concept of clinical psychology and psychiatry as applied sciences impinges on clinical assessment as applied to children and adolescents. We argue that the key defining feature is the use of experimental concepts and stratagems in the planning and undertaking of clinical assessment. The starting point has to be some type of clinical question. That is so whether the assessment is designed to lead to diagnosis, to the design of treatments, or to their evaluation (Mash & Terdal 1981). Psychiatrists are irritated by referrals that simply say, 'This is John Brown. Please see and advise.' Psychologists, equally, take exception to requests that just state that the referral is for 'IQ testing' or 'tests of language'. That is not to say that there is not a place for screening assessments of various kinds. Some form of medical screening is desirable in all clinical referrals, and some medical investigations should be undertaken as a routine (see Bailey, Chapter 10). For example, assessments of hearing and vision, and screening for chromosomal abnormalities, should be part of the routine in the case of all children referred for serious developmental disorders. In the same way, the high frequency with which psychopathology is associated with scholastic retardation and/or cognitive deficits means that screening for them should be a routine matter in clinical assessment.

This may be carried out through obtaining information from schools, or clinics may choose to undertake some form of screening testing.

Nevertheless, a clinical question should constitute the starting point for most referrals for clinical assessment—either psychological or psychiatric. An applied scientific approach, we suggest, involves several key elements. First, there is a need to identify the key clinical issues. Those may be implicit or explicit in the clinical question posed but the starting point, nevertheless, needs to be a reconsideration and reconceptualization of those clinical issues. The second, and most basic step, constitutes the translation of the clinical issues into testable questions. These necessarily involve a consideration of alternative hypotheses and a decision on how one hypothesis may be pitted against another (Rutter *et al.*, 2001). Naturally, that requires a knowledge of the range of possible stratagems that may be employed for this purpose. This is the essence of experimental thinking.

For this testing to be undertaken satisfactorily, the clinician needs to consider how to ensure that the testing will be based on high-quality data that are relevant to this individual and which have the appropriate meaning in relation to the clinical issues being considered. Some of the key technical issues that concern psychometric testing, the development of diagnostic interviews, the construction of questionnaires, and the use of medical testing and investigations, are considered in other chapters and will not be discussed further here (see Sergeant & Taylor, Chapter 6; Angold, Chapter 3; Verhulst & Van der Ende, Chapter 5; Bailey, Chapter 10). The main principles apply to clinical work with all age groups but the assessment of children involves, in addition, the need to adopt a developmental perspective. This requires a good understanding of developmental psychology (Rutter & Rutter 1993) and of developmental psychopathology (Rutter & Sroufe 2000).

Fombonne (see Chapter 4) discusses how all of these need to be put together for case identification and Rutter & Taylor (see Chapter 2) consider how this fits into an overall approach to clinical assessment and diagnostic formulations. Here we focus more narrowly on the special considerations with respect to data quality as they apply to experimental or applied scientific approaches in clinical evaluation.

Hypothesis testing almost always requires some form of quantification. That is because the essence of an experiment lies in the manipulation of one variable, under controlled conditions, to determine if, in a systematic and regular fashion (as shown across a range of varying conditions) this causes another variable to ‘move’. This can only be carried out if there is a way of determining that the initial ‘manipulation’ truly involves a substantial change in the first variable and if the predicted change in the second variable is robust to the extent that it exceeds the variations that may be expected by chance. Occasionally, this may involve some qualitative categorical alteration, rather than a quantified dimensional change but, either way, quantification (of the presence/absence variety or of a point on a continuum variety) has occurred.

In both psychology and psychiatry, there has been much debate in recent years with respect to the merits and demerits of quantitative and qualitative approaches (Rutter, 2001). This is a false dichotomy and the polarization between the two research approaches has been unhelpful. Qualitative researchers have rightly been critical of the mindless application of quantitative methods before determination of the meaning of the phenomena to be assessed. Some form of qualitative analysis will almost always need to precede the application of quantitative methods (see Rutter & Nikapota, Chapter 16, for a consideration of this issue in relation to social group comparisons). On the other hand, hypothesis testing requires quantitative research. The main reason that this is so derives from epidemiological considerations. First, because almost all psychopathology is multifactorial in origin, even in relation to a single case, it is crucial to be able to test whether a particular effect is a consequence of one factor rather than another (see below). For obvious reasons, that can only be done if there is adequate quantitative measurement of both the risk factors and the psychopathology. Secondly, all human groups (whether they involve members of the general population or patient samples) are very heterogeneous. For good reason, qualitative studies (which tend to be quite intensive) need to use relatively small samples. That is perfectly acceptable for the purpose of gaining a better understanding of what is happening, such understanding being used to generate testable hypotheses. On the other hand, it is not acceptable for testing hypotheses, because small heterogeneous samples inevitably mean uncertainty as to whether the findings refer to the psychopathological defining feature of the sample or to some other source of heterogeneity. Most research questions require a *combination* of qualitative and quantitative methods and the same applies to the assessment of individual cases. They have a different mix of strengths and limitations and both approaches are required.

In considering clinical assessment, we turn first to diagnosis. Apart from the applied scientific methods we advocate, four other approaches to diagnosis are possible and we need to consider whether their use now means that experimental methods are no longer needed in diagnosis, even if they are needed in other aspects of clinical work.

First, there are the *algorithmic approaches* based on standardized diagnostic instruments. Thus, both DSM-IV (American Psychiatric Association 1994) and the research version of ICD-10 (World Health Organization 1993) have formulae that generate diagnoses once the specified set of criteria have been met. Moreover, computer programs have been written to enable people to do this entirely through computer software without the need for the manual counting of numbers of particular sorts of symptoms, duration and other inclusionary and exclusionary specifications. Undoubtedly, this has been a most useful advance but two basic problems remain. There is the key question of the validity of the data that are read into the algorithm. The agreement among different instruments and among different algorithms has been found to be only moderate (Volkmar *et al.* 1992; Farmer *et al.* 1993; McGuffin & Farmer, in press). As we discuss

below, experimental approaches can be helpful in testing the validity of the basic data. Very few psychiatric diagnoses have an unambiguous external validating criterion and, hence, it is most unlikely that the precise algorithmic criteria will ultimately prove to be fully valid (see Taylor & Rutter, Chapter 1).

Secondly, diagnoses may be determined by *pattern recognition*. The late Jack Tizard, a most important mentor for both of us, often remarked that he saw this approach as the one that was most different between medicine and clinical psychology. He expressed amazement at the surprising ability of good medics to recognize rare and unusual syndromes that they had seen only once before some 30 years ago or indeed may never have seen, relying only on textbook descriptions. It is certainly true that this constitutes a key part of medical training and, at its very best, works well. Moreover, this human skill is one in which the top level minds can often defeat supercomputers despite the immensely greater capacity of the computer to test vast numbers of possibilities very swiftly. It was this pattern recognition skill that enabled chess masters to defeat supercomputers at chess for a long time. The skill, it is true, does not involve experimental thinking at all in the ordinary sense. However, it would be a grave error to think that this is how most medical diagnoses are made (let alone psychiatric ones). Rather, diagnosis consists of putting together very complex sets of data, weighting different elements appropriately, and considering possible interactions among risk and protective factors. There is no question that computers are usually very considerably better at this than are human minds. That is why computer diagnoses have come to have an increasingly important role in medical diagnoses. For them to work really satisfactorily, of course, there must be some external diagnostic criterion and, when that comes in the field of psychopathology, computers are likely to play an increasing part there as well. On the other hand, as we discuss below, ending up with the ‘correct’ diagnosis is not all that clinical assessment is about and hypothesis-testing approaches are likely to continue to be important for a long time to come.

A third approach is provided by *quantified* diagnostic methods that are based on the well-justified assumption that many disorders (in medicine as a whole and not just in psychopathology) represent extremes on some continuously distributed liability dimension. Thus, just as hypertension may be diagnosed on the basis of a blood pressure above a certain predetermined and specified level, so mental retardation may be diagnosed by an IQ score below some particular criterion point. Similarly, depressive disorder may be diagnosed by a depression symptom score above a certain threshold on some standardized measure. Unquestionably, this approach has considerable utility but very few diagnoses can be made on the basis of a single dimension. It is usual to need to consider patterns of symptoms and to assess functional consequences. At a more basic level, however, it is essential to determine whether the test score (whatever the test may be) has the meaning that is required for its use in diagnosis. Just as it is necessary to check whether a high blood pressure may reflect excessive alcohol consumption, smoking, exercise or anxiety, so it is crucial to test whether a low IQ score reflects a

limited cognitive capacity rather than a lack of engagement in the task, negativism, the distorting effect of psychopathology or situational features. That is where experimental thinking needs to come in.

Finally, diagnoses may rest on some *qualitative* abnormality that is a necessary requirement for the diagnosis, even though it may not be a sufficient one. There are examples among mental disorders where a particular abnormality is both a necessary and sufficient feature. For example, this applies to chromosome abnormalities (as with Down syndrome) and with other entirely genetic disorders (such as the fragile X anomaly or Huntington disease). However, these account for a tiny proportion of mental disorders. The situation is quite different with multifactorial disorders. Nevertheless, even with them, it may possibly turn out that one or more genetic mutations are a necessary basis for the diagnosis, even though they are not a sufficient one (because the disorder requires the operation of other genetic or environmental risk factors). Certainly, molecular genetics has the potential to deliver diagnostic tests of this kind (see McGuffin & Rutter, Chapter 12) but it is most uncertain whether genetic factors will operate in this way (as a necessary risk factor) for most forms of psychopathology. Also, it needs to be appreciated that many diagnostic tests in internal medicine involve a crucial experimental element. Most diagnoses are based on an abnormal pathophysiology that relates to function, rather than to a fixed feature that is independent of circumstances. Thus, the glucose tolerance test for diabetes, the exercise tolerance test for cardiac function, the various sensitivity tests for allergies and tests of respiratory function, all involve determining changes of some kind in response to a particular stimulus, but not to other stimuli. As we discuss below, this is similarly true of most psychological tests.

In short, an experimental way of thinking is likely to continue to have a central role in clinical assessment for many years to come. Its operation is central to the whole of biology and medicine and not something that is peculiar to mental disorders or psychopathology. Moreover, it is a need that applies to both clinical psychology and clinical psychiatry. It was for that reason that the authorship of this chapter combines disciplines. In the remainder of this chapter, we consider various different applications of applied scientific thinking in clinical assessment. The examples we use span both psychometric testing and psychiatric diagnostic methods because we wish to emphasize the generality of the application of the concepts we discuss. However, we have deliberately chosen more examples from psychology than psychiatry because, quite mistakenly, it is often assumed that, with well-established psychological tests, experimental thinking is not needed. Nothing could be further from the reality.

It should be added that the current trend to encourage the use of well-designed assessment and treatment protocols in order to ensure high standards in service delivery will not obviate the need for an applied scientific approach. There is much to be said for the use of standardized approaches but, as Kanner (1958) emphasized years ago, the problems that children present at the clinic do not adhere to textbook descriptions. The systematic standardized protocols provide an excellent starting point, but

clinicians need to appreciate the extent and importance of individual differences. This will often require the undertaking of individually tailored scientifically based assessments of the kind we describe here.

Obtaining valid psychometric test scores

Psychological tests vary considerably in the extent to which standardization data on appropriate populations have shown them to have adequately high reliability and validity. Other things being equal, a clinician will want to use instruments for which there is the best data demonstrating high reliability and validity. However, a differentiation needs to be made between a reliable and valid *instrument* and a reliable and valid *assessment* (Berger & Yule 1972). The latter concerns the qualities of the testing of a particular child under particular circumstances.

Although written 30 years ago, Berger & Yule's (1972) suggestions with respect to the testing of young disabled children with a possible language disorder are relevant. They argued that motivation is important in all testing and the tests constructed for use with children need to incorporate items that will arouse and maintain their interest. This is particularly the case with disabled children who may have experienced frequent failure and may therefore be unwilling to participate in, and persist with, items that they perceive as difficult. The clinician may choose to deviate somewhat from the prescribed order of testing procedures, and to intersperse simpler items among those likely to tax the child. It is usually wise to begin testing at a point much below the level at which a child is thought to be capable in order to provide the child with sufficient successes to encourage him or her to attempt more difficult tasks. Clark & Rutter (1979) showed that this was particularly important with some autistic children who tended to move into a stereotyped pattern of responses if they encountered a series of items that they could not deal with. Also, if the child appears to enjoy a particular task and is unwilling to attempt others, it is often a good idea to allow the child to work at what they like on condition that they attempt other tasks later. Similarly, it may, in some circumstances, be appropriate to allow the child to respond in a non-standardized way that provides the same information. Thus, Clark & Rutter (1979) described an example of a 'negativistic' child who became amenable to testing when allowed to say what the answer was, rather than to point to the correct solution. Board forms of Raven's Coloured Progressive Matrices (Raven *et al.* 1990) have also been devised to allow disabled children to demonstrate their choice by picking up the piece that provides the correct answer, rather than to use pointing (which some autistic individuals do not do well). Comparable adaptations of tests have also been devised for children with severe impairments of hearing or vision (see Hindley & van Gent, Chapter 50).

Sometimes, it is appropriate for parents to be present during the assessment in order to allow the child to be more at ease and also to help as a translator of instructions and responses. This is a two-edged sword, however, and it is most important that par-

ents appreciate the importance of allowing the tester to obtain the child's response without parental help. Certain items on cognitive tests require the child to complete the task correctly within prescribed time limits, and some give bonus points for rapid solutions. Particular care needs to be exercised when using these timed items with disabled children. Those with motor coordination problems, or those who are highly distractible, are most likely to be penalized with timed tests. Special considerations also apply to the testing of children who lack speech, or whose understanding of speech is limited. It is essential to differentiate between items failed because the child could not perform the task and items 'failed' because the child did not know what task it was they were supposed to perform. When this is in doubt, instructions should be given in some form (such as mime or demonstration) that avoids the use of spoken language.

These principles played a major part in Stutsman's (1948) development of the Merrill-Palmer scales many years ago. It was appreciated that young and disabled children often get tired, distracted or oppositional. That is why the test was devised to take account of circumstances in which items are refused or have to be omitted for some reason. Standardization of the test is now out of date and lacks qualities that are now regarded as essential. Nevertheless, the approach has many advantages and it may well be that modern day test construction pays inadequate attention to the realities of young children's engagement and interest and lacks adequate steps for dealing with items refused.

Clinicians need to be very sensitive to the fact that the more that they depart from standard test administration procedures, the more cautious they must be in the interpretation of test findings. Nevertheless, for reasons discussed below, adequate psychometric testing requires determination of the tasks that the child can perform as well as those leading to failure. The meaning of the test score is crucially dependent on this mixture of passes and failures and on the ability to determine the features that go along with each. When we started in clinical practice, some four decades ago, it was very common for psychologists to report that disabled children (especially those with autism) were 'untestable'. As Berger & Yule (1972) commented, this is simply a statement that the psychologist has failed in his or her endeavour and it says nothing about the child except that he or she was difficult to test. The challenge with such difficult children is to use the reports of others, and the psychologist's own observations, to think of ways in which the child may be induced to be engaged in the relevant tasks and to persist at them. It will readily be appreciated that finding how to do this will provide invaluable information on the features that affect the child's behaviour as well as bringing about a means for obtaining a valid test assessment.

One particular concern that occupies a major place in the literature on cognitive testing is the desire to develop and use culture-free or culture-fair psychological tests. There are both good and bad aspects of this concern. The positive side is that it is appropriate, indeed essential, to use forms of assessment that are not biased because of an individual's particular experiences

or lack of experiences—in exactly the same way that it is essential to use tests that are not biased by a person's disabilities in vision, hearing or language. The negative side is that the concept seems to presuppose that it would be possible to devise a pure measure of innate cognitive capacity that is not open to the influence of experience. Theoretically, this is nonsense. Intelligence, just like other psychological qualities, is multifactorially determined and its development will be influenced by experiences as well as by genetic background. The concept is also misleading because, in so far as constitutional features are strongly operative, they set a reaction range and not a particular level of performance. Also, psychological tests are measures of performance and not of some hypothesized internal quality as it might be if the child's experiences had been different.

That does not mean that the issue of the effects of culture on test performance can be ignored: on the contrary. However, what it does mean is that it may be more appropriate to examine the positive effects of culture directly rather than try to devise tests that are free of them. The example of the Brazilian street vendors mentioned by Rutter & Nikapota (see Chapter 16) is illuminating. What was important in studying their mathematical skills was to devise ways of testing that were relevant to the particular circumstances in which they had to function in real life. A highly unusual clinical example was provided by a young man seen by one of us some 40 years ago. He originated from an isolated rural community in one of the smaller Caribbean islands and on coming to London encountered a form of life that was entirely different to anything he had ever experienced before. He lacked family ties and emotionally he rather 'fell apart', ultimately being admitted to hospital with what seemed a psychotic-like disorder. Formal psychological testing gave rise to a score in the mentally retarded range but this seemed out of keeping with his behaviour as observed on the ward. It was appreciated that he was virtually unschooled and that the test tasks might well have a quite different meaning for him than for other people in the standardization sample. He was a fisherman by trade and, after some discussion with staff in the occupational therapy department, it was decided to give him the run of the materials in that department with a request that he construct the type of fishing basket that he used in the Caribbean. The result was spectacular. To begin with, he came into his own emotionally and became highly engaged in the task. From our point of view, we observed with awe his skill in using an unfamiliar set of materials to make a complicated basket involving a sleeve that went into its interior. The rationale was that the fish swam down this sleeve that had a very large opening and swam out of the narrower end into the middle of the basket and was thereby caught, because it was much more difficult for the fish to find the entrance to the interior end of the sleeve. It rapidly became obvious that, although this task could not give rise to a cognitive 'score', he clearly was not mentally retarded. The circumstance was a highly unusual one, but the general principle has a wider application. That is, as with the Brazilian street vendors, it may be worthwhile to make positive use of the cultural variations (rather than avoid them) and to seek ways of tapping skills,

rather than finding failures, although, as always, it is the pattern of the two that is most informative.

Two other issues warrant mention. First, it is necessary to differentiate between the use of psychological assessment to consider performance in a person from a quite different background who is going to return to that background, and the rather different issues with respect to someone from a very different culture who is going to need to live in an industrialized country with all the usual expectations about schooling, jobs and the like. The former case might, for example, be relevant with respect to a clinical referral from abroad in relation to a child living in circumstances quite different from those of London (where we practise). The second point is that when there has been a very major change in life circumstances, test findings may have a quite different meaning with respect to their predictions for future performance. For example, in the children adopted into UK families from Romanian orphanages, the shift from profound deprivation to somewhat above-average family environment was followed by major cognitive gains (Rutter *et al.* 1998a; O'Connor *et al.* 2000).

Determining the validity of a test score

There are three main ways in which the validity of a score may be assessed in an individual case. First, use may be made of the psychologist's own observations of the child's motivation and persistent engagement in the tasks involved in the test. It is not always easy to differentiate between task failure and a lack of adequate engagement but careful observation of the child's performance, together with information from parents and teachers on the child's response to tasks, will usually provide an adequate lead. Other things being equal, if task failure occurs on tasks that obviously interest the child and attract adequate engagement, it is much more likely that the failure reflects lack of competence than if a child has only made a half-hearted attempt to do what was required.

The second approach is provided by an internal analysis of the pattern of task passes and fails. The basic assumption, or hypothesis, underlying the test is that success or failure reflects task difficulty rather than extraneous features such as distraction, anxiety or motivation. Accordingly, it is necessary to examine the pattern of item responses to determine if there is a reasonably consistent hierarchy with successes on easier items and failures on more difficult ones. Some tests, such as Raven's Progressive Matrices (Court & Raven 1995), build this in to the test construction so that there is a systematic progression from easy items to more difficult ones, back to easy ones and on to more difficult ones, and so forth. This is not usual in other tests but, nevertheless, there is a means of assessing the association with the task difficulty by going across subtests. There should always be caution about the validity of an overall score that is made up of a mixture of passes and failures on both more difficult and easier items. This will usually require further testing in order to determine what explains the pattern. Consistency across differ-

ent tests or across separate testing occasions can also be helpful. When the test findings do not show a consistent pattern of response to task difficulty, an experimental approach will be needed in order to pit against each other alternative hypotheses about the reasons for these discrepancies.

The third approach is provided by examining the consistency between the test findings and other assessments of performance that derived from observations by the clinician or reports from parents or teachers. From a psychiatric perspective, it has been our practice always to use observations and reports in order to come up with a clinical expectation of test performance level (whether this be in relation to general intelligence or language or scholastic attainment) *before* hearing about test findings. It is only by having some sort of quantified other assessment that it is possible to determine whether there is a discrepancy to be explained. However, in doing this it is essential not to be content with some overall impression but rather to have thought through carefully what it is in the observations or reports that give rise to the expectation. This may be, for example, reports or observations of problem-solving skills outside the test situation, or it may involve the child's level of curiosity and organized exploration of the environment, or it may involve the style of approach to problem-solving (e.g. whether it is random trial and error or systematic and organized). The observations may involve the extent to which the child attempts, and succeeds, in finding out how toys and how sold objects 'work' or it may involve complexity in play (Rutter 1985a).

As Berger & Yule (1972) emphasize, it is never acceptable to leave discrepancies between test findings and parental reports unexplained; their existence is *always* an indication for a critical hypothesis-testing study of possible reasons for the discrepancy. The reasons may lie in the nature of the task (e.g. the child having more cues at home than in the controlled test situation), or in the parent's or teacher's interpretation (or misinterpretation) of the child's behaviour, or in the nature of the cognitive skills being assessed. If the parental report suggests marked skills or deficits on clinically important abilities that have not been tapped by standardized tests, other tests should be used to sample the additional functions. In cases where the child seems able to perform the task at a higher level at home than he or she does in the clinic, and when no reasons in the nature of the task seem to explain this discrepancy, the psychologist should seek to repeat observations in the home (or in the school if that is relevant) in order to determine the explanation for the discrepancy. Psychological assessment is complete only when this has been accomplished and when it has given rise to an explanation for the discrepancy.

An example of this kind arose with respect to a clinical referral of a boy who had suffered a very severe head injury. The school that the boy had attended both before and after the injury had concluded that the boy, of previously superior intelligence, had been left mentally retarded by the injury. To everyone's surprise, standardized testing, by contrast, showed that his overall IQ was still well above the population mean (although not as high as it is likely to have been before the injury). Observations in the classroom and of the boy coping with work at home

seemed to indicate that he was indeed performing poorly. One possibility was that the successful test performance was a function of the tasks being very short. Accordingly, a different set of tasks was constructed that required more prolonged persistence. The boy performed equally well on these and that explanation could be ruled out. It was similarly possible to rule out the possibility that his failures reflected undue distraction by extraneous stimuli. Eventually, it appeared that the key feature involved the requirement for initiative and individual decision-making in more open-ended tasks. This provided important clues as to how he might be helped to improve his school learning.

A very different example was provided by a young girl who had been referred because of puzzlingly variable uncooperative behaviour. Her school record made it clear that she was of above average intelligence and therefore it was a surprise to find that on standardized cognitive testing her score was only about 80. However, the psychologist also reported that although the girl had been cooperative throughout the testing, had spoken appropriately and seemed to be engaged in the tasks, her behaviour did not seem normal in that she appeared not quite 'with it'. This contrasted with her style of interaction when seen by the psychiatrist and a discussion of possibilities led to an arrangement whereby the next time that the child seemed to be behaving in the reported somewhat unusual fashion, an EEG was to be performed instantly. Interestingly, when this was carried out, it showed that she was in petit mal status. At first sight, it seemed impossible that she could be functioning as well as she was (albeit below her best) while having a continuous set of minor epileptic seizures. However, a careful examination of the EEG record showed that there were very brief breaks and apparently these were enough to enable her to function. Subsequent cognitive testing both within and outside periods of petit mal status confirmed the low average functioning in the one and the superior functioning in the other.

A further example is provided by a girl referred because of acquired aphasia with epilepsy (see Bishop, Chapter 39). Standardized testing showed that her understanding of spoken language was negligible but her parents reported that, despite her virtually complete loss of use of spoken language, she seemed to understand surprisingly well what was said to her. Both our observations in the clinic and parental reporting suggested that this might be because of her use of non-language information to guess correctly what was being communicated. Systematic observation, using situations that varied according to the level of possible other information that was available to the girl, confirmed that this was indeed the case. Once more, the resolution of the discrepancy provided an important lead as to how best to help her.

A more structured experimental design was needed to investigate several cases of supposed 'facilitated communication' in autistic individuals, seen at a time before this concept became fashionable. Although the details were slightly different in each case, what they had in common was that in all ordinary circumstances the young people were performing at an extremely low

level, whether assessed on the basis of standardized test performance or spontaneous behaviour at home or at school. By contrast, when cognitive performance was assessed by any means involving the mediation of a facilitator (in two cases a parent but in the third case a therapist) a surprisingly high level of knowledge or understanding was shown. In each case, it was necessary for the child to rest their hand on the arm of the facilitator (or vice versa) and to use a system of pointing to letters or spelling out words on a kind of simplified typewriter. Observations confirmed that the reports of performance using this type of facilitation were indeed correct and there was every reason to suppose that the facilitator was not consciously manipulating what the child was doing. It quickly became apparent that the challenge was to account for the successes with facilitation, rather than the failures without it. Furthermore, it was clear that nothing would be gained by structuring the circumstances so that there could be failure with the facilitated task. That was because it would be easy to account for such failure on the basis of motivational influences. Instead, it was decided that the way ahead lay in tackling head-on the two main alternatives—that the correct answers derived from the facilitator or that they derived from the child. This led to the stratagem of so organizing the task that one or other of them would have to give the right answers to the wrong questions. The need to undertake this testing was fully explained but the precise details of how this was to be carried out were not revealed in advance (by agreement with those concerned). The child and the facilitator were each given the same set of questions but they were in a different order, without this being obvious to either of them. In all three cases, replicated testing showed that the answers reflected the questions as evident to the facilitator and not those evident to the child. Subsequent systematic studies of small groups of young people showing facilitated communication used a broadly comparable strategy with much the same results (Montee *et al.* 1995; Bebko *et al.* 1996).

These four rather different examples illustrate the range of ways in which an experimental, or quasi-experimental, approach to hypothesis testing in relation to the validity of a test score may be undertaken. The facilitated communication example approximates to a single case research investigation (Yule & Hemsley 1977); the epilepsy example involved the use of testing outside the psychological domain; and the other two examples required only variations in a more ‘ordinary’ exploratory clinical approach. In all four cases, however, it was necessary to ask questions about the validity of the test findings, to pose alternative explanations, and to devise means of differentiating among these alternatives.

Exploring reasons for situational variation in behaviour

It is a commonplace in both research and clinical practice to find that children’s behaviour in one situation is not the same as that in another, or that their behaviour with one person differs from that with another. It is necessary in both research and clinical

practice to develop hypotheses with respect to possible causes of the variation, and to devise means to test which explanation or explanations are valid. Apart from the usual need to consider how hypothesis testing may be undertaken, there is clearly a requirement to have adequate measures of both the child’s behaviour and the situational or interpersonal circumstances. In addition, it is necessary to check that the apparent situational variation is real. The alternative is that the behaviour is actually similar across situations but that it is being perceived differently by different people. Again, the approach may be illustrated by giving a few varied examples.

The first example concerned a request from a particular school in relation to an apparent ‘epidemic’ of hysterical attacks in the classroom (McEvedy *et al.* 1966; Moss & McEvedy 1966; Benaim *et al.* 1973). This was a new phenomenon in an otherwise well-functioning school and it was also noteworthy that this was only occurring in some lessons and with some teachers. Observations showed that the behaviour of one girl constituted the usual initiator of similar behaviour in others. Also, it became apparent that the ways in which different teachers responded to what was happening made quite a difference to whether it spread. The details in both cases provided the lead on how the school might deal with the situation and the limited ‘epidemic’ soon came to an end.

Another quite different circumstance in which explanations of situational variation are needed concerns reports that a child’s behaviour is influenced by diet. Thus, it is relatively common to have reports that, for example, children are more hyperactive when they have ingested foods that contain additives or when they have eaten particular foods, such as chocolate. The approach needed is reasonably straightforward in principle, although often very difficult in practice. The first need is to consider alternative hypotheses for the apparent variation in behaviour. In most cases, the two chief contenders are chance variations and the influence of other features. Thus, the clinician needs to consider whether the variation might be caused by the fact that at the times when behaviour is worse the child is in a different situation, or is tired or excited for reasons unconnected with the content of the food. Sometimes, careful history-taking makes it evident that the supposed connection with foods is so inconstant and weak that it is most unlikely to represent a causal effect. However, quite often, it is necessary to go on to some more systematic documenting of temporal relationships. In most cases, a key step is to identify specific time-limited behaviours that can serve as an index of the behavioural disturbance that is at issue. The parents may then be asked to keep a careful daily diary of the occurrence of such behaviours, together with possible circumstances or precipitants (other than food) that might be relevant. It is only when procedures of this kind provide evidence that indicates a strong case for an association with particular foods that it is justified to undertake the more searching experimental testing of the hypothesis. Basically, this requires going to a very simple diet and then experimentally adding, one by one, in blind fashion, different types of food substance (Egger *et al.* 1985; Carter *et al.* 1993). Single case studies

of this kind are arduous and demanding and are not to be engaged in lightly. Nevertheless, they do have a place and the results have shown that, although most claims that specific foods have a predictable worsening effect on behaviour cannot be substantiated, they have proved valid in some instances and have led to effective and worthwhile therapeutic interventions.

Similar issues may arise in relation to parental responses to a ‘problem’ behaviour. For example, some years ago, one of us saw a young mother who was at her wits’ end because her toddler would not sleep through the night. She had received conflicting advice from family and friends. One big issue was whether she should allow the child to have a nap in the middle of the day. Some people advised her to ensure that he did *not* have a nap; she should keep him awake so that he was sufficiently tired at the end of the day to go to sleep promptly. Others urged her to let the child have a nap when he wanted, on the grounds that to prevent it would merely make him irritable and oppositional. The mother was asked to keep a systematic sleep diary over a period of several weeks. A simple statistical test showed that on days when he was kept awake he would not settle at night, whereas on days when he had a nap, he slept through the night. This had seemed counterintuitive but data settled the issue.

Another example of the same kind was provided by a child who had been placed in a residential unit after a series of foster and adoptive placements had broken down. The unit had a good reputation for preparing children to move on to new families but, in this case, they were faced with what seemed to be unpredictable aggression. The main concern was over infrequent severe outbursts, but minor episodes were more common. On the principle that low-frequency high-amplitude behaviours can often be understood by looking at high-frequency low-amplitude equivalents, all episodes of aggression were systematically charted. The next step was to examine the temporal pattern in order to relate it to possible precipitants. It quickly became apparent that aggression was particularly likely to follow his sessions with the art therapist who was undertaking ‘life story work’ with him. It appeared that he was not yet ready to face the pain of his past, and a different approach proved more effective with him. Individual differences, as ever, are crucial.

Very comparable issues arise with respect to the possibility that mood disturbances are a function of phases in the menstrual cycle or that a marked change in a child’s behaviour represents some fundamental alteration in their physical condition. For example, a consultation was sought by a residential institution for young people with autism in relation to a particular child who had shown a marked escalation in quite dangerous aggressive and destructive behaviours. They were concerned that it might reflect some unusual form of epileptic disturbance or some neurological deterioration. Again, careful history-taking from staff at the institution and from parents led to several alternative possibilities that needed to be considered. There had been marked changes of staff, the young person was now primarily looked after by someone new, and there had been possibly important changes in schedule and expectations. The problem required, again, selecting the key behaviours that gave the prime

cause for concern with respect to the changes and a recording system was instigated, being planned jointly with staff, to test out the various possibilities. In this particular case, the evidence showed that the variations were related fairly systematically to changes in the institution and that when these were modified in ways that seemed likely to be helpful, there was a substantial reduction (although not elimination) of the aggressive and destructive behaviour. In another somewhat similar referral, the approach taken was similar but the answer was rather different. In the second case, the variations in behaviour seemed likely to be a function of a cyclical mood disturbance. This is not easy to gauge in non-verbal autistic individuals but appropriate medication proved helpful. It is often said that, if you want to understand a behaviour, introduce experimental changes to alter it. Hypothesis testing in assessment has a two-way relationship with therapeutic intervention: each can inform the other.

Sometimes the need is to check the validity of the referrer’s perception of the problem. When working with teachers on part of a school-based clinical intervention project, concern was expressed over an apparently highly intelligent 6-year-old who ‘never settled to do any work’. The teacher was helped to define and operationalize what she meant by ‘work’, and then to undertake a simple binary on/off task observation every fifth minute for 1 hour each morning. The results showed that the boy was on-task 60% of the time. This led to a redefinition of the problem and a focus on reinforcing his on-task behaviour, which was plentiful. Soon he was working at a level above the average for the class.

Reports that a child’s behaviour is much worse at school than at home, or vice versa, are extremely common and clinicians need to decide whether systematic investigation is indicated or whether the evidence from research, together with the particular findings in this case, provide enough leads to indicate some of the likely features and therefore some of the elements that might constitute a focus for intervention. The hypothesis generation requires a knowledge of what might be relevant in the school environment as judged from studies of school effectiveness (Maughan 1994; Mortimore 1995, 1998), together with psychopathological evidence of the possible importance of features such as structure, group instruction, task demands and so forth. Similarly, hypotheses about relevant features in the family and in the home need to be guided by evidence from observational studies that have systematically investigated different features (Patterson 1982). It is usually helpful when focusing on situational variation to try to identify situations and circumstances that have comparabilities across the settings showing variation. It may then be most appropriate to move to a functional analysis of the behaviours in that situation (see below).

Functional analysis of behaviour

Systematic approaches to functional analysis of behaviour developed as an intrinsic element of the development of behavioural methods of treatment (see Herbert, Chapter 53).

However, in a more general sense, they are inherent in all forms of clinical assessment. In seeking to understand the nature of disturbed behaviour that has constituted the basis for referral, it is necessary to develop and test hypotheses about alternative explanations. For example, with respect to faecal soiling, it may have arisen because the child has failed to gain control of bowel function that ordinarily arises in childhood, or it may arise because the bowel has become blocked through impaction and there is seepage of faecal material around the blockage, or the child may have no blockage, have full control of bowel function, but for psychological reasons is depositing faeces in inappropriate places (Rutter 1975; see also Clayden *et al.*, Chapter 47). Various predictions follow from these alternatives. Thus, the form and consistency of the bowel motions is likely to be normal in the first and third alternatives but abnormal in the second. Also, the spatial deposition of faeces is likely to be relatively haphazard in the first two possibilities but systematic and psychologically meaningful in the third. Of course, there may be a combination of features and there are also other possibilities. The basic point, however, is that the clinician needs to adopt an experimental approach to the development and testing of clinical hypotheses.

Similar issues arose with respect to school non-attendance in which the main alternatives lie between avoidance of school as part of truancy associated with an antisocial propensity and avoidance of school for emotional reasons associated either with separation anxiety in relation to the family or fear of some aspect of the school situation (Hersov 1960a,b; Eysenck & Rachman 1965). In the same sort of way, these alternatives give rise to predictions about the details of the function of school non-attendance.

Functional analysis needs to be applied to the somewhat different issue of predisposing circumstances and immediate provoking stimuli or controlling contingencies. It can be important to determine the extent to which disruptive behaviours or emotional disturbance are most likely to arise when children are tired or hungry, when they are being required to do things that they do not want to do, when they are unable to communicate their needs or wishes (a particular issue in relation to autism, see Rutter 1985b; Howlin & Rutter 1987), or when maternal depression is associated with increased family discord or impaired parenting, or when father goes away from home on work, or when it is an anniversary of some particularly stressful situation. The analysis with these issues is broadly comparable to those already considered in relation to situational variations.

The more detailed 'blow-by-blow' sequential analysis of the circumstances most likely to provoke a particular behaviour or cut it short requires a careful systematic attention to particular episodes of behaviour. The well-based assumption is that, although there are major individual differences in children's liability to show different forms of psychopathology, there are also important situational influences on whether such psychopathology is manifest and how long it continues. The issues are well illustrated in the pathways involved in substance use and abuse (see Rutter, Chapter 28) or suicidal behaviour (see Shaffer &

Gutstein, Chapter 33) or antisocial behaviour (Rutter *et al.* 1998b; see also Earls & Mezzacappa, Chapter 26). Such a behavioural analysis needs to be guided by both what research has shown as likely features to influence behaviour and what seems to be happening with this particular individual. A hypothesis-testing approach is obviously the way to proceed.

However, an important caveat is that the most important feature may not be what parents or teachers do after a particular behaviour has occurred but, rather, what they do to avoid it happening in the first instance. Thus, skilled parenting may have less to do with efficient disciplinary methods or social problem-solving strategies or coping techniques than with an accurate picking up of social cues and an appropriate use of diversionary tactics. This was well illustrated in one study of children's and parents' behaviour negotiating a supermarket (Holden 1983) and in other studies of parenting strategies (Gardner *et al.* 1999).

Ordinarily, functional analysis of behaviour tends to be thought of in terms of the features in the immediate situation that influence the occurrence of behaviours. However, precisely the same issues and approaches are relevant in relation to the possibility that the key influences on behaviour derive from meaningful connections with some past experiences. At one time, psychoanalytic psychotherapies were largely predicated on this basis; that the origins of mental disorders lay in internal thought processes in relation to past experiences, real or imagined. These approaches have become outmoded, at least as applied in their original form, because theoretical assumptions have not proved valid, because it became obvious that there was a need to take the immediate life situation into account, and because therapeutic methods lacked efficacy as compared with other forms of intervention. Nevertheless, the general notion that past experiences may have contemporary relevance is valid as shown, for example, by the persistence of post-traumatic stress disorder symptoms in some cases (see Yule, Chapter 32), by the long-term sequelae of sexual abuse in some circumstances (see Glaser, Chapter 21), or by the ways in which the experience of past relationships influences people's approach to current ones (Cassidy & Shaver 1999). However, if these possible connections with past experiences are to be used in clinical assessment (as they should be) it is important that ways be found of translating the notion into some form of testable hypothesis to which experimental thinking may be applied in putting the hypothesis to test.

Analysing test score discrepancies

Throughout the history of psychological testing, there has been an interest in the inferences that may be drawn from discrepancies between scores on two different tests or subtests. Thus, there has been a wish to draw conclusions about brain function when large differences have been found between verbal and performance subscores on the Wechsler scales, or from instances when performance on some skill such as language or reading is markedly lower than that expected of the child's age and overall

level of intelligence. Three rather different issues have to be considered in relation to the topic of score discrepancies (Yule 1989). First, there is a need to appreciate the relatively wide confidence limits that surround most subtest scores. That is to say, it is very common for a child to obtain some particular score on one testing occasion and a somewhat higher, or lower, score on a subsequent occasion. The method of dealing with this is a straightforward statistical one requiring no hypothesis testing. With many tests (such as the Wechsler scales) tables are provided on the reliability (the likelihood that the same pattern would be found consistently over repeated testing) of different sized discrepancies. These data indicate whether the pattern is truly characteristic of the child, but they do not indicate whether it is statistically unusual.

The answer to this second, although closely related, question requires data on frequency of discrepancies in the general population of different sizes. Again, statistical tables are available for many tests and the findings generally show that discrepancies have to be quite large for them to be regarded as statistically rare.

The third question concerns the clinical meaning to be attached to a statistically unusual discrepancy. This immediately raises a base rate problem when trying to use a relatively common finding (a large discrepancy) to predict a rare phenomenon (such as brain damage) (Yule 1989). The key consideration is that differences between groups may provide a misleading expectation of the meaning of a finding in an individual case, unless attention is paid to base rates (Meehl & Rosen 1955). Thus, in the Isle of Wight survey (Rutter *et al.* 1970) verbal performance discrepancies of 25 points or greater on the Wechsler Intelligence Scale for Children (WISC) were twice as common in children with neurological disorders as in controls (14 vs. 7.5%). However, when the base rate of neurological disorders (6.4 per 1000) was taken into account, this translated into a chance of only 1 in 60 that a child with a large V-P discrepancy would have a neurological disorder (Yule 1989). The practical point is that even when there is a very strong association between features (one of which is rare), false positive predictions will be usual simply because normality is much more common than the abnormal disorder being predicted.

Some assistance is provided by paying attention to patterns made up of several different indices. For example, longitudinal studies have shown that various social abnormalities, developmental delays and attentional deficits all predict the later development of schizophrenia (Rutter & Garmezy 1983). Each of these is relatively common in the general population and of very little use for individual prediction. However, the combination of all three is much rarer, but is fairly common in the abnormal group. The findings in this instance are still, even in combination, not sufficiently distinctive to be of value in individual diagnosis, but the principle is one of utility. It is always worthwhile to consider whether there are several different indices that could be put together in this way and, if there are, whether data are available on the frequency of particular pattern occurrences.

A further problem concerns the supposed purity of the function being tapped by a particular test or subtest. Research findings are clear-cut in indicating that most tests reflect a wider range of skills than might be anticipated from the name or description of the test. Thus, most of the so-called non-verbal tests on the Wechsler Scales actually are influenced to some extent by language and language-related skills. Accordingly, care needs to be taken before assuming that an unusually high or low score is indeed measuring what it purports to measure. In many instances, a full understanding of this is not crucial in the clinical assessment of an individual case. Nevertheless, occasionally it is important, and the appropriate single case design means to investigate the meaning of unusual talents or deficits, as illustrated by studies of idiot savants (Hermelin 2001). These are individuals who have highly precocious skills in one narrow area that enable them to perform at levels well above those achieved by most people in the general population, despite the fact that their own level of overall intelligence is in the retarded range. A high proportion of such individuals show autism. One of the questions that needs to be addressed is whether their unusually high level of performance in their special talent constitutes some trick of rote learning or whether it is based on the same sorts of cognitive processes employed by more generally talented individuals. The style of investigation has involved setting the tasks in ways that allow, or prevent, different rule-based strategies, or different sources of information, to be used. Very similar strategies are relevant for the investigation of particular severe deficits.

A further issue concerns the clinical implications of marked discrepancies (giving rise to either skills or deficits). There has often been a wish to jump from test findings to inferences about brain lesions. Thus, for example, tests may be labelled as 'left hemisphere' or 'right hemisphere' tests (Prior 1979) or tests of frontal lobe function (Prior & Hoffman 1990). Sergeant & Taylor (see Chapter 6) point to the many problems involved in such inferences. So far as childhood is concerned, a crucial consideration is that lateralized or localized lesions incurred in early life do not lead to the same patterns of psychological functions that they do when the lesion has been incurred in adult life (see Goodman, Chapter 14; Vargha-Khadem *et al.* 1992; Rutter 1993). Particular genetic conditions can and do give rise to relatively distinctive psychological profiles in some instances (see Skuse & Kuntsi, Chapter 13) but there is rather less specificity to the supposed cognitive and behavioural phenotypes than sometimes claimed. They are real, and clinically important, but attention needs to be paid to individual variability as well as to syndrome specificity.

A rather different clinical implication has been that the identification of particular test score patterns may indicate which form of intervention is likely to be most effective in this child—giving rise to so-called 'prescriptive teaching'. The intention is clearly laudable and, in the future, it may prove possible to use test findings in this way (Sternberg 1997; Sternberg *et al.* 1998). However, this remains a field in which claims rather outstrip accomplishments and caution is needed in moving from test findings to the planning of intervention strategies. On the other

hand, if a hypothesis-testing single case approach is followed (Berger 1994) it can be clinically worthwhile. The difficulty remains as to whether it is better to build on areas of strength, or concentrate attention to countering areas of weakness, or of finding ways to circumvent the difficulties.

Designing assessments to elicit specific psychological features

For many years *projective tests* used to comprise a major part of the psychological assessment in many clinics. The basic idea was that by presenting people with ambiguous visual stimuli, such as inkblots, as in the Rorschach test, or pictures, as in the Thematic Apperception Test, the meaning that individuals read into these ambiguous stimuli could be used to tap their innermost thoughts, of which they might not even be aware. Furthermore, it was thought that responses could lead to relatively strong diagnostic inferences. Such tests have now largely fallen out of regular usage because empirical findings have shown that the tests have many problems in interpretation and do not give rise to reliable diagnoses as assessed in other ways (Klein 1986). Nevertheless, the basic strategy of using tasks or situations to tap particular realms of behaviour, rather than to rely simply on their occurrence in unstructured situations, or to rely on reporting, remains clinically useful. The well-established clinical assessment tools of this kind are not projective in quite the same sense as the ambiguous pictures. Several different examples may serve to illustrate the approach. In each case, research findings were used to hypothesize the sorts of tasks or settings that might be expected to elicit the relevant behaviours and the tests were constructed in ways designed to isolate the specific psychological features of interest.

Ainsworth's 'Strange Situation procedure' is an example (Ainsworth 1967; Ainsworth *et al.* 1978). It was designed to use very brief separation and reunion episodes to tap qualities of security or insecurity in selective dyadic attachments (see O'Connor, Chapter 46). It was originally developed in Uganda, then further tested and developed in the USA and subsequently used in many different countries. Although it is not without its critics (Lamb *et al.* 1984), it has proved a remarkably robust measure of certain important attachment qualities. It has been important, however, that studies of abnormal groups of various kinds indicated the need to modify the scoring procedures in order to pick up qualities that were not captured by the original scoring system (Main & Solomon 1990; van Ijzendoorn *et al.* 1995). It does not pick up so clearly some of the key unusual features associated with attachment disorders in institutionally deprived children (see O'Connor, Chapter 46) and because of that, and because of the very limited age range to which it is applicable, it is not a tool that can be recommended for ordinary clinical use. Nevertheless, the principles are applicable and it may be that further developments using methods that are more appropriate to tapping variations in attachment behaviour in older children (Waters *et al.* 1995; Cassidy & Shaver 1999) may give rise

to tools that could be used for individual clinical assessment, although that point has not yet been reached.

The Autism Diagnostic Observation Schedule (ADOS) (Lord *et al.* 2000) provides a rather different example. It arose out of an appreciation that it was not particularly informative simply to observe possibly autistic individuals in an unstructured fashion and, at least with younger children, it was not possible to interview them in the ordinary way. Accordingly, various situations providing 'presses' for various forms of social initiatory, socially responsive behaviours, types of play or types of communication, were devised. Empirical research findings showed that it was not particularly useful to score whether or not the children performed particular actions in relation to these situations but the findings also indicated that standardized ratings of social and communicative behaviour were possible. Settings tapped a rich variety of behaviour, the ratings were reasonably reliable, and they had reasonable diagnostic differential validity. The half an hour or so period of observation is not sufficient on its own to give rise to a diagnosis, but the evidence does show that it contributes in a most valuable way to diagnosis when combined with parental reports as also obtained using standardized interviews such as the Autism Diagnostic Interview (Lord *et al.* 1994). Training is required for the use of this assessment but it has come increasingly to be used as part of ordinary clinical assessments in tertiary care clinics that see a large number of children with possible autism spectrum disorders.

It has been a universal experience that the kind of structured diagnostic interviews that are appropriate for older children do not work so well with very young children. Accordingly, a variety of interview techniques, using pictures and play stimuli, have been developed (see Angold, Chapter 3). Similarly, in an attempt to avoid direct, possibly leading, questions about experiences of sexual abuse, there has been the development of play-based interviews using anatomically explicit dolls (see Glaser, Chapter 21). In each case, it seems likely that the 'props' have been useful in getting the children engaged and in stimulating them to talk about relevant experiences. On the other hand, there is the twin risk that the props themselves may bias the information given because of the particular leads they provide. The remedy does not lie in either an uncritical acceptance of these approaches or an equally uncritical dismissal of their use. Rather, it is necessary to approach their use in an empirical way. In so doing, it will not be appropriate to rely on any overall statistic of reliability or validity. Rather, in relation to the situations in which they are used, it will be important to consider rates of false positives and false negatives and also to consider which of these is the more important in the circumstance in which they are to be used (see Fombonne, Chapter 4).

A range of psychometric tests to assess different functions have been devised (see Sergeant & Taylor, Chapter 6) and some of these include the element of response to particular stimuli; e.g. the continuous performance test, in which one of the key aims is to assess children's task performance in circumstances that have, or do not have, distracting stimuli (Rosvold *et al.* 1956; Conners

2000). Portable galvanic skin response (GSR) measures are also available to provide biofeedback to anxious children when they face feared situations.

Assessment approaches, of a quasi-experimental kind, have also been developed to assess both patterns of family interaction and patterns of social cue perception. For example, Goldstein *et al.* (Goldstein 1995) developed a method in which different family members were interviewed separately, differences among them in their perceptions of joint behaviour were identified, and the family was then brought together for a videotaped session in order to discuss these revealed differences. The idea was to provide a standardized stimulus that provided a potential for conflict in order to see how the family dealt with disagreements and differences. Video clips have also been developed to tap people's ability to identify different social cues and to assess the extent to which their interpretations of behaviour (as, for example, in relation to hostility or anxiety) were consonant with those of other people (Roeyers *et al.* 2001). Brown & Rutter (1966) (Rutter & Brown 1966) used parental interviews to tap the emotions expressed when parents talked about their children in response to neutral questions. This gave rise to a measure that came to be called 'expressed emotion' and subsequently to modifications based on a 5-min speech sample (Magaña *et al.* 1986) either in response to a request that parents simply talk unprompted about their children or talk in response to a series of neutral questions about their qualities (Sandberg *et al.* 1993). In each case, the development is hypothesis-based in the sense that standardized stimuli have been devised in order to elicit particular forms of behaviour in ways that are meant to be unbiased. In each case, in addition to the usual matters of standardization, reliability and the like, there is the key question of the extent to which the behaviour in these standard situations is or is not representative of behaviours shown in the more ordinary circumstances of life.

It is clear from numerous studies that these approaches have real value, but equally they also have important limitations. For the most part, the procedures are ones largely confined to research use at the moment, although at least some of them have the potential for development into procedures that might be applied in ordinary clinical assessment.

Conclusions

Throughout the last century, clinical psychology has paralleled clinical medicine in its aspiration that clinicians should be 'scientist-practitioners'; such a concept has had its critics but it is interesting that a recent British survey showed a continuing general endorsement of the evidence-based scientist-practitioner model (Kennedy & Llewelyn 2001). These authors emphasized, as we have done, the range of diverse approaches to scientific enquiry and the importance of a critical pragmatic approach to the integration of research into practice, as well as the need for a high degree of responsiveness to the cultural and institutional contexts of practice. We agree. There are important

ways in which psychology and psychiatry differ but they agree in showing the need for, and value of, a style of applied scientific thinking in approaching clinical assessment. Deliberately, we have referred to applied scientific thinking, rather than experimental designs, because the range of applications is so broad, extending from something that is little more than thoughtful questioning clinical enquiry, to a scientific investigation that approximates to a piece of research that can be applied to individual cases. This is not the whole of clinical assessment, as we have striven to emphasize, but it is an important, we would argue, essential, part of what is involved and it is an aspect that draws as heavily on the clinicians' creative and innovative skills as on their academic knowledge.

Children's Testimony

Stephen J. Ceci, Livia L. Gilstrap and Stanka A. Fitneva

Introduction

Every day courts, social services, mental health professionals and law enforcement personnel are faced with the difficult job of deciding whether to believe a child's report of abuse or neglect. It can be devilishly difficult to sort out the truth in such cases, and it is becoming increasingly common for courts to look to the field of developmental psychology for help. The relationship between research, practice and the law is complicated (see Little, Chapter 71). Consider the following case, which illustrates some unfortunately typical ingredients in such cases, and by implication suggests some areas of need that developmental psychologists might address.

Children's testimonial behaviour in the real world

Case of State of New Jersey v. D.G.

In the State of New Jersey v. D.G., the defendant was an enlisted man in the US Navy. He married a woman who had two children previously. One of her children, Michelle, was four and a half years old at the time of the alleged abuse. Michelle claims that her stepfather asked her to accompany him on an errand one day, and during it he took her to an empty house that the family was planning to move into.

'Michelle stated that the defendant . . . laid down next to her and proceeded to place his hands under her shirt. Defendant touched and squeezed her breasts, fondled her vagina, and kissed her on the mouth. He then pulled off her shirt and pants, removed his own pants and climbed on top of her. Michelle testified that the defendant put his 'dinky' into her and then that he cleaned up the 'wet stuff' on the bed with a towel. He then told her to clean herself up and get dressed.

The pair then proceeded to a pizza place and then returned to the great-grandmother's house.' (State of NJ v. D.G. 1999, WL 64702)

Three weeks later, while Michelle was playing with two girls, her 'Aunt Sandy' found her lying on the bed with these girls who had their pants down to their knees and one of them had her hand down Michelle's pants. Aunt Sandy testified that she 'freaked out' and called the girls bad names. She ordered Michelle to sit alone and told her she was very upset with her.

Aunt Sandy testified that she took her daughters to the bathroom, washed them, and attempted, in her word, to 'deprogram' them. One of these girls told Aunt Sandy that Michelle wanted to 'lick her pee-pee'.

Forty-five minutes after being scolded and isolated, Aunt Sandy returned to Michelle and questioned her. Although she purported to have calmed down by then, she said that Michelle still seemed nervous. At first, Michelle allegedly blamed the behaviour on Aunt Sandy's two daughters; however, after more questioning she stated that her stepfather did those things to her. Michelle testified that Aunt Sandy asked her: 'What made you do this? Did anybody ever do anything like this to you to make you do this?' Michelle replied that her stepfather stuck his 'thing' in her and then 'peed on the bed', wiping it up with a towel. Michelle begged Aunt Sandy not to tell her mother. (Michelle's mother testified for the prosecution that the stepfather was 'a fanatic about towelling himself off after intercourse even after ejaculating inside her'.)

Several days after the incident with the two daughters of Aunt Sandy, Michelle was interviewed by a female detective trained to conduct sex abuse investigations. Her Aunt Sandy accompanied her to this interview. During this interview, however, Michelle failed to make a disclosure about her stepfather, saying only that he touched her 'boobies'. After frequent failed attempts to get Michelle to talk, the detective sensed that she was scared and was holding back. She stopped the videotaped interview because Michelle's nose began to bleed and brought her to a bathroom to stop the bleeding. Then the detective asked Aunt Sandy to reassure Michelle about talking to her. Aunt Sandy put Michelle on her lap and told her to tell the detective the truth. Approximately 7 minutes later, the videotape was turned back on and the interview proceeded. Now on video Michelle proceeded to claim the stepfather had put his penis into her vagina.

The following week, Michelle was examined by a paediatrician who specialized in sexual abuse. Although he found no physical evidence that was diagnostic of sexual trauma to Michelle's genitalia (not unusual, even in cases of known sexual penetration), this paediatrician did report that Michelle demonstrated with an anatomically detailed doll that she had been raped, plus she told him that the stepfather had rubbed his penis against her 'private'. Based on Michelle's doll use and her oral description of events, the paediatrician concluded there was a 'high likelihood that sexual abuse had occurred'.

Michelle alleged that her mother beat her in an attempt to get

her to recant her allegations. She was sent to live out of state with her biological father. When Michelle returned from his home, however, she accused him of raping her in a similar manner (e.g. including the wiping off with a towel). When examined again by the paediatrician, Michelle recanted her allegation against her stepfather but made three different allegations of sexual abuse against her biological father. In the following 6 months, Michelle told her Aunt Sandy, a social worker and an investigator that she had been lying about her stepfather. To confuse matters even more, Michelle recanted her recantations at various times.

Just before the case came to court, Michelle met with the prosecutor and detective and told them her stepfather did not rape her, but after further questioning she told them that her mother had urged her to deny the rape. During the trial, Michelle's testimony changed somewhat from her prior statements. A child abuse expert testified that it is not unusual for abused children to change their statements, especially when they believe that others will not believe them or will criticize them. The jury convicted the stepfather; he was sentenced to a 7-year term of imprisonment.

The case of *State of New Jersey v. D.G.* illustrates many of the challenges facing those who must interview alleged child victims. Should we believe Michelle's claims of abuse, or her recantations, or her recantations of her prior recantations? And was Michelle's behaviour with anatomical dolls diagnostic of abuse? These are a few of the questions that courts turn to developmental psychology for answers. In this chapter we will briefly review the relevant scientific research from the field of children's testimonial competence. We will address each of the following six topics: historical research on suggestibility; recent trends in suggestibility research; whether statement consistency is diagnostic of an accurate report; the use of anatomical dolls in interviewing; boundary conditions beyond which children are hypothesized not to be suggestible; and conclude with the application of suggestibility findings for forensic interviewers.

Historical research on suggestibility

Scientific researchers have examined the question of children's testimonial competence for more than a century, since a study by W.S. Small (1896). Small first asked several students to come to the front of the classroom and smell a clear liquid in a bottle that was an essence familiar to children of that era. After these children announced their answers (claiming it was a familiar fragrance), Small asked the rest of the class to raise their hands if and when they could smell the same fragrance when he sprayed it into the air in front of their classroom. In actuality, the bottle he sprayed contained only distilled water, yet many children claimed to smell its fragrance after seeing classmates' hands raised. Small repeated this practice with sounds, sights (apparent movement of a toy), and other stimuli, and he tested children both in classroom groups as well as individually. He concluded that young children were highly suggestible, particularly when they were in groups. We will return to this claim below as it con-

nects historical research with both more modern research and with actual testimonial situations of past and present.

From the beginning, the dominant view among researchers has been that young children are suggestible—more so than older children and adults. With a few notable exceptions, early scientific studies reported that young children are vulnerable to a variety of suggestive techniques and pressures, such as leading questions, peer pressure, repeated questioning, the tendency to perceive conditions as conforming to expectancies created by adults, and the need to comply with adults' wishes.

One of the earliest scientific researchers of children's suggestibility was Alfred Binet, the French psychologist best known as the father of the modern IQ test. Binet's (1900) book on suggestibility continues to have a role in modern discussions of the topic. Indeed, although Binet's experimental methods may now appear relatively primitive, he reached several conclusions that have continued to be echoed by later research.

First, Binet concluded that young children were highly suggestible. Like others after him (Lipmann 1911; Dale *et al.* 1978), Binet argued that suggestibility reflects the operation of two different factors: cognitive and social. The first factor, which he called 'auto-suggestion', develops within the child without outside influence because it fulfils his or her expectation of what it supposed to happen. In one of Binet's experiments, five lines of increasing length were presented to children of ages 7–14, followed by a series of 'target' lines that were of the same length as the longest (final) line of the series. Children tended to be influenced by the expectation of ever-increasing lines; their reproductions of the target line were systematically too long because they expected that it would be longer than the line that had preceded it. Binet questioned the children after the study and found that many knew that the lines they had drawn were incorrect; they were able to redraw them more accurately on demand. Binet claimed that this demonstrated that children could escape the influence of auto-suggestions.

Binet's second factor was the desire to conform to the expectations or pressures of an interviewer, and thus reflected a form of mental obedience to another. For example, Binet showed that children sometimes asserted that they witnessed non-existent events that they were led to expect. Binet reported that one of the external forces that could affect children's responses was the examiner's language. In one of his studies, he showed children between the ages of 7 and 14 years a poster that contained six everyday items. He asked children a series of questions, some of which were misleading (e.g. implying that a button was affixed to a poster with thread rather than glue). He found that these children often went along with the erroneous suggestion (e.g. claiming to have seen the thread). Some children were asked for their free recall—to write down everything they observed, without being aided by specific questions. These children were the most accurate, although they recalled very little. Other children were asked direct questions about the objects (e.g. 'How is the button attached to the board?') These children, although not as accurate as children in free recall, were significantly more accurate than children who were asked leading questions that sug-

gested an inaccurate answer (e.g. 'Wasn't the button attached by a thread?') who in turn were more accurate than children asked highly misleading and suggestive questions that assumed factually incorrect information (e.g. 'What was the colour of the thread that attached the button to the board?'). Binet did not test questions that were correctly leading (e.g. 'Wasn't the button glued?'). Subsequent research has demonstrated that such questions are answered with the highest degree of accuracy.

All modern commentators agree on this relationship between the nature of questioning and accuracy: free recall is the most accurate (although yielding the sparsest recollections); followed by responses to direct non-leading questions; then by responses to leading questions suggesting an inaccurate answer; and finally by misleading questions (Cunningham 1988; Ceci & Bruck 1993; Ceci & Friedman 2000).

Binet also noted that children's answers to questions are often characterized by exactness and confidence, regardless of their accuracy level. Even among adults, there is low correlation between an eyewitness's confidence and accuracy (Bothwell *et al.* 1987). When the children in Binet's study were later asked if they had made any mistakes, they did not correct their inaccurate responses to misleading questions. Binet concluded that the children's erroneous responses and subsequent high confidence reflected gaps in their memories, which they attempted to fill in order to please the experimenter. Once an erroneous response was given, Binet surmised that it became incorporated into their memory. This assumption on his part was based on the fact that, in contrast to the auto-suggestion study, in which children could later re-draw the line correctly, children in this study were unable later to correct their wrong answers.

Finally, Binet concluded that children are more suggestible in groups than when alone. When a group of three children was shown the same six everyday objects, asked a series of misleading questions, and told to call out the answer to each question as quickly as possible, children who responded second and third were more likely to give the same answer as the first respondent—even if that answer was inaccurate.

The late seventeenth century Swedish witch trials present an interesting analogue to Binet's finding of group conformity effects. Sjoberg (1995) analysed the statements given to parish priests by 809 children and reported that they were more likely to claim to have witnessed celestial apparitions, witches flying on brooms, and so forth, if they gave their testimony to the parish priest after waiting in line with other witnesses outside the rectory to attend prayer meetings. Sjoberg believes this was because they were influenced by other witnesses who also were waiting in line. 'Only 59% of the children testifying at other places than prayer meetings were sure about the real life quality of their experiences of the witches' sabbath whereas as many as 91% were sure about it after standing in line with others at prayer meetings. The differences were significant.'

Other early twentieth century researchers reached results consonant with Binet's, and drew further conclusions that continue to find support. The Belgian psychologist J. Varendonck, a contemporary of Binet's, conducted a number of experiments on

children's suggestibility with the specific intent of demonstrating the unreliability of children's testimony and so enabling him to provide expert testimony in a murder case (Varendonck 1911). In one study, 7-year-old children were asked about the colour of a teacher's beard. Sixteen of 18 children provided a response, whereas only two said they did not know. The teacher in question did not have a beard. In another demonstration, a teacher from an adjoining classroom came into Varendonck's classroom and, without removing his hat, talked in an agitated fashion for approximately 5 minutes. (Keeping one's hat on when entering a room was uncommon then because it was considered a sign of rudeness in that society.) After this teacher had left the classroom, the children were then asked in which hand that teacher had held his hat. Only 3 of the 27 students claimed that the hat was not in his hand.

Varendonck, as well as other researchers in this early period, emphasized one of the points found by Binet, that questioning by influential adults could lead children to make false statements. According to the German psychologist William Stern, children viewed such suggestive questions as imperatives (Stern 1910). Further, both Varendonck and Stern provided early support for the proposition that repeat questioning can have a particularly powerful effect. Stern concluded that a child was likely to remember his or her answers to earlier questions better than the underlying events themselves.

Research by Lipmann (1911) and colleagues (e.g. Piaget 1986) in the same period, also suggested that very young children often have difficulty distinguishing fantasy from reality. More generally, researchers in the 1920s and 1930s consistently found that younger children were more suggestible than older ones (Otis 1924; Messerschmidt 1933; Burt 1948). At the same time, scientists also recognized that even adults can be suggestible to a significant degree (for details, see Loftus 1979).

For several reasons, this early research is of limited usefulness in analysing issues of forensic significance. Most obviously, although some of the early researchers, including Binet and Varendonck, had forensic use in mind, the subject matter of the questions they posed bore little resemblance to the subject matter of statements that children give in actual cases. In the early experiments, children were often asked leading questions about details that they likely regarded as peripheral and of little significance, such as the colour of a strange man's beard in one of Varendonck's (1911) studies, which of several lines was longer in Binet's (1900) study, or whether they smelled a non-existent fragrance when a liquid was sprayed in front of the classroom that in reality was distilled water in Small's (1896) study.

'... Most research on children as eyewitnesses has relied on situations that are very different from the personal involvement and trauma of sexual abuse. Researchers have used brief stories, films, videotapes, or slides to simulate a witnessed event. A few have used actual staged events, but these events—for example, a man tending plants—are also qualitatively different from incidents of child abuse. The children are typically bystanders to the events, there is no

bodily contact between the child and adult, and it is seldom even known whether the events hold much interest for the children. Of even more importance, the questions the children are asked often focus on peripheral details of the incident like what the confederate was wearing, rather than on the main actions that occurred, or more to the point, whether sexual actions were committed.’ (Goodman & Clarke-Stewart 1991)

In contrast to laboratory research, in actual forensic investigations—most of which involve abuse of the child herself—the child is usually questioned about central, bodily actions, often experienced rather than merely witnessed, and frequently associated with embarrassment, fear and pain.

Thus, whatever the early experiments might show about the reliability of children under the conditions of the experiments, they lack *external* or *ecological validity* for the context of principal contemporary significance. That is, they cannot be relied on with confidence to show how suggestible children are in the real-world context of interest—when a child makes an allegation of abuse. Nevertheless, this brief historical review indicates that recent research findings on the suggestibility of children is not a modern departure from earlier understandings; on the contrary, it fits in squarely with what has been the dominant view for a full century.

Defining suggestibility

Traditionally, suggestibility has been defined as ‘the extent to which individuals come to accept and subsequently incorporate postevent information into their memory recollections’ (Gudjonsson & Clark 1986; see also Powers *et al.* 1979). This definition implies that:

- 1 suggestibility is an unconscious process;
- 2 suggestibility results from information that was supplied *after* an event; and
- 3 suggestibility is thought to influence reports via incorporation into the memory system, not through social pressure to lie or conform to expectations.

This traditional conceptualization and demonstration of suggestibility is too restrictive to aid in understanding real case studies like that presented at the beginning of this chapter. Therefore, many researchers have broadened the definition of suggestibility to encompass what is usually connoted by its lay usage. Suggestibility is defined as the degree to which the encoding, storage, retrieval and reporting of events can be influenced by a range of internal and external factors. By adding ‘reporting’ to the definition, we broaden the definition of suggestibility to include false reporting. False reporting implies that it is possible to accept information while fully conscious of its divergence from the originally perceived event, as in the case of acquiescence to social demands, lying or efforts to please loved ones. This broadened definition of suggestibility does not necessarily involve the alteration of the underlying memory; a child may still remember what actually occurred but choose not to report it for motivational reasons. By removing ‘postevent’ from the definition, we

imply that suggestibility can result from the provision of information either before (e.g. in the form of expectations or stereotypes) or after an event.

Thus, this broader conceptualization of suggestibility accords with both the legal and everyday uses of the term, to connote how easily one is influenced by subtle suggestions, expectations, stereotypes and leading questions that can unconsciously alter memories, as well as by explicit bribes, threats and other forms of social inducement that can lead to the conscious alteration of reports without affecting the underlying memory.

Recent trends in suggestibility research

Beginning in the late 1970s, there was a resurgence of interest in the area of children’s suggestibility, which has continued to the present. This virtual explosion of research was fuelled by various factors: a dramatic increase of reports of child abuse and increasing recognition of the commonness of abuse; greater receptivity by courts to expert psychological testimony; increased focus of social scientists on socially relevant issues; and increasing interest in the study of eyewitness testimony of adults (Ceci & Bruck 1993). Thus, researchers became increasingly concerned by the frequency with which children failed to report abuse, by the fact that when they did allege abuse the reports were met with scepticism and also, later, by the possibilities for contamination of their reports. Although virtually all researchers agree that these two possibilities exist, they disagree about the likelihood of each occurring. Additionally, there is vigorous disagreement in interpretation of the recent studies, with some seeing them as supporting the view that children are highly suggestible, and others seeing these studies as evidence for children’s resistance to suggestions.

Lyon (1999) has termed the group of researchers who emphasize children’s suggestibility the ‘New Wave’. In contrast to the so-called New Wave research, those who focus on children’s testimonial strengths have reported studies showing that, in the absence of strongly suggestive questioning techniques, preschool-age children are capable of providing courts with highly accurate recollections. In response to this claim, researchers have provided evidence that actual front-line interviewers routinely employ highly suggestive techniques when questioning young children, leading to the expectation that potential suggestibility errors may occur (Ceci & Friedman 2000). Below, we briefly review some of the studies that are used by each of these camps to bolster their competing claims.

Rather than attempt a full summary of modern research on suggestibility, we begin by discussing four illustrative studies conducted by Goodman *et al.* We have chosen Goodman because she is the scholar most favoured by child advocates and critics of the so-called New Wave research. Yet, her studies provide strong evidence that children, especially young children, *are* suggestible to a significant degree—even about abuse-related questions.

Paediatric examination study

In a study by Saywitz *et al.* (1991), girls whose genitalia and anus were touched during a paediatric examination were much more likely to report that touching in response to doll-aided directed questioning than in response to open-ended questions. In fact many studies have found that young children provide little information to open-ended questions although the information they do provide tends to be highly accurate. This highlights the potential benefits of directed questioning. However, in the Saywitz *et al.* study, although the vast majority of girls whose genitalia had *not* been touched during the exam correctly denied a genital touch, during directed questioning one out of 35 (2.86%) did answer affirmatively when asked about a genital touch, and two out of 36 girls (5.56%) answered affirmatively when asked about an anal touch. Thus, directed questioning can also lead to false allegations of touching.

A common finding in the literature is that directed questioning elicits both more accurate details and more inaccurate details (Ceci & Friedman 2000). We could conclude, as Saywitz *et al.* did, that 'although there is a risk of increased error with doll-aided direct questions, there is an *even greater risk* that not asking about vaginal and anal touch leaves the majority of such touch unreported' (Saywitz *et al.* 1991, emphasis added). However, the data on young children's suggestibility in the face of directed questioning suggest a more conservative approach to its use that acknowledges both the potential benefits and the potential risks.

Delayed inquiry study

Goodman *et al.* (1989) asked 3–6-year-olds to play a game with a strange man for approximately 5 minutes. During this time, the man did not engage in any behaviours that were sexually provocative. Four years later, 15 of these same children, now between 7 and 10 years old, were re-interviewed and asked what they could recall of their prior experience with the strange man. To create an 'atmosphere of accusation', the interviewers said such things as: 'Are you afraid to tell? You'll feel better once you've told.' Goodman & Clarke-Stewart wrote that 'the children were more resistant to abuse-related than to non-abuse-related suggestions'. Nevertheless, these children were quite susceptible to abuse-related questioning: five of the 15 children agreed with the interviewer's false suggestion that the stranger had kissed them or hugged them, two out of the 15 agreed that they had their photo taken by the stranger, and one child even agreed she had been given a bath by him. Goodman & Clarke-Stewart acknowledged that some of these errors 'might lead to suspicion of abuse' (Goodman *et al.* 1989).

Trailer study

Rudy & Goodman (1991) conducted a study in which pairs of 4- and 7-year-olds were left in a trailer with a strange adult. One child watched while the adult played games with the

other, helped her dress in a clown's costume, lifted her onto a desk, and took two photographs of her. Each child was asked various types of questions 10–12 days later, some of which involved actions that might be of special concern in child abuse investigations, such as, 'How many times did he spank you?' and 'Did he put anything into your mouth?' Rudy & Goodman reported that the 7-year-olds 'did not make a single commission error to the specific abuse questions'. The authors concluded that 4-year-old participants made very few commission errors (3%), while the 4-year-old bystanders evidenced a slightly higher, but still low, error rate (7%) (Rudy & Goodman 1991).

Mount Sinai study

Eisen *et al.* (1998) conducted an experiment involving 108 children between the ages 3 and 15 who were examined as part of a 5-day assessment period for children with suspected histories of abuse at Chicago's Mount Sinai Hospital. The important focus of this experiment was of increasing ecological validity by studying children who were actually involved in abuse investigations. The authors expressed the view that, because of various problems that they suffered, this group could be more suggestible than the children typically involved in suggestibility studies. 'It is also possible', they wrote, 'that abused children are hypervigilant regarding abusive actions or abuse suggestions and, as a result, would be more resistant to such questioning than non-abused children' (Eisen *et al.* 1998). On the first day of their stay, children received a medical check-up. On the second day, the children were given an anogenital examination, and swabbed for culture. On the fifth day, the children were interviewed, and the interview included misleading or other suggestive questions. Eisen *et al.* concluded:

'Despite performing more poorly than their older counterparts, the 3–5-year-olds still demonstrated *relatively good resistance* to misleading information in answering abuse-related questions. When presented with misleading questions related to abusive or inappropriate behaviour by the doctor and/or nurse (e.g. 'How many times did the doctor kiss you?'), 3–5-year-olds answered 79% of the questions without making commission errors.' (Eisen *et al.* 1998, emphasis added.)

The unstated implication is that this group made commission errors in answering 21% of misleading abuse-related questions. Furthermore, the authors pointed out that 'approximately 40% of the errors made by the 3–5-year-olds in response to misleading abuse-related questions were produced by only 6 of the 29 children in this group.' Thus, although the group's proportion of commission errors to misleading abuse-related questions was relatively low on average, some children were more suggestible than others. 'If such children were interviewed in an abuse investigation', the authors acknowledged, 'a false accusation could potentially result' (Eisen *et al.* 1998). Children in the older groups did substantially better, but still answered a fairly sizeable percentage of the misleading abuse-related questions incorrectly, 16% for the 6–10-year-olds and 9% for the 11–15-year-olds.

These studies by Goodman *et al.* are each important for understanding children's intellectual development and in revealing the underlying mechanisms of suggestibility and memory. As we have shown, it has been understood since the time of Binet (1900) that a child's free recall tends to be more accurate than his or her responses to suggestive questioning. However, free recall also tends to be extremely sparse. When asked for free recall, children usually give correct but very brief answers, and they often omit important details. This is especially so for very young children, and it is especially true in the abuse context because of the possibility of embarrassment and threats from the alleged perpetrator. One response of researchers such as Goodman has been to emphasize the potential value of suggestive or other directed questioning in securing disclosure of abuse. Abuse investigators have used more directive and focused approaches, including leading and repeated questions, in an attempt to secure useful information from the child and some modern research highlights the potential value of these techniques.

Consider the study by Saywitz *et al.* (1991), discussed above. When girls whose paediatric examinations had included an exterior vaginal and anal examination were asked for their free recall, only 8 of 36 (22%) correctly mentioned the vaginal touch and only 4 of 36 (11%) mentioned the anal touch. Directed questioning with the aid of anatomically correct dolls raised these numbers to 31 (86%) and 25 (68%), respectively. Thus, directed questioning will often be more effective than requests for free recall in prompting disclosures of abuse.

On the other hand, there is risk of creating false positives by suggestive questioning. Although the four studies we reviewed used suggestive questions ('Did the doctor touch you there?' 'How many times did he spank you?' 'Did he put anything into your mouth?' 'How many times did the doctor kiss you?'), they did not use highly suggestive techniques, such as repeating the suggestive questioning over time (Poole & White 1993, 1995), coercion or peer pressure. This is a point that the authors recognized. In three of the four studies, the suggestive techniques employed were embedded in neutral or supportive interviews. These studies therefore provide weak tests of young children's vulnerability to suggestion. Even in this research, however, the evidence shows that error rates for false claims range between 3 and 40%. They do not indicate how high these error rates might go in the presence of a web of motives, strong suggestions, threats and inducements. As we will now show, such highly suggestive techniques can produce much higher error rates.

Impact of highly suggestive techniques

As we have indicated, the studies described above may underestimate the susceptibility of young children when confronted with stronger suggestions. To test this hypothesis, a number of attempts have been made to design and conduct studies that incorporate stronger forms of suggestions—including suggestive techniques that have been used by investigators in some well-publicized child abuse cases (see Ceci & Bruck 1995 for review

of several well-publicized cases). Among these stronger forms of suggestion that research has shown to be detrimental are repetition of question within the same interview (Poole & White 1993), stereotype inducement (Leichtman & Ceci 1995), guided imagery (Ceci *et al.* 1994), peer pressure and selective reinforcement. Numerous studies have shown that when exposed to these forms of suggestion the error rates of children can be very high, sometimes exceeding 50%. Moreover, this phenomenon holds true even when the questions concern events that supposedly affect the child him- or herself as opposed to events to which he or she was supposedly a bystander; even when the questions are central, rather than peripheral to the supposed event; and even when the questions concern abuse-related matters. For the sake of brevity and symmetry with the research we have already reviewed, we will present below only a subset of evidence that falls into this category.

Garven *et al.* (1998) used strong suggestions (e.g. reinforcing answers that were consistent with interviewers' hunches and invoking pressure to conform) based on tactics used in the McMartin daycare sexual abuse case. These researchers found a 57% false claim rate as to various behaviours in which an adult had supposedly engaged, vs. only a 17% error rate when weaker suggestions were used. In a follow-up publication (Garven *et al.* 2000), these researchers found between 35 and 52% false claims—including statements that the adult had tickled the child's tummy or had kissed the child on the nose—in response to strong suggestions, vs. 13–15% when these were not used. The following exchange in their study is an example of a combination of conformity pressure with positive reinforcement:

- I: The other kids say that Paco took them to a farm.
Did Paco take you to a farm?
C: Yes.
I: Great. You're doing excellent now.

Other researchers who have used these stronger suggestive techniques also have reported high error rates for claiming a strange man 'put something yucky into their mouths' during a visit to a science exhibit (Poole & Lindsay 1996), took off their clothes and kissed them (Lepore & Sescio 1994), or touched them inappropriately (Rawls 1996).

Studies focusing on repeated questions include a study by Bruck *et al.* (1995) in which 3-year-olds were repeatedly asked strongly suggestive questions about a doctor touching their anogenital regions (e.g. 'Can you show how Dr Emmett touched your vagina?'). Among children whom the doctor did not touch, fully 50% falsely claimed the doctor had inserted objects into their anogenital cavities. After a third exposure in a period of a week to an anatomically correct doll, one 3-year-old child reported that her paediatrician had tried to strangle her with a rope, insert a stick into her vagina and hammer an earscope into her anus. Similarly, Steward *et al.* (1996) interviewed children aged 3–6 years three times after a paediatric clinic visit. With each interview, children's false reports of anal touching increased; by the final interview, which took place 6 months after the initial visit, more than one-third of the children in this study falsely reported anal touching.

Poole & White (1991) interviewed 4-, 6- and 8-year-olds and adults immediately and 1 week following a staged encounter with a man. Another group of subjects were interviewed only once, after a delay of 1 week. Some of the repeated questions were open-ended ones (e.g. 'What did the man look like?'), whereas others were closed or yes/no ones (e.g. 'Did the man hurt Melanie?'). Poole & White reported that the 'repeat-interview' 4-year-olds were significantly more likely than the 'single-delayed' ones to give a false affirmative answer to the closed question while the repetition of the open-ended questions did not result in more errors. Collapsing across age and gender of subjects, those in the repeat condition were significantly more likely to report that the man hurt Melanie (60%) than were those in the single interview condition (33%).

Finally, in a study by Rawls (1996), 30 5-year-olds and seven 4-year-olds participated in a series of benign play events with a male adult. Over the course of four interviews, the children were asked both open-ended questions such as 'Where were you with X?' and 'What sort of things did you do with him?', and closed questions such as 'Do you know why he touched that part of your body?' Rawls reported that nearly one-quarter of her sample falsely claimed the man inappropriately touched them, with three of the children (10%) falsely reporting genital touching, two (7%) falsely reporting anal touching, and two additional children reporting mutual adult-child touching (e.g. claiming the adult pretended to rub cream into their bodies). The authors stated that 'reports of mutual undressing without touching were also common, although this often reflected a confusion between dress-up items and ordinary clothes.' Similarly, in the so-called Monkey Thief study, Bruck *et al.* (1997) found that over half of the youngest children made false claims of witnessing a theft of food in their daycare facility when they were exposed to repeated suggestions and pressures. (For additional examples of false claims—involving bodily touching or witnessing a bicycle theft—see Cassel & Bjorklund 1996; Ornstein *et al.* 1997).

Taken together, the above studies indicate that if very young children are subjected to questioning techniques that are *highly* suggestive, their rates of making false claims, even on abuse-related questions, may be very high. However, these studies are of limited utility for forensic purposes unless children are in fact exposed to these techniques in the real world of abuse investigation. Elsewhere, we have provided evidence that front-line interviewers use, on average, 8–10 suggestive utterances per interview (questions such as 'He forced you to do that, didn't he?' (Lamb *et al.* 1996; see Ceci & Friedman 2000 for review of this evidence).

Since this article has been in draft, Warren *et al.* (2000) have presented a paper, based on interview transcripts with child protective service workers in a southern state of the USA, that in their view provides some support for the contention that the most egregiously suggestive practices are used only rarely by front-line interviewers of children. The interviews they analysed contained far fewer egregious practices than the studies we listed above. But their data revealed that some particularly sugges-

tive techniques, although usually constituting a small part of the interaction in any given interview, are quite common in that they appear in most interviews at least once. Even a single occurrence of such a technique is capable of derailing the entire interview. Perhaps most strikingly, the interviewers in Warren *et al.*'s analysis invoked negative consequences such as telling the child, 'You haven't told us anything' in 28 of the 42 (67%) interviews. In 40 (95%) of the interviews, the interviewer repeated a question, in an attempt to elicit a new answer, even though the child had unambiguously answered the question in the immediately preceding portion of the interview. In five (12%) of the interviews the interviewer told the child about information received from another person. In 37 (88%) of the interviews the interviewer invoked positive consequences on at least one occasion for an answer, although the researchers report that this occurred mainly in the context of the early rapport-building part of the interview. In 14 (33%) of the interviews the interviewer invited the child to speculate about past events or to use imagination or solve a mystery.

Taken together, the data on practices employed by front-line interviewers indicates that highly suggestive techniques are very common.

Is statement consistency diagnostic?

Consistency of a child's report is often one of the most important criteria used by professionals in evaluating the reliability of children's allegations of abuse (Conte *et al.* 1991), whereas inconsistency in young children's reports lowers their credibility in the eyes of mock jurors (Ross *et al.* 1990; Leippe *et al.* 1992). Several studies have found that when preschool-age children are interviewed twice about an event, about 30% of the information they recall is consistent across interviews, and it tends to be highly accurate (Fivush & Schwarzmueller 1998; Fivush & Shukat 1995). However, accuracy rates when suggestive questioning is used may differ from those of Fivush *et al.* in which there was no suggestive questioning. Perhaps repeated opportunities to reminisce are an advantage if the interviewer avoids using suggestive questioning. We turn to this possibility next.

Based on two findings from a recent study by Bruck *et al.* (in press) that: (i) the length of children's narratives remained the same with repeated interviews; and (ii) the number of their new reminiscences during each new interview were greater for false than true narratives, one would predict that the same details are more likely to be repeated in true compared to false narratives. This was tested directly in analyses that included spontaneous as well as prompted utterances.

We examined how frequently children reported an event in one interview that had been reported in a previous interview. Thus, we examined consistency of utterances beginning at the third interview (because the first interview was a baseline interview that was of necessity not included, so the first comparison was between the second and third interviews), asking whether these details had been mentioned in any previous

interview. Similarly, we examined how many utterances in the fourth interview had been mentioned in previous interviews, and how many in the fifth interview had been mentioned in any of the previous interviews. Numerators were then divided by the total number of utterances in each interview. This measure reflects the proportion of details in each interview that had already been provided by the child in previous interviews.

It was discovered that the true reports were more consistent than the false reports. Summing over the third, fourth and fifth interviews, consistency rates were 67% for true reports about negative events, 50% for true reports about positive events, 30% for false reports about negative events, and 25% for false reports about positive events. The consistency in narratives increased between the third (35%) and fourth interviews (47%), with no change between the fourth and fifth interview (47%).

In summary, repeated suggestive questioning takes a toll on children's accuracy, with increasing errors over time and the consistency of false reports exceeding that of true reports.

Is intercourse positioning with anatomic dolls diagnostic?

Anatomically detailed dolls are frequently used by professionals when they interview young children about suspected sexual abuse. It is thought that the dolls facilitate disclosure by providing props that help young children describe complex and embarrassing events as well as providing them with the appropriate non-verbal cues to facilitate memory retrieval (Boat & Everson 1996). These techniques, which have been especially designed to overcome language, memory and motivational (e.g. embarrassment) problems when interviewing children about sexual abuse, may be potentially suggestive. However, existing data indicate that the dolls do not facilitate accurate reporting (Goodman & Aman 1990) and it also appears that the use of dolls increases errors for younger children (3- and 4-year-olds) when asked to demonstrate certain events that never happened (Gordon *et al.* 1993) or when they are asked to use the dolls to act out an experienced medical procedure (Goodman *et al.* 1997).

Recent studies by Bruck *et al.* (1995, 1997) give examples of the potential suggestion inherent in doll use when interviewing about genital touch. Three- and 4-year-old children had a medical examination, with some of the children receiving a routine genital examination. The children were then interviewed about the examination. During the interview they were given an anatomical doll and told, 'Show me on the doll how the doctor touched your genitals.' A significant proportion of the children who had not been touched (particularly the girls) showed touching on the doll. Furthermore, when children who had received a genital examination were asked the same question, a number of children (particularly the girls) incorrectly showed that the doctor had inserted a finger into their genitals; the paediatrician did not do this. Next, when the children were given a stethoscope and a spoon and asked to show what the doctor did or might do with these instruments, some children incorrectly showed that

he used the stethoscope to examine their genitals and some children inserted the spoon into the genital or anal openings or hit the doll's genitals; none of these actions occurred. We concluded that these false actions were the result of implicit suggestions (communicated through a number of requests that the child use the dolls to show and talk about touching of the genitals and buttocks) that it is permissible to show sexualized behaviours. Also, because of the novelty of the dolls, children were drawn to insert fingers and other objects into their cavities.

A number of recent studies have raised concerns about the use of dolls with young children, who generally have difficulty with symbolic representations. Deloache *et al.* have argued that because young children exhibit general problems in symbol-referent relations, they therefore may have difficulty in using dolls as symbols of self and colleagues. Some of Deloache's work confirms this prediction. In these studies (Deloache & Marzolf 1995; Uttal *et al.* 1995), a sticker was first placed on a child or on a researcher, then the child was asked to use a doll to show where the sticker was placed. Children between the ages of 2.5 and 3.5 years made many errors when they used a doll to show where the sticker was placed on their own body. However, they were much more accurate when asked to represent one doll with another doll or when the sticker was placed on the research assistant and the child showed on his or her own body where the sticker had been placed. From these findings, Deloache concluded that children do poorly when they have to use dolls as a symbol of a person.

Although there is concern about the use of dolls with 3-year-old children, the results of a study by Saywitz *et al.* (1991) suggest that these concerns do not extend to 5- and 7-year-old girls. In their study, half of the children had received a genital examination and the other half had received a scoliosis examination in which the child's genitals were not touched by the doctor. When questioned several weeks later, most of the children in this study who had received a genital examination made omission errors (they failed to report genital or buttock touching when they were asked for a verbal report of their examination, or they failed to show on the dolls what had actually happened). However, when the experimenter pointed to either the genitalia or buttocks of the doll and asked a direct question, 'Did the doctor touch you here?', a substantial majority of the children now correctly assented to buttock or genital touching, thus reversing their earlier omission error. In contrast to the Bruck *et al.* findings, children who received the scoliosis examination (with no genital touching) never made false reports of genital touching (errors of commission) in either the verbal free recall or the doll enactment conditions. For this group, errors of commission were very low when the experimenter pointed to the genital or anal region of the doll and asked, 'Did the doctor touch you here?'

In summary, the dolls in the Saywitz *et al.* study of older children did not promote false reports of touching, and when used in a very directive manner, they reduced children's resistance to talk about anogenital touching, and reversed their former false denials.

Are there boundaries beyond which children are not suggestible?

There is still some controversy regarding the boundary conditions for younger children's greater suggestibility. Some argue that suggestibility is diminished or even non-existent when the act in question concerns a significant action, or when the child is a participant as opposed to a bystander, or when the report is a free narrative (Goodman *et al.* 1990; Fivush 1993). The strongest claim of this sort is that children are not suggestible about personally experienced central actions, especially those that involve their own bodies.

While it is probably true that children are somewhat less prone to false suggestions about actions to their own bodies as opposed to neutral non-bodily acts, the literature clearly does not support the strong view that bodily acts are impervious to suggestion. There are numerous demonstrations of how suggestive interviewing procedures can lead children to make inaccurate reports about events involving their own bodies and at times these reports have been tinged with sexual connotations. As noted earlier, young children have made false claims about 'silly events' that involved body contact (e.g. Did the nurse lick your knee? Did she blow in your ear?), and these false claims persisted in repeated interviewing over a 3-month period (Ornstein *et al.* 1992). Young children falsely reported that a man put something yuckie in their mouths (Poole & Lindsay 1995). Three-year-olds falsely alleged that their paediatrician had inserted a finger or a stick into their genitals (Bruck *et al.* 1995). Preschool-age children falsely alleged that some man touched their friends, kissed their friends on the lips and removed some of the children's clothes (Lepore & SESCO 1994). Studies of children who have undergone a radiological procedure (a voiding cystourethrogram) accord with this claim (Goodman *et al.* 1997). These children have their bladders pumped with fluid and are encouraged to urinate on the table in front of the medical staff. Later, they are asked suggestive questions about whether they were kissed during the procedure, etc., and the results indicate that children are suggestible about such matters.

Additional examples are provided by research by Goodman *et al.* In one study, 3-year-olds gave false answers 32% of the time to questions such as, 'Did he touch your private parts?', whereas 5-year-olds gave false answers 24% of the time (Goodman *et al.* 1990). In response to questions such as, 'How many times did he spank you?', 3-year-olds gave false answers 24% of the time, while 5-year-olds gave false answers only 3% of the time (Goodman & Aman 1990). When 3-4-year-olds were interviewed about events surrounding an inoculation, there was an error rate of 23% on questions such as, 'How many times did she kiss you?' and 'She touched your bottom didn't she?'. Many of these children replied 'yes' even though these events did not occur.

Taken together, one can safely conclude that, compared to older children, young children, and specifically preschool-age children, are at a greater risk for suggestion about a wide variety of topics, including those containing sexual themes.

Conclusions

Notwithstanding the above conclusion, it is clear that children—even preschool-age children—are capable of accurately recalling much that is forensically relevant. For example, in many of our own studies, children in the control group conditions recalled events flawlessly. This indicates that the absence of suggestive techniques allows even very young preschool-age children to provide highly accurate reports, although they may be sparse in the number of details. There are a number of other studies that highlight the strengths of young children's memories (see Goodman *et al.* 1992; Fivush 1993 for a review). What characterizes many such studies is the neutral tone of the interviewer, the limited use of misleading questions (for the most part, if suggestions are used, they are limited to a single occasion) and the absence of the induction of any motive or stereotype for the child to make a false report. When such conditions are satisfied, it is a common (although not universal) finding that children are relatively immune to isolated suggestive influences, particularly about sexual details.

An important implication of the studies that focus on the strength of children's reports is that although children are generally accurate when they are interviewed by a neutral experimenter, who asks few leading questions, and when they are not given any motivation to produce distorted reports, there are occasionally a few children who do give bizarre or sexualized answers to some leading questions. For example, in the Saywitz *et al.* (1991) study of children's reports of their medical examinations, one child, who never had a genital exam, falsely reported that the paediatrician had touched her buttocks and on further questioning claimed that it tickled and that the doctor used a long stick. In a study of children's recollection of their visit to a laboratory (Rudy & Goodman 1991), one young child claimed that he had seen bones and blood in the research trailer (see Goodman *et al.* 1992 for additional examples). Thus, young children occasionally make spontaneous, strange and unfounded allegations, and the individual difference factors that may contribute to these bizarre narratives are unknown. However, as Goodman *et al.* point out, many of these allegations can be understood by sensibly questioning the child and parents further. Still, interviewers must be especially cautious when dealing with younger children because they are disproportionately suggestible to deviation from the ideal neutral interview. This leaves three important questions.

- 1 What is it about younger children that makes them more susceptible than older children?
- 2 Why do some children provide spontaneous elaborate false reports?
- 3 What do these findings tell us about who should interview and what types of training interviewers should be given?

Why younger children may be more susceptible to suggestive interviewing

Not a great deal is known about factors that lead some children

to create embellished false narratives and colleagues to resist this tendency. Despite vigorous research activity on this issue, there is much that we know does not account for variation among children. For example, differences in intelligence (above the borderline retarded threshold level) do not appear to discriminate between children who develop false narratives and those who do not; nor do a variety of personality attributes, such as need for compliance, need for closure, and dissociation. The few factors that have been found to be associated with false narratives are source monitoring ability (keeping track of the source of memories) and memory strength. In general, younger children lack well-developed source monitoring skills, and this may be a major reason why they produce more false narratives than older children and adults. If a child learns about an event from a story read to them, or even through a dream, they are more likely to later believe that they learned of it through actual participation. Similarly, younger children's memories are weaker and fade quicker than older children's memory traces, and this, too, may be a reason they create more false narratives. In studies of individual differences among children of the same age, these same factors appear to be associated with differences in false narratives. Children who have stronger memories are more resistant to suggestions about those memories.

Interviewer training and selection

There is not a great deal of data on who should interview, although people prone to emphasizing their own authority or who have an ingrained bias or expectation as to the outcome of an interview which cannot be dissuaded by training are probably not ideal candidates. Some data on the effectiveness of specific interviewer training programmes has emerged (Warren *et al.* 1999), but more research needs to be carried out in this area. The types of interviewer behaviours that should be encouraged, however, have received attention and we have discussed many of those: open-ended questioning; the use of directed questioning with caution and only in the most neutral manner; avoiding any stereotype induction; minimizing motivation to provide specific answers; and not introducing information or preferences to the child.

It is important to note that both areas of research have contributed to a growing body of knowledge that is beginning to influence the training of forensic interviewers. These findings have resulted in texts that provide interviewers with clear real-world recommendations on interviewing (Ceci & Bruck 1995; Poole & Lamb 1998). Changes in interviewer behaviour to more open-ended questioning helps both victims of child abuse and victims of false accusations.

Family Interviewing: Issues of Theory and Practice

Ivan Eisler

Introduction

Conjoint family interviews, whether as part of assessment or treatment, have become a standard part of child psychiatric practice. A well-conducted family interview will provide the clinician with an important source of information about the family and opportunities for intervention that are not available when family members are seen on their own. Like other clinical interviews, the family interview will generally have a mixture of objectives—making an engagement with the members of the family, obtaining information and observing family process for purposes of assessment and making therapeutic interventions.

The family interview has a number of distinct features in comparison with an individual interview, which gives it both strengths as well as certain weaknesses. It offers the opportunity to observe family members in direct interaction, which can give unique insights into the way the family is currently functioning and the way it is organized around the presenting problem. The family interview is also well suited to explore the perceptions and meanings that different family members hold about the problem, which can lead to new understandings of the part it might be playing in their lives. If the family members experience the clinician as someone who has a real interest in their different points of view and takes each of them seriously, the opening up of different perspectives in this way can be an important starting point for the process of therapeutic change. On the other hand, as Cox (1994) has argued, the family interview is not ideally suited for the gathering of historical data about the individual (or family) and its ‘public’ nature may make it more difficult, and sometimes inappropriate, to discuss issues that family members may feel are private or awkward to talk about in the family context.

A useful framework for thinking about the family interview (both in terms of understanding the observed family process and also as a way of framing some of the specific techniques and interventions that may be used by the clinician when seeing the family) is provided by family systems theory. Before outlining this theoretical framework, an important caveat needs to be made.

Clinicians sometimes assume that the principal reason for a family assessment is to identify dysfunctional patterns of family functioning, which may be the underlying cause of the child’s problem and which need to be corrected if the child is to be helped. Over the years a variety of theoretical family models (see Jacobs & Pearse, Chapter 57) have been put forward to explain

the development of a range of disorders from schizophrenia (Bateson *et al.* 1956; Lidz *et al.* 1957), through anorexia nervosa (Palazzoli 1974; Minuchin *et al.* 1975) to conduct disorder (Patterson 1982). These models, based on careful clinical observations, are often very persuasive and have been highly influential, leading to important developments in family therapy (Dare *et al.* 1995). Paradoxically, alongside the growing evidence for the effectiveness of family interventions for most child and adolescent disorders (Alexander & Parsons 1973; Patterson *et al.* 1982; Russell *et al.* 1987; Henggeler & Borduin 1991; Joanning *et al.* 1992; Kazdin *et al.* 1992; Borduin *et al.* 1995; Webster-Stratton & Hammond 1997; Eisler *et al.* 1997, 2000; see also reviews by Carr 2000a,b), there is also increasing evidence that many of the theoretical models, such as Bateson’s double-blind theory (Bateson *et al.* 1956) or Minuchin’s model of the Psychosomatic Family (Minuchin *et al.* 1978) are flawed (Olson 1972; Kog *et al.* 1985; Eisler 1995a).

While it is undoubtedly true that relationships within the family, the emotional climate and the patterns of family interaction are an important part of the complex matrix that contributes to the development and/or maintenance of individual psychopathology, the evidence that specific family factors or particular forms of family organization are directly associated with certain disorders is not very persuasive. Poor family functioning, family discord, inadequate parenting or neglect are generally higher in clinical samples than in control groups (Sawyer *et al.* 1988; Friedman *et al.* 1997; Beavers & Hampson 2000) but this is likely to be a reflection of a complex interaction over time between the effect of the family environment, personality and temperamental characteristics of the child, the impact of the developing disorder on the family, resilience factors as well as mediating genetic factors (Fergusson & Lynskey 1996; Rutter 1999). This is highlighted by behavioural genetic research showing the differential impact of the family environment on children within the same family (Dunn & Plomin 1990; Reiss *et al.* 1995; Rutter *et al.* 1999).

When observing a family in the clinic setting it is all too easy to forget the complexity of the interaction that has led to the current situation and to jump to the conclusion that the observed pattern of family functioning can provide the explanation of why the child has problems. Such a conclusion is not only diagnostically simplistic but also therapeutically unhelpful as it reinforces feelings of guilt and blame which family members, and parents in particular, are likely to experience (Reimers & Treacher 1995). The clinician needs to be sensitive to the fact

that inviting the whole family to attend together may be interpreted by them as an indication that the family is seen as the source of their child's problem.

Family systems theory

The idea that the family can be thought of as a *system* may seem at one level self-evident, as clearly the family is an entity that is more than just a collection of individuals. Members of a family are intimately connected, they have a shared history, they may share certain beliefs and values, they take on particular roles and they find themselves responding to one another in predictable ways. The connectedness of the elements of the system and the notion that what happens in one part of the system has an effect on the rest of the system fits well with our notion of the family, but accords less well with how we think of individuals. It seems to take away from the value that we attach to individuals, their individual feelings, beliefs and their ability to make choices about individual actions.

A similar tension arises when we consider individual development as being part of an evolving family system. If children as well as parents are considered 'merely' as elements in the system, how do we account, for instance, for the differences in power between parents and children to influence the evolving system? Even though we may readily accept that parents and children influence each other mutually, we still want to emphasize that it is primarily parents who socialize their children, and not vice versa. While at a theoretical level it may be possible to integrate the essentially linear notions of individual development and growth with the systems notion of circular causality (Minuchin 1988), in practice there is always likely to be a tension between the two perspectives. There is a danger therefore that we either concentrate on the individual without taking sufficient account of the family context, or that we focus on the family to the extent that we lose sight of the needs of individual members and, in particular, the child (Strickland-Clark *et al.* 2000).

It is beyond the scope of this chapter to discuss family systems theory in detail but the following are the key features (for more detailed accounts see Gorell Barnes 1985; Eisler 1993; Dallos & Draper 1999).

The social context of behaviour

Individual behaviour and individual personal characteristics need to be viewed in the social context in which they occur. It is a familiar observation that individuals will behave differently in the different contexts in which they find themselves. At the simplest level, every behaviour is both a response to the previous behaviour and, at the same time, a stimulus for the next element of behaviour in the sequence (such sequences often being recursive, so that behaviours may be mutually reinforcing). The way in which even a simple sequence of behaviours evolves is complex, as it depends on the meaning attached to the observed behaviour as well as the anticipation of future response(s). For instance, an

anxious child may complain of feeling sick before going to school, which may evoke a worried response from the child's mother which in turn may reinforce the child's anxiety. Mother's response will have been determined not only by her perception of the situation but also by her anticipation of how others (father, school, etc.) are likely to respond. If father perceives the child's behaviour as manipulative and/or views mother's worried response as something that is fuelling the anxiety in the child, he may try to play down the urgency of the situation. Mother may see this as father's lack of understanding (or lack of concern) and she may respond by highlighting the seriousness of the situation, which will have an effect on both the father's and the child's further response. Each of the behaviours is only fully comprehended when both the preceding behaviours and anticipated responses are taken into account. In fact, without knowing the social context, it is difficult to know what meaning to attach to a particular behaviour.

Patterns of interactions in families

Over time families develop a set of patterns of interactions which become relatively stable. These patterns are connected to the beliefs, perceptions and expectations that different members of the family have, some of which may be shared and may also become relatively fixed (Byng-Hall 1986; Papp & Imber-Black 1996). Some patterns are related to the structure or the hierarchical organization of the family and the different roles that the family members take on, reflecting family beliefs, often strongly influenced by cultural or specific family traditions, about the nature of family life, gender roles, parenting tasks, etc. Subtler patterns of family process, of which family members themselves may not be always aware, can be observed in the moment-to-moment interaction in the family. When a family discussion is observed, relatively stable patterns can be observed of who-speaks-to-whom, turn-taking, interruptions, etc. (Lennard & Bernstein 1969). More complex patterns, e.g. in the way that a family handles disagreement or conflict, will also be characteristic of a particular family (Minuchin *et al.* 1978; Street & Foot 1984); so that, for instance, when a teenage daughter and her father start having a disagreement, mother will step in and diffuse the argument. In families with an ill child, the symptomatic behaviour will often take on a central role in the process of family transactions to the point where much of what happens seems to revolve around the symptomatic behaviour in a way that may both reinforce the symptom and in turn be maintained by it.

Stability and change in families

The family system evolves through alternating periods of stability and periods of change in response to the changing developmental needs of its members and/or external pressures. The stability and predictability of the family environment is an important aspect of family life, as it provides the context in which the individual developmental needs of its members are met. For

instance, the child's need for dependence and attachment require a degree of stability and constancy in the family but, as the child develops, the family must find ways of meeting his or her needs for independence and separation as well (Langmeier & Matějček 1975; Byng-Hall 1991; Eisler 1993). Thus, as the family evolves through the predictable stages of the family life cycle (Carter & McGoldrick 1989), it needs to be able to adapt and change its habitual style of functioning. These transitional points in the family life cycle (whether in response to developmental changes or to unpredictable events, such as bereavement or family break-up, migration, major societal change, etc.) create pressure on individual family members and may lead to increased psychological morbidity (Hetherington 1989; Sartorius 1996; Gorell Barnes *et al.* 1998; Ritsner & Ponizovsky 1999). The way the family adapts may be a crucial factor in determining the extent of individual vulnerability to such pressures (Walsh 1997).

Current systems theory (von Foerster 1981; Hoffman 1990; Dallos & Draper 1999) emphasizes that the clinician, in exploring the family system, is never a passive detached observer looking in on the system, but has an active role observing him- or herself in interaction with the family. This has important implications for thinking about the way family interviews are conducted and how descriptions of interaction are made, which will be discussed later on in the chapter. It is best illustrated by an example. Clinical accounts of families often include descriptions of 'overprotective' parental behaviour (Levy 1939; Minuchin *et al.* 1978). Such a label is limited, in that it does not take into account the interaction between the parent's protective behaviour and the child's dependent behaviour and often ignores the context in which it occurs (e.g. a serious illness in the child). Equally importantly, it assumes that the clinician is a detached observer who is simply describing a behaviour and is not influenced by his or her own relationship with the family. However, the parent who is described as 'overprotective' is probably also being experienced by the clinician as someone who is reluctant to heed the advice to give the child more independence, thereby frustrating the well-meant efforts of the clinician. The description of overprotectiveness therefore has to be seen both as a reflection of the observed parent-child relationship and also of the relationship between the clinician and the family.

Social and cultural context of the family

Earlier family therapy texts tended to treat the family as a normative entity and took little account of the enormous diversity of family life and the role of the wider social and cultural context in which the family is placed. These issues are noted also in Jacobs & Pearse (Chapter 57) and will not be discussed in detail here. However, it is important to stress that awareness and sensitivity to cultural and social diversity of families is a crucial factor in how we as clinicians relate to families, the language that we use, the meanings that we attach to our observations of family interaction, as well as the choice of therapeutic interventions

and our expectations of the effect that these might have on the family (Lau 1984; Hodes 1985; Messent 1992; Wieselberg 1992; Gorell Barnes 1994, 1998).

The other aspect of the wider social context that the clinician needs to keep in mind is the family's position in relation to other professionals or agencies. Often there is a network of helpers within health, education or social services, with whom the family has an ongoing relationship. These relationships have an important bearing on what the family expects of us, how the family members present themselves and how they experience our interventions. At times the network of professional relationships can become quite disabling, creating a sense of neediness and helplessness, which is met with further provisions of support, making any resources that the family itself has more and more invisible (Cooklin *et al.* 1983; Imber-Black 1988; Boyd-Franklin 1989). Exploring the relationship that the family has with the professional network can therefore be an important part of understanding how the family is functioning.

Practical aspects of family interviewing

How and when clinicians use family interviews in their clinical practice varies considerably. This is largely determined by theoretical preferences, although factors such as the age of the child, the nature of the presenting problem or other factors, such as research or training needs, may also have a role. Different considerations may also apply, depending on whether one is thinking of the family interview as part of engagement, assessment or treatment, although clearly the distinction between the three is somewhat arbitrary. An assessment interview is a starting point for the development of a treatment alliance but, at the same time, enquiring sympathetically about the problem, clarifying its nature and asking how it affects different family members is also a very powerful therapeutic intervention in its own right. By the same token, however thorough the initial diagnostic assessment interview has been, during the process of treatment new information and new connections will emerge, adding to or changing the initial conclusions that were reached during the assessment stage. For the purposes of this discussion the distinction between engagement, assessment and treatment is useful, because it may help to clarify some of the ideas of when and how it may be useful to include family interviews in clinical practice.

The family interview as a context for engagement in treatment

For the systemically orientated clinician, the family interview is both the principal assessment instrument as well as the main context for therapeutic interventions. Most family therapy texts therefore assume that a family interview will also be where the engagement and the negotiation of the treatment contract takes place. Not all clinicians use the family interview to this extent, seeing it perhaps primarily as just one of the components of a comprehensive assessment and would not necessarily think of

inviting the whole family to the first meeting. However, there will be many instances when it is useful to start by seeing the family together. Children and adolescents seldom seek psychiatric help for themselves and how they are to be engaged in the treatment process has to be considered alongside of how one engages the parents. For young children, being seen together with the parents, at least initially, may feel less threatening than being seen on their own. There may also be advantages, as will be discussed later, in seeing a reluctant child or adolescent in the context of a family meeting, as it may be possible to engage them even without them taking a particularly active part.

Whether the family is initially seen in a conjoint interview or separately may make a difference to their expectation of future treatment and perhaps also to their perception of why they are being asked to attend as a family. In a randomized study in which a conjoint family assessment was compared with separate parent and child assessments, Cox *et al.* (1995) found that there was a significantly higher failure rate of attendance for subsequent appointments if the mode of contact (conjoint or separate) was changed after the initial assessment. There is also evidence that families in which both parents attend the first interview are more likely to continue in treatment than when only the mother attends (LeFave 1980). Engaging the whole family may be more difficult where there is hostility, criticism or generally poorer family functioning (Szmukler *et al.* 1985; Dare *et al.* 1990; Hampson & Beaver 1996a), particularly if the style of treatment does not provide sufficient structure and containment (Hampson & Beaver 1996b).

The family interview as part of assessment

In one sense the case for including conjoint family interviews in a comprehensive assessment is the most obvious. The family interview certainly provides an ideal opportunity to assess the patterns of relationships, the emotional climate of the family and a chance to see the way in which the family has become organized around the symptomatic behaviour of the child. However, to argue that such information can only be obtained by seeing the family together would be to overstate the case. A number of studies have shown that, when global measures of family functioning are used (family or marital satisfaction, family competence, family health, etc.), self-report measures correlate highly with clinical ratings of observed interaction in both clinical (Miller *et al.* 1994; Hayden *et al.* 1998; Beavers & Hampson 2000) and non-clinical samples (Stevenson-Hinde & Akister 1995). Ratings on individual subscales showed moderate but significant correlations both between individual family members' self-reports and between self-report and observer rating, with the exception of ratings of affective expressiveness and behavioural control (Miller *et al.* 1994; Stevenson-Hinde & Akister 1995). Comparisons have also been made of ratings of Expressed Emotion (one of the most widely used measures of family atmosphere) from individual and family interviews (Szmukler *et al.* 1987; Hodes *et al.* 1999) showing a moderate to strong correlation of ratings between the two settings.

The above studies suggest that while conjoint family interviews may provide a richer and, in some cases, more meaningful picture of family functioning, if the principal aim is to assess the overall level of family functioning, individual interviews should provide a reasonably accurate picture. Indeed, in some instances, individuals may be more willing to report negative aspects of family functioning when they are interviewed on their own (Haynes *et al.* 1981).

The question of whether to include conjoint family interviewing in an overall assessment cannot be answered simply on the basis of comparing the quality of information obtained from individual or family interviews but must also depend on the context and the purpose for which the assessment is made and how the information is to be used. Where the primary aim is to provide a detailed considered assessment on which important decisions about the child might be made (e.g. for a Court report), a combination of family and individual interviews would be advisable. In such cases an open-ended unstructured family interview could be usefully supplemented by one of several available structured family interviews and clinical rating scales that have been developed based on well-defined theoretical models of family functioning: the McMaster Model of Family Functioning (Epstein *et al.* 1978; Bishop *et al.* 1980; Miller *et al.* 2000); the Beavers Systems Model of Family Functioning (Beavers & Hampson 1990, 2000); or the Olson Circumplex model (Olson *et al.* 1989; Olson 1990, 2000). These measures are well researched and have satisfactory psychometric properties (see also Grotevant & Carlson 1989; Kerig & Lindahl 2001 for reviews of family assessment measures). Research and/or training needs might be additional factors weighing in support of the use of such measures.

The potential disadvantage of such an approach is that the assessment of family functioning can easily become a search for family dysfunction. All too often there is at least an implicit assumption that the primary aim of family assessment is to uncover areas of poor functioning, that can be corrected by providing treatment for the family. The evidence that well-functioning families benefit more from family therapy than poorly functioning families (Hampson & Beavers 1996a) suggests that correcting family dysfunction may not be a necessary ingredient of effective family interventions.

The above points highlight the importance for family assessment to focus at least as much on family strengths, family resources and family competencies as on areas of poor functioning. While assessing strengths and resources is an important aspect of any comprehensive diagnosis, it is particularly important if the aim is to engage the family in treatment. A family assessment that is a prelude to (or perhaps more accurately the initial phase of) family treatment is above all a way of answering questions of *how best to work with the family*; questions about *whether or how the family might need to change* should come second. The manner in which we engage the family in this process and the nature of the evolving therapeutic relationship is probably more important than whether the family is seen together or separately.

The family interview as part of treatment

The different ways in which family interviews are used in the context of treatment are discussed in detail in Jacobs & Pearse (Chapter 57) so only some general points will be made here. If one assumes that the impact of a clinical interview experience is directly related to how 'new' the experience is, then clearly the family interview, in exploring a multiplicity of perspectives, always has the potential of having a significant impact on the family and, as Tomm (1987a) pointed out, affords considerably more therapeutic opportunities than clinicians sometimes realize. Positive results have been reported following single session interventions with the family (Boyhan 1996; Campbell 1999; Hampson *et al.* 1999). Because one of the aims of the family interview is to gain access to the different perceptions of individual family members, there are always opportunities for new meanings and new perspectives to emerge. Not all family members will have the same knowledge and understanding of the problem and some may be involved for the first time in discussing the problem openly. Some connections, particularly ones that are linked with the non-verbal processes occurring in families, may have been outside of the awareness of all the family members. The fact that the family interview is an experience shared with other family members means that sometimes even seemingly trivial things occurring during the interview can have quite a powerful effect.

One should not automatically assume that these effects are necessarily always experienced as positive by the family. The process of bringing out unspoken or hidden meanings into the open may sometimes be quite painful for them (Gorell Barnes 1998). This may be particularly true if the family feels judged or criticized, or if the interview itself becomes acrimonious or hostile and is dominated by mutual criticisms among family members. Some of these issues will be addressed in more detail later in the chapter.

How the family is most effectively involved in the treatment process varies depending on the type of problem (Carr 2000b), although there is also evidence that how families respond to treatment may be dependent on an interaction between type of family organization and therapeutic style. Hampson & Beavers (1996b) found that families rated as high on general family functioning responded best to an open collaborative therapeutic style, whereas disorganized families, with unclear internal boundaries, were more likely to do well when the therapist adopted a less open and more directive style. This was particularly true for families where there was open conflict and hostility.

Who should be included in the family interview?

To some extent this will depend on the specific aim of the particular interview and the subsequent plans for how the family should be involved in treatment. In general, it is useful to start by inviting all members of the family living in the household. This provides the fullest picture of the family, both in the way that dif-

ferent family members might be affected (e.g. a 'non-problem' sibling who may be sidelined by the amount of attention that is demanded by the 'problem' child in the family) but, more importantly, the presence of siblings often makes it easier to see some of the family strengths and resources that would otherwise remain hidden.

While one ought not to be rigid about who should come to the family meeting, it is important not to accept too readily that certain members of the family should be excluded, either because the family feels it would not be appropriate for them to attend, or because there is a view that they would refuse anyhow. Often the apparent unwillingness or inability to attend, e.g. because of work commitments on the part of father, turns out to be more to do with his sense that he would not be able to help anyhow and when the clinician stresses his or her belief that father has an important part to play in helping the child, the initial reluctance is usually readily overcome. If a family is being seen as part of ongoing treatment it can sometimes be helpful to see different subgroupings of the family (parents, siblings) on different occasions as this may allow different perspectives to emerge (Eisler 1995b; Gustafsson *et al.* 1995).

Who should be seen when divorced or step-families are involved may be more difficult to decide. It is usually best to start, as one does with intact families, by inviting the existing household. Inviting divorced parents to subsequent meetings may be useful, although care needs to be taken that this is not interpreted as signalling to the children that the aim of such a meeting is to re-create the old family (Robinson 1990). Where the parents have new partners, and where there may be complex step-family arrangements, it is important to take care not only in who is being invited but also in the way in which the invitation is made. Asking the family to help clarify who has what role in relationship to the children (for the purpose of knowing who should be coming to the family meetings) is often useful in helping to clarify boundaries and in exploring where the family is in the process of its life cycle transition. Such clarification can help to provide a greater sense of coherence for the children affected by the family break-up and this in itself may be an important part of helping them to adjust to the transition (Gorell Barnes *et al.* 1998).

Engaging the family and observing family process

It is important at the start of the initial meeting with the family to engage all family members in an age-appropriate way. This requires relating to all family members in a way that makes it clear that their different viewpoints are valued and that the reason they have been asked to come as a family is because they are seen as a resource for helping to deal with the problem, rather than being seen as its cause. It is useful to start by asking relatively low-key social questions about schools, jobs, interests that the children might have, how far the family had to travel for the appointment and so on. This phase of the interview should generally be unhurried and relaxed, making sure that all the family members are included in the interchanges in a way that is appro-

priate for their age. Although the primary goal during this phase is to allow the family to feel more at ease and to get a sense that they are being taken seriously, it also provides the therapist with an opportunity to make initial observations about patterns of interaction and the structure of the family. Who speaks to whom, how family members respond to one another, who is attended to, who finds it easy or difficult to join in the conversation, how disagreements or conflicts are handled, how the children are helped to settle down, etc., will all provide important initial impressions about the family. If the family is being interviewed in a room with a one-way screen or video cameras it is important, during this initial phase, to point these out to the family and explain the role of the observing team, stressing issues of confidentiality.

While much of the initial family interview is likely to be concerned with obtaining information about the nature and history of the problem, the ways in which the family has tried to tackle the problem, and so on, the presence of the whole family makes this a different kind of exercise from individual history-taking. Asking the views of different family members requires the family to reflect on the problem and on their relationship to the problem in new ways, especially if the questions are formulated in a relational manner (as will be described in the following section). Thus, although the focus remains primarily on the presenting problem, the clinician is beginning to collect information about the way the family may be organized in relationship to the problem. The clinician may develop certain hypotheses about the nature of these links which will lead to further questions and the response to these will provide further evidence about the usefulness or otherwise of such hypotheses. This information comes both in the form of the verbal response to the question but also from the non-verbal responses of the different family members.

Specific interview techniques

It is beyond the scope of this chapter to cover in depth the variety of techniques that have been developed for interviewing families (Palazzoli *et al.* 1980; Penn 1982; Tomm 1987a,b, 1988; Burnham 1986; Dallos & Draper 1990; l'Abate 1994). The following provides a brief outline of some of the different styles of questioning that have proved useful in family interviews. Tomm (1988) suggests the following classification.

Lineal questions

These are questions that are asked to orientate the clinician in determining what the problem is, what the family sees as the nature or the cause of the problem, etc. All interviews will include some questions of this type: 'What is the problem that you have come with?', 'How long has it been going on for?', etc. The disadvantage of lineal questions is that they tend to elicit a rather automatic response. Families tend to have a preferred, and often well-rehearsed, way of presenting their problem which may be quite fixed and expresses not only their belief about the nature of

the problem but also often connects with feelings of helplessness, guilt, blame and resentment. This preferred 'story' may be shared by some, though not necessarily all, family members. Tomm (1988) argued that lineal questions, particularly if they are the only type of questions asked, may invoke defensiveness and guilt or lead to criticism among family members.

Circular questions

These differ from lineal questions not only in form but also in their underlying assumption. They are questions that make the assumption that individual problems are connected or embedded in patterns of relationships, and the aim of these questions is therefore to illuminate or make visible what these patterns are. So for instance, instead of simply asking 'What is the problem?', one might ask 'How would different people in the family describe your problem?', 'Who worries about it?', 'Who else worries?', 'When people get worried about how unhappy you are, does it make you more or less depressed?' Other questions might require family members to describe what they make of behaviours that they observe, or speculate about thoughts and feelings of other family members. For instance, instead of asking just about the duration of the problem, the therapist might ask, 'When did your family first notice that you had a problem?' or 'What effect did it have on you when your parents started talking about the problem?' Additional questions might be asked about the way different people in the family responded to the problem and what interactions this might lead to; 'When your mother shows her worry, what does your father do?'

Asking circular questions around the problem often starts to provide a basis for describing the problem in a more contextual way and also allows for alternative descriptions to be heard. For instance, the family might explain that 'Mum is the one that worries most, because she's at home much more, whereas dad is always at work and doesn't really know what's going on', implying that the father, perhaps, cares less than the mother does about the child. Asking the question 'How much time does your father spend worrying about you when he is at work?', 'What is the difference between the way he shows his worry and the way your mother shows hers?' may elicit an alternative description, namely that father feels quite isolated and excluded but prefers not to show this because he fears that he will be told once more that he does not really understand. The unexpected nature of these questions and the sometimes surprising responses may provide both the clinician and the family with alternative ways of viewing the problem, or may bring out a new aspect of behaviour that had not been part of the family's awareness. This can open up new options for the family to act on in search of new solutions.

Strategic questions

These are questions that are used with the primary aim of influencing the family in a particular way rather than to obtain information and are analogous to giving instructions but, because

they are formulated as a question, this may not always be immediately apparent. 'Why do you let your mother speak for you?' is as much a statement which implies that it would be better for the adolescent to speak for him- or herself, as a question asking for an explanation. Challenging interventions of this kind can be useful at times but should be used sparingly, as they can induce feelings of guilt and they may also undermine the therapeutic relationship with the family (Tomm 1988).

Reflexive questions

These are questions that are also intended to influence the family but are less directive, instead requiring family members to reflect on how things might be different under changed circumstances, or if they took a different course of action: 'What would happen if you were able to hide your worry when your daughter got depressed?', 'If your mother didn't try to help next time you have a row with your father which one of you would be more likely to find a way of ending the argument; who would be the one to suggest a compromise solution?' Reflexive questions will typically introduce an alternative way of framing a particular behaviour, opening up new possibilities and challenging the assumptions that may underlie a particular pattern of behaviour. They may address an emotion or an aspect of behaviour that is not being expressed overtly and may only be guessed at. They may include an implicit assumption: 'What will you argue about with your mother when you are no longer bulimic?'—implying both that there will be change and that arguments between adolescents and parents are normal. Reflexive questions, like circular questions, assume that behaviours and the meanings that we attach to them are part of the relational context of the family and that there may be more than one meaning that might be attached to a particular behaviour. The aim is for the family to reflect on this context and to explore the way in which thoughts, feelings and behaviours of different family members connect and how they might change. The following example provides an illustration.

During an interview with a family with a daughter suffering from bulimia the therapist noted the critical tone of mother's voice when she described the bulimic behaviour of her daughter. The daughter would mostly turn away from her mother but occasionally would snap back, which would evoke a very defensive response from her mother. After this happened several times the therapist turned to the daughter: 'When your mother talks about your bulimia are you more aware of her irritation or of her worry about you?' to which the daughter replied, 'I know she's very worried but her irritation drowns that out.' At which point mother joined in: 'I know I sound terribly critical but I'm so worried and I can't stop myself.' Acknowledging mother's anxiety made it possible to also talk about her being critical without it sounding as if the therapist was criticizing her for being critical. The pattern of criticism–irritation–defensiveness–criticism was broadened to include mother's anxiety and both mother's and daughter's sense of guilt.

It is important for the clinician to be able to use a range of

interview styles with families and to have a repertoire of different types of questions. Circular questions, for instance, can be extremely useful in illuminating patterns of relationships in the family and this in itself may be an important and powerful part of the therapeutic process. However, such questions are most usefully applied when the interviewer has a clear hypothesis about the nature of the family relationships and the part played by the symptomatic behaviour in the family organization (Burnham 1986). When the interviewer has a clear focus, one question will naturally lead to the next one, helping to confirm or disconfirm the particular hypothesis. If, however, such questions are used without a clear focus they are more likely to create confusion and a sense of alienation (Reimers 1999; Strickland-Clark *et al.* 2000).

Using genograms

Constructing a family tree is a useful way of enquiring about family history, family beliefs, patterns of relationship over time but also to assess some of the strengths and resources that the family might have, which they themselves may have lost sight of (for detailed discussions of the use of genograms see McGoldrick & Gerson 1985; Bloch *et al.* 1994). This is best performed when an opportunity presents itself, arising spontaneously from a conversation with the family, e.g. about the extended family or a piece of family history that the family themselves have mentioned. 'I need to have a clear picture of who fits where, perhaps you could help me draw a family tree so that I can see this', could be a way of introducing the idea. It is important that the way in which the discussion about the family is conducted highlights that one is enquiring about the family primarily because one is interested in having a better understanding of the wider family context and in particular of the family strengths, resources and resilience, rather than because one is searching for family pathology.

One should enquire not only about individuals and events from the family history but also about the nature of the relationships, looking for patterns across generations in dealing with relevant life cycle transitions, identifying important beliefs and values that the family holds, etc. Enquiring about differences between traditions and beliefs on the mother's and father's side of the family, and which of these and how they have been incorporated into their own family, can provide a useful starting point for a discussion amongst family members. If there are younger children in the family they can be asked to help in drawing the family tree and encouraged to ask questions about the details of the families of their parents of which they are unsure.

When techniques such as genograms are used during family interviews a degree of caution is needed. It is all too easy to read into a genogram far more than is actually warranted and relatively trivial matters may be included and interpreted as giving the 'true' picture of the family. It is therefore particularly important not to try and interpret the meaning of such patterns too readily and it is generally more useful to ask the family what they themselves make of the patterns that they have identified.

Tracking and responding to the interaction process

Awareness and sensitivity to the processes within the family are important, not only as ways of assessing the nature of the relationships within the family, but also as an important part of the process of joining the family and introducing change (Minuchin & Fishman 1981). For instance, if one notices that questions directed towards an adolescent are repeatedly answered by one or other of the parents, one might want to check out how readily such a pattern might change. This might be done non-verbally, by fixing the adolescent's gaze more intently next time one asks a question, or leaning forward so that it is more difficult for someone else to join in the conversation. Alternatively, one could ask a question or comment in a way that draws attention to what is happening; 'I have noticed that you often let your mother speak for you; it is as if you thought she has better answers than you do.' When commenting on family process it is always important to recognize that the same phenomenon can be described in a number of ways: ranging from neutral (questions addressed to the daughter are more likely to be answered by the mother than by the daughter herself); through ascribing agency to one or other participant in the interaction (mother speaks for daughter; daughter lets mother speak for her); to overtly critical (mother behaves in an intrusive way; daughter cannot be bothered to answer any questions). Even quite neutral comments may appear critical to family members and the clinician therefore has to be careful in choosing an appropriate style of comment or question. Andersen (1987) recommended that reflections of this kind are best done in a tentative way rather than being pronouncements or authoritative interpretations that are likely to come across as being judgemental.

Interviewing families with young children

All too often when a family with young children is seen, the children become passive participants of a discussion between the adults. Even very young children can be effectively included in family interviews, provided they are engaged in an age-appropriate way. This can be aided through providing toys, drawing materials, etc., and using creative and play techniques in a similar way that they would be used in individual interviews with a child. Engaging a child effectively is often very reassuring for parents, who may feel unsure whether bringing the child to a psychiatric setting is the right thing to do. The choice of language in talking to parents about their child's problems is also important with young children present as it may be difficult for the child to understand what is being said. Often it is better to ask the parents to explain things to the child, rather than the clinician doing this directly as this may be both less threatening for the child and also reinforces the sense that the parents are the experts in their own child.

With very lively active children the first task is to create a working environment in which what family members have to say can be attended to. This is best achieved by actively collabor-

ating with the parents. Asking the parents for advice on how best to occupy young children 'so that we can also talk' will both reinforce the parents' sense that they are being taken seriously and also may make it easier for the child to join in spontaneously at some point during the interview. Little is gained from trying to talk to the parents until one has assisted them to help the children settle down and play in a way that both the parents and the clinician are comfortable with. Children are often reluctant attendees in a psychiatric setting and may not be too keen to take part in discussions at first. Making it clear at the start of the session that everyone in the room will have an opportunity to have their say, while stressing that it is also fine to sit and listen, is important for some children, to avoid making them feel that they are being put on the spot. When the pressure on them to join in is removed, children will often join in spontaneously. Joining with a child in creative play or talking about a drawing he or she has made can also provide an opportunity for the child to have his or her voice heard in the session (see also Dare & Lindsey 1979; Lerner 1996; Wilson 1998).

A similar situation can sometimes arise with an adolescent who may be reluctant to talk, while the parents may have an expectation that the 'experts' will succeed where they themselves have been unable to get through. While sometimes such an adolescent may be more willing to talk when seen individually this is, by no means, always the case. The advantage of a family interview is that even a reluctant or unwilling participant can be included in an interview through indirect means. Making it clear that the therapist respects the adolescent's right not to speak can avoid an unhelpful battle. This can be done in a way that respects the adolescent's autonomy while at the same time making sure that he or she is not being simply ignored. One might say: 'I often find that young people, when they come here, feel that its best for them not to say too much at first, which is fine, but if you want to say how things are from your point of view I would obviously be interested to know. I do need to know your parents' views about things as well but I want to make sure that we don't simply ignore you, so I will check from time to time whether you want to add something.'

Problems and pitfalls of family interviews

Personal and intimate issues

There will always be areas and topics that are either too difficult or inappropriate to raise in the context of a family interview. The distinction between difficult and inappropriate may sometimes be obvious (e.g. discussing the sexual relationship of the parents in the presence of their children) but more often than not the two tend to get blurred. Often the reluctance to talk about certain topics in the presence of the whole family is either to protect other family members from painful feelings or to avoid the reopening of a disagreement or a confrontation. The appropriateness or otherwise of discussing specific topics will vary from family to family, which will be determined partly by their social,

cultural and religious background, but may also be idiosyncratically connected to specific aspects of their own family history and beliefs. Sometimes the uncertainty that the interviewer feels about whether or how to raise a particular topic may be as much to do with his or her own feelings and attitudes on the subject as they are to do with the family themselves. It is important that it is always made clear to the family that they have a choice about what is to be discussed. Asking questions that help to clarify what the family find appropriate, or asking for permission to talk about a certain subject, will often make it possible to talk about the issue without the discomfort that would otherwise accompany it or prevent the discussion altogether.

As clinicians we are sometimes driven by a quest for ‘complete’ information in order to make sure that we have not missed anything important. This may be justified from an assessment perspective, but clinically it is sometimes more important to respect that families maintain control over the flow of information. It is also important to recognize that the fact that a particular area has not been addressed directly does not automatically mean that the clinical interventions are less effective. In a study that compared two forms of family intervention in anorexia nervosa—conjoint family therapy and a separated family therapy in which the parents were seen as a couple, and the adolescent was seen separately by the same therapist—it was found (Eisler *et al.* 2000) that the conjoint family therapy produced more individual psychological change than did the separated therapy. This was in spite of the fact that some of the areas for which this was true (e.g. psychosexual adjustment) the topics were seldom addressed directly in the conjoint family interviews.

Unequal relationships with family members

With some families the clinician may find it difficult to maintain an equal relationship with all family members. This is particularly true with families where there is an open dispute between family members and where simply being sympathetic to an account from one person may give the impression that one is taking sides. For instance, the parents may have a disagreement as to how best to respond to the difficult behaviour of their child. The clinician may feel more sympathetic to one or the other of the parents, not necessarily because of believing that that parent’s approach is better or more effective but more because of the way he or she perceives the parents overall. Strictly speaking, it is never possible to be entirely neutral, as any act implies that one has taken a certain position and even the overt expression of neutrality itself implies that one is preferring the *status quo* and does not take into account that different family members (children, adults, men, women) are not in equal positions with respect of being able to bring about change. A recognition of this is of particular importance when working with families where there is abuse or violence (Goldner *et al.* 1990; Glaser & Frosh 1993).

Critical or hostile interactions may be difficult to contain

Interviewing families where there is open conflict, hostility or frequent criticism is particularly difficult. Studies of family therapy have shown that such families are more likely to drop out of treatment (Szmukler *et al.* 1985) and are less likely to benefit from conjoint family therapy (Hampson & Beavers 1996a; Eisler *et al.* 2000). There is some evidence that with this type of family a relatively structured directive style of interviewing may lead to a better therapeutic outcome than when a more open collaborative interview style is used, whereas the reverse seems to be the case with other types of families (Hampson & Beavers 1996b). Criticism and hostility are often accompanied by feelings of guilt and self-blame (Besharat *et al.* 2001) and conjoint family interviews that are unable to provide sufficient containment may reinforce such feelings. In such cases it is sometimes better not to see the whole family together, or at least to postpone conjoint meetings to a time when the family is well engaged and some of the painful feelings have been addressed in separate sessions.

It has been a recurrent theme in this chapter that one of the risks of inviting the whole family for conjoint family interviews is that it will be understood by the family as suggesting that they are the cause of the problem. Even when it has been made clear that the purpose of seeing the family is to help them rediscover their own resources as a family, feelings of guilt and blame are very easily re-ignited. A number of studies have shown that even when family interventions are effective they may be perceived as blaming by the family (Squire-Dehouck 1993; Reimers & Treacher 1995).

Confidentiality, boundaries and family secrets

As mentioned earlier, when interviewing families, issues arise around confidentiality and boundaries that are different, to some extent, from individual interviews with patients or parents. Family interviews, by definition, are more ‘public’ than individual interviews. This is not only because of the presence of more people in the room but also because family interviews are often conducted with other people observing through one-way screens or using a video link. This is partly to do with the history of the development of family therapy, which places strong emphasis on the importance of the observing team providing an outside perspective (Palazzoli *et al.* 1978; Hoffman 1981; Boscolo *et al.* 1987), partly with the development of a variety of intervention techniques that make use of the different views held within the team (Papp 1980; Andersen 1987), and also with the way in which family therapy training has developed through trainees being supervised ‘live’ (Liddle *et al.* 1988). There is some empirical evidence that the input of the observing team enhances the efficacy of family interventions (Green & Herget 1989a,b) but it is also clear that families often find the

experience unpleasant or at least uncomfortable, particularly if not enough thought has been given to how such devices should be introduced to the family (Howe 1989; Reimers & Treacher 1995). Reimers & Treacher (1995) found that much of the negative effect on the family of having an invisible team behind the screen could be mitigated by introducing the team members to the family at the beginning of the first session.

Getting informed consent for having an observing team or using a video is part of good practice but it is also a useful way of emphasizing that we respect the family's boundaries and their right to act as gatekeepers to the amount of intrusion that they will allow as part of the clinical process. Demystifying the process by introducing the members of the team to the family and perhaps showing the children how the camera works, can also help in making the family feel more at ease and facilitate the engagement process.

Respecting boundaries within the family is no less important. There are a number of contexts where the clinician needs to be particularly aware of confidentiality issues when seeing families. One is when interviewing a family with an adolescent who may quite appropriately feel that there are aspects of his or her life that he or she does not want to talk about in front of parents. The difficulty arises when the issues of privacy and confidentiality concern behaviours that are potentially risky or dangerous (e.g. self-harm), or symptoms that are clearly of clinical significance and may need to be discussed with others. The clinician will need to be both sensitive to the internal family boundary issues while at the same time making it clear that in some cases issues of safety or health might override issues of confidentiality. For instance, an adolescent girl suffering from anorexia may be reluctant to talk about the absence of her periods in front of her father or brother but at the same time this may be part of the general picture of her trying to hide the seriousness of her illness from the family. The clinician may therefore agree to discuss this in an individual meeting, while making it also clear that her parents need to know the extent of her illness in order to be able to help her. If the adolescent is seen on her own it is important to restate the confidentiality of the individual interview as well as its limits.

It is sometimes assumed that there is an advantage in seeing adolescents on their own as a way of promoting the process of individuation/separation from the family. While it is possible to use individual sessions to address such issues, there is always the danger that the therapist gets co-opted into a parental role and the adolescent's independence may become largely illusory (e.g. as would be the case of the adolescent who is always brought by a parent who then sits in the waiting room while the adolescent is seen individually). If, instead, the individual sessions are combined with, or replaced by, family meetings in which one regularly checks on the appropriateness of what is being discussed in the family context, the issue of separateness/independence is addressed much more directly.

Another type of situation sometimes arises, particularly with families with younger children, when sensitive issues for the family or family secrets are touched on. While one should not as-

sume that anything that is difficult for the family to talk about should be avoided, one also has to respect that when and how a family talk about such issues may determine whether it has been a useful experience for them or not (Karpel 1980). This is particularly important to bear in mind with families with quite young children, as the clinician can sometimes be too 'skilful' in helping the children to talk about things that they actually would rather not say, with the child then perhaps feeling disloyal to the family. It is therefore important that one emphasizes that as clinicians we have to be free to ask even the most awkward questions but the family always has the right not to discuss any particular issues if they feel that the time, the place or the constellation of people in the room is not right.

Conclusions

The conjoint family interview is undoubtedly a valuable part of clinical practice in child psychiatry, regardless of the theoretical orientation that the clinician adopts. Seeing the whole family together provides valuable information that would otherwise be inaccessible to the clinician, about patterns of interaction and family function which the family may not necessarily be always aware of and therefore not always be able, or willing, to provide information on. The aim of this chapter has been to emphasize, both in the account of the theoretical framework and in the account of some of the interviewing techniques, the interactive nature of the task. The clinician interviewing the family is not a neutral detached observer but is an active participant entering into a relationship with the family which inevitably contributes to the picture that he or she forms about the family. This has implications not only for the way that the clinician conducts family interviews and the judgements drawn from them, but also for the effect that the interview is likely to have on the family.

Introduction

The presenting problems seen by individual clinicians vary considerably, reflecting differences in disease prevalence, the organization of psychiatric and paediatric services and the particular interests and expertise of practitioners. The relative importance of the medical history, physical examination and investigations naturally also varies from patient to patient. Some readers may anticipate that this chapter will be irrelevant to their daily practice, whereas neuropsychiatrists may bemoan a lack of detail. In charting a course between Scylla and Charybdis, the overarching objectives are to remind practitioners of the importance of assessing and treating the whole patient, of the need consciously to question the significance of historical information and any physical findings, and to highlight some of the recent developments in investigations, particularly in genetics and neuroimaging.

One of the initial goals is to identify any biological factors that may underlie the referral disorder, as well as to assess growth, nutritional status and general health. In many general child psychiatry outpatient services, identifiable biological factors may be infrequent. However, worldwide these factors are as relevant now as ever, both because of the increasing impact of environmental (particularly infectious) agents on children's health, and because of the advances in identifying genetic influences on developmental and psychiatric disorders, with the associated implications for diagnosis and management. Thus, in the last 5–10 years, HIV and tuberculosis have had a devastating effect upon children in the developing world. Recent wars, political upheavals and changed attitudes have also coincided with an increased incidence of sexually transmitted diseases (with the associated risk of vertical transmission), substantial transnational movement of refugees and a growth in international adoption — all trends that require continuing vigilance for infectious diseases. In parallel there has been a worldwide increase in the non-medicinal use of drugs by the young, with all the attendant psychiatric, social and physical risks.

Previous chapters deal with assessment of psychopathology and the family environment and the measurement of cognitive deficits and developmental delays. Nevertheless, this information will often not be adequate to identify somatic ('organic') aetiologies. This is an important goal because identification of causal influences is necessary to provide optimal treatment, specific advice on prognosis and likely complications and, occasionally, genetic counselling or screening of at-risk relatives. In

ordinary outpatient practice, the amount of detail that it is necessary to obtain from the history, physical examination and investigations will vary according to the nature of the presenting complaint and local circumstances. Thus, this chapter is structured according to the nature of the presenting difficulties and the level of examination and investigation that they require. By necessity, this approach is illustrative rather than exhaustive; the goal is to encourage clinicians to go through a problem-solving approach with each case that they assess. The strategy outlined here is not intended for tertiary services dealing with unusual cases, or for research.

General child psychiatry cases

In most individuals presenting with one of the common disorders of behaviour or emotions, there are unlikely to be aetiological somatic conditions. The starting point is for clinicians first to satisfy themselves that the disorder is what it seems; in other words, are the history and symptomatology typical, the age and nature of onset in keeping with the provisional diagnosis, as well as the clinical course and response to treatment. Usually the clinical picture will be straightforward, but clinicians need to be alert to mention of any physical abnormalities (particularly neurological symptoms such as gait disturbance, clumsiness, or visual changes), an unusual or partial clinical picture, or impairments that seem disproportionate to the degree of symptomatology. These aspects of the history may require clarification to establish if they signify a somatic disorder. On the rare occasion that suspicions are aroused, bodily systems should be reviewed as this will usually provide some of the most obvious pointers to neurological dysfunction or systemic disease (see Edgeworth *et al.* 1996).

Next, the clinician needs to consider whether there is any history suggestive of cognitive impairments in the form of mental retardation, specific developmental delays, chronic difficulties with school work or deteriorating school performance. Again, cognitive difficulties indicate the need for a much more probing history and thorough physical examination (see below). It is not uncommon for mild mental retardation to go undetected until middle childhood and many children first come to attention because of behavioural problems, often associated with poor school performance. Consequently, when patients do not have routine psychometric assessment, the clinician will need to take sufficient history to exclude cognitive difficulties.

A further step is to enquire about any pertinent environmental aetiological factors; drug and alcohol abuse are particularly relevant. Children at increased risk for substance abuse include those with parents who abuse drugs or alcohol, who are in dysfunctional or divorced families, who are subject to abuse and who are under- or overcontrolled by their parents (Belcher & Shinitzky 1998; Milberger *et al.* 1999). It is important always to enquire directly about drug and alcohol abuse, especially in those who smoke. That is because young people who use drugs or alcohol often do not seek help for these problems but are seen because of associated difficulties, such as school underachievement, delinquency, teenage pregnancy and depression (Belcher & Shinitzky 1998). Indeed, alcohol abuse is one of the few factors associated with eventual suicide in adolescents who self-harm (Hawton *et al.* 1993). Identifying drug and alcohol abuse can require clinical acumen, knowledge of familial and individual risk factors, as well as familiarity with the locality. The clinician will also want to establish whether there is any possibility that the child has been subject to abuse; if so, a full physical examination is indicated to search for signs of old and fresh injuries, malnourishment and general neglect. A detailed examination to determine if there is any evidence of sexual abuse should be performed by clinicians (usually paediatricians or police surgeons) with the relevant training and experience.

Before proceeding to the physical examination, the clinician needs to consider several further issues. First, are there any medical conditions relevant to the psychiatric disorder? For instance, behavioural problems are not uncommon amongst children and adolescents with chronic conditions such as diabetes (see Mrazek, Chapter 48), and some drug treatments, such as high-dose steroids, can lead directly to mental state changes. Secondly, in areas of the world where serious infectious diseases are endemic the clinician should enquire directly about relevant symptomatology. That is not because these diseases are common causes of behavioural difficulties (although they are occasionally implicated), but because the physician's concern is with the health of the whole individual, and ensuring that a child receives treatment for tuberculosis, malaria or other serious diseases is a crucial aspect of clinical management. Thirdly, the clinician needs to consider whether the young person's behaviour may itself lead to medical complications. Thus, the drug-using adolescent is at increased risk for contracting a variety of infectious diseases, as well as for criminal behaviour. HIV and hepatitis B may be acquired from contaminated needles and individuals may also be exposing themselves to sexually transmitted infections. The earlier adolescents initiate sexual activity the less likely they are to use a condom and the more likely they are to have unprotected sex with multiple partners; the risks are not trivial because one in every eight adolescents aged between 13 and 19 in the USA has had a sexually transmitted disease (Rome 1999). Part of overall management is to ensure that at-risk individuals are subsequently screened for sexually transmitted and other infectious diseases. Finally, it may be relevant to enquire about medical problems in other family members; e.g. a family

history of thyroid disease may be linked to an adolescent onset of anxiety disorder.

A psychiatric diagnostic assessment should always include a physical examination, albeit sometimes limited in scope. Often an appropriate examination will have been undertaken by referrers, and repetition will not advance the diagnostic process. Nevertheless, if the history suggests an unexpected somatic condition, clinicians should search specifically for the relevant signs. In some settings, not all children will be seen initially by medical staff and the need then is to ensure that an appropriate physical examination has either already been undertaken or can be arranged in a timely manner. It is also helpful to ensure that non-medical staff have some basic training in the features of the history and mental state that indicate a possible organic aetiology and are able routinely to measure height, weight and head circumference.

Clinicians usually begin the physical examination as soon as they meet a patient, whether or not this is performed consciously. An abnormal facial appearance is often most obvious when first seen. Similarly, the patient's language or speech may raise the possibility of neurological or cognitive impairments, and abnormal movements may be noted in the waiting area that the patient is later able to suppress. How the patient rises from a chair, their gait, and possibly stair climbing, can all be observed *en route* to the interview or examination room. Whether the patient looks well or ill, obese or malnourished, well cared for or unkempt should also guide the extent of the subsequent examination.

It is worth paying some attention to the environment for the physical examination proper. If this is to be satisfactory then the room needs to be warm, well lit (but able to be blacked out) and private. In addition to the usual medical equipment, a fixed rule for measuring height, accurate weighing scales, a non-stretchable tape measure, a vision testing chart and a Wood light should be available. A parent or chaperone should usually accompany children and adolescents.

When there is no suspicion from the history or mental state that the child has a somatic condition, when there is no evidence of cognitive deficits and when the patient's appearance has not caused concern, what should be the minimum physical examination? All patients should have height, weight and head circumference measured and these percentiles plotted. One reason for measuring growth is to identify any deviations from normal which in combination with behavioural difficulties, cognitive deficits or physical signs raise the possibility of an underlying syndrome. Another reason is to detect suboptimal development associated with systemic disease or malnutrition. Unless co-operation is limited, growth should usually be measured at the beginning of the examination because some abnormalities may not be apparent until charted, and these should always prompt a search for recognized associations. Clinicians should also be aware that there have been significant upward secular trends in height, weight and head circumference in the developed world over the last century, but there are considerable vagaries in the extent to which growth charts are based on up-to-date data.

If growth parameters are abnormal, the clinician needs to consider the possible underlying causes and also whether the combination of particular behaviours and abnormal growth may signify a syndrome. Short stature and/or microcephaly should both prompt the clinician to review whether there is clear evidence that intelligence is in the normal range; when there is doubt, consideration should be given to psychometric testing. Abnormal growth parameters should also lead to a full physical examination. In the absence of mental retardation or cognitive difficulties, the usual causes of suboptimal growth in developing and developed regions are quite different. In developed countries short stature is usually constitutional, and chronic illness is a much more frequent cause of short stature than are hormonal abnormalities. An appropriate history should already have alerted the clinician to impaired growth as a consequence of feeding difficulties (see Stein & Barnes, Chapter 45). Worldwide, malnutrition is the most common cause of growth retardation and is frequently compounded by parasitic infections; these infect over 3.5 billion people (Albonico *et al.* 1999), and intestinal helminths are the main disease burden in children aged 5–14 years (World Bank 1993). The other major cause of impaired growth or weight loss in the developing world is tuberculosis, which is the leading cause of death as a result of infectious disease: a problem exacerbated by the HIV pandemic and drug resistance (Zumla *et al.* 1999). Clinicians working in areas where parasitic and other infectious diseases are endemic will usually be familiar with their presentation, but a high index of suspicion is also required by those working with exposed immigrant communities, refugees and international adoptees.

Tall stature is usually either constitutional or linked with obesity. However, it is also a feature of several syndromes associated with behavioural disturbance and/or learning difficulties. By and large, clinicians are less aware of the significance of increased as opposed to decreased growth and several syndromes that are not uncommon can easily be missed, especially if they are not associated with obvious cognitive difficulties. Thus, if the diagnosis of Klinefelter syndrome, which affects approximately 1 in 800 males, is not made prenatally, it is very unlikely to be made at all during the first decade (Abramsky & Chapple 1997). Affected males show increased growth and weight associated with eunuchoid proportions, delayed or incomplete puberty and small testes and penis; most individuals are eventually karyotyped for hypogonadism or infertility. Klinefelter syndrome is associated with an increased rate of learning disabilities, poor impulse control and a range of psychiatric disorders (Rovet *et al.* 1996; Smyth & Bremner 1998). 47XYY syndrome affects approximately 1 in 1000 males, about half of whom are diagnosed because of developmental delay or behavioural problems (Abramsky & Chapple 1997; see also Skuse & Kuntisi, Chapter 13). The additional Y chromosome causes increased growth, and body, head and craniofacial dimensions are greater than in control and male relatives (Grön *et al.* 1997). Children with Sotos syndrome show prenatal onset of excessive size with significantly increased growth in infancy. They have a relatively large span and large hands and feet as well as macrocephaly.

Obesity is usually a consequence of excess calorie intake and insufficient exercise, and often it becomes a problem during adolescence. Much less frequently it signifies a congenital or acquired syndrome. Because many of these disorders are characterized by hypogonadism and delayed puberty, obesity should always prompt a full physical examination. Some of the congenital syndromes include major malformations that should already have aided their identification.

Small head size may be a familial or ethnic trait, and may be proportionate to height. Similarly macrocephaly may also be a normal variant and often has a familial basis (Lorber & Priestley 1981). An estimate of pubertal status can usually be obtained from the history from parents and/or the young person. There is considerable variation in the timing of normal puberty, but the physical changes are considered delayed if not evident before 13 years in girls or 14 years in boys, and precocious when seen before 8 years in girls or 9 years in boys. If the history raises the possibility of abnormal timing then the patient should have a full physical examination. The differential diagnosis of disorders of pubertal timing is complex, although some causes are linked with psychiatric and/or cognitive difficulties.

In patients for whom there is no a priori reason (from the history, mental state examination, cognitive testing and measurement of growth) to suspect a concomitant somatic disorder, it is difficult to justify a full physical examination that includes complete undressing. What should the physician do? First, the clinician should check the patient's face and hands for any evidence of obvious dysmorphic features that may signify a perturbation in development. Secondly, there needs to be an examination to identify any signs of drug use. The arms should be examined for evidence of intravenous or subcutaneous drug injection in the form of needle tracks, abscesses, areas of hyperpigmentation, or scar tissue from healed abscesses. Long-term stigmata of oral or nasal ingestion of drugs are minimal, with the exception of inhalation of solvents from a bag which may produce a circumoral rash. Pupillary constriction or dilatation and tachycardia may be seen acutely with many drugs. The clinician should then ensure as a minimum that there are no localizing neurological abnormalities, no evidence of gait abnormalities (an early sign in most progressive neurological disorders) or significant coordination problems, and no visual impairments detectable with a testing chart or hearing difficulties to whispered voice. When young people are assessed who have not had routine developmental surveillance or access to medical services, the physical examination should include undressing and examination of all bodily systems.

Sometimes patients will refuse an examination or be extremely unco-operative. A flexible discussion with the patient and their family, the co-opting of doctors with whom the patient has a rapport, or an attempt at a different time or in a different place will usually be successful. Neither should the utility of repeating an examination be overlooked. That situation is most likely to arise if the diagnosis remains uncertain, the clinical picture deteriorates or the disorder is unusually resistant to appropriate treatment. In these circumstances, signs may be detected that

were previously overlooked or whose significance was not appreciated initially.

There is currently no evidence to suggest that routine medical investigation of all child psychiatry patients makes clinical or economic sense. In the absence of symptoms or signs, are there any other indications for routine screening investigations? First, depending on local circumstances, clinicians will want to consider whether a urine screen for drugs should be routine in newly presenting adolescents or only in those with identifiable risk factors (see Weinberg *et al.*, Chapter 27). Urinalysis should not be restricted to any reported drug of abuse because multiple drug abuse is common. Some drugs, such as cannabis, may appear in the urine for several weeks after consumption, the psychostimulant methylenedioxymethamphetamine (MDMA) or ‘ecstasy’ disappears within 24 h whereas hallucinogens—such as lysergic acid diethylamide (LSD)—will not be detected by urinalysis at all. Secondly, international adoptees are at especial risk of infectious diseases and if they have not had an infection screen at time of entry into the country (Hostetter 1999), the clinician should consider which infectious agents should be excluded. Thirdly, if it is planned to administer psychotropic medication, renal and liver function should be checked (also thyroid function if lithium is to be administered) and, if administration of drugs with cardiac effects is anticipated, then a baseline electrocardiogram (ECG) should be obtained (see Heyman & Santosh, Chapter 59).

Individuals with disorders that involve specific cognitive deficits or developmental delays

In neurodevelopmental disorders, such as attention deficit disorder (ADHD), some form of abnormal brain function is likely to be present, but the association with identifiable medical conditions is much weaker than in individuals with mental retardation. Parents will sometimes wonder whether obstetric or neonatal difficulties were a factor in aetiology, and clinicians will occasionally be faced with the need to differentiate between possible obstetric causes of psychopathology and a suboptimal obstetric history that is a consequence of a genetic susceptibility.

The first task is to clarify whether these difficulties are manifestations of a more pervasive abnormality. Thus, it is essential that a comprehensive developmental history is obtained in all areas of functioning to establish whether the child has a general or specific cognitive difficulty or evidence of motor dysfunction. Also, language delay and symptoms of inattention and overactivity are common in children with pervasive developmental disorders. There should be no diagnostic confusion with cases of clear-cut autism, but it is not unusual for children with milder variants of pervasive developmental disorders (such as Asperger syndrome) to receive an initial diagnosis of ADHD, ‘communication disorder’ or dyspraxia. Thus, the clinician needs to obtain an adequate history of social development. Secondly, these difficulties are usually developmental in origin and the clinician

should be particularly alert to symptoms that arise later in childhood in case they are the initial manifestations of either progressive neurological disorders or abuse.

The next task is to obtain a detailed obstetric and neonatal history. Illegal drug use during pregnancy is now a considerable problem in some communities and should be enquired about in at-risk groups. Drug use is linked with suboptimal pregnancy outcome (Loebstein & Koren 1997), an increased risk for perinatal acquisition of HIV (Belcher & Shinitzky 1998) and subsequent child abuse (Jaudes *et al.* 1995). Similarly, fetal alcohol syndrome now affects at least 2.8 in 1000 live births (Sampson *et al.* 1997) and an alcohol history should be obtained routinely in these cases. It has been suggested that even in the absence of a suggestive pattern of craniofacial dysmorphism (see below), symptoms such as hyperactivity and language delay may be consequences of alcohol use during pregnancy; so-called fetal alcohol effects (Weinberg 1997). When alcohol use was not obviously excessive, the clinician needs to be cautious about assuming an aetiological role when genetic vulnerability may be more relevant. It should also not be forgotten that parental alcohol abuse is an ongoing risk factor for injury, poisonings and medical hospitalizations.

Language difficulties are more common amongst twins than singletons and the rate of multiple births in the developed world has increased significantly over the last two decades, in part because of infertility treatment (D’Souza *et al.* 1997). Currently, there is no clear evidence of an increased risk of psychopathology associated with assisted reproduction. Nevertheless, conception by subzonal injection of spermatozoa appears to have been associated with a skewed sex ratio and a slightly elevated rate of major malformations (Patrat *et al.* 1999) and twins conceived by *in vitro* fertilization are at significantly higher risk for prematurity and associated neonatal morbidity and mortality than spontaneously conceived twins (Moise *et al.* 1998). Indeed twins and other multiples are a vulnerable group, as twinning is associated with prematurity, low birth weight and increased perinatal mortality, as well as an elevated rate of congenital anomalies (Myriantopoulos 1976). The rate of cerebral palsy is also increased, particularly when a comultiple suffers a fetal or neonatal death (Pettersson *et al.* 1998). Thus, when assessing twins (or singleton survivors) clinicians need to obtain a thorough history of the obstetric course and neonatal period. Quite how one interprets a history of obstetric adversity that is not a clear cause of brain damage is problematic in both singletons and twins. Clinicians may need to reassure parents that mild obstetric difficulties are not likely to be aetiological factors.

The role of genetic influences in the causation of ADHD and specific developmental delays has been increasingly recognized (see McGuffin & Rutter, Chapter 12; Schachar & Tannock, Chapter 25), and the clinician should enquire directly about whether other family members are affected by similar difficulties, although the absence of a family history does not preclude genetic influences in complex disorders. Rarely, postnatal environmental aetiologies may need to be considered in the genesis of these difficulties. Thus, paediatric autoimmune neuropsychi-

atric disorders associated with streptococcal infection (PANDAS) have been suggested to represent a distinct clinical entity from rheumatic fever (Garvey *et al.* 1998; see also Rapoport & Swedo, Chapter 35). Affected children show motor hyperactivity, new problems with attention and impulsivity, clumsiness, choreiform movements and emotional lability. The validity of the syndrome as a separate entity remains somewhat uncertain (Garvey *et al.* 1998) and the streptococcal-induced disease remain largely a clinical diagnosis because investigations provide only ancillary evidence (Thatai & Turi 1999).

Interpreting the significance of symptoms of inattention and overactivity and developmental delay depends on knowledge about the child's overall level of cognitive functioning. Accurate diagnosis and optimal management requires comprehensive psychometric assessment and ideally the clinician should be aware of the findings before conducting a physical examination. In practice, this will often not be possible and if evidence of mental retardation subsequently becomes available the clinician should consider whether further examination is warranted.

In terms of the physical examination, several causes of abnormal growth associated with learning difficulties are noted above. The full fetal alcohol syndrome is associated with pre- and/or postnatal growth deficiency (and usually mental retardation). Short stature is also a minor disease manifestation of neurofibromatosis 1 (NF1)—the most common single gene disorder to affect the nervous system—with about one-third of patients having a height at or below the third percentile (North 1998). The rate of mental retardation in NF1 patients is only slightly elevated, but specific learning disabilities affect between 30 and 60% of children. Head circumference is also increased.

In patients with a neurodevelopmental disorder a more thorough physical examination should be conducted that includes undressing, attention to dysmorphic features and examination of all bodily systems. Most children dislike undressing in front of strangers and only the area to be examined should be exposed at any one time, unless there is a concern about disproportion. The examiner should also be able to make full use of humour and any available props.

The major skin and eye manifestations of NF1 to look out for include *café au lait* spots, axillary freckling, cutaneous neurofibromas and iris hamartomas (Lisch nodules). Particular attention should be paid to the neurological examination and handedness noted; language delays are sometimes early manifestations of neuromuscular disorders and the clinician is quite likely to identify neurological soft signs. These refer to a heterogeneous collection of motor delays and problems with coordination that do not indicate a localized abnormality in the central nervous system.

When the age of onset and clinical picture is typical, there is no evidence of mental retardation, and growth parameters and the physical examination are unremarkable, there are no indications for routine blood or urine tests. When the history is atypical, cognitive difficulties are more widespread than anticipated

or there are dysmorphic features or other physical signs, a high-resolution karyotype should be obtained and any suspected single gene or other disorders tested for specifically. Occasionally, the assessment will reveal that the child has mental retardation or a progressive disorder. Although there is some evidence that at a population level an allele of the dopamine D4 receptor gene (LaHoste *et al.* 1996) and a variant of the dopamine transporter gene (Cook *et al.* 1995) may confer a modest increased risk for ADHD, testing for these alleles is not currently useful at an individual level. Similarly, a potential susceptibility locus for language disorder has been localized to chromosome 7 (Fisher *et al.* 1998; Lai *et al.* 2000) and there is evidence for a susceptibility locus for reading difficulties on chromosome 6p (Cardon *et al.* 1994; Grigorenko *et al.* 1997; Fisher *et al.* 1999), but the potential clinical application of these findings awaits further study. Although there has been much research interest in the use of structural and functional neuroimaging in elucidating the brain basis of language and reading disorders, these investigations are not currently indicated in straightforward cases. The clinician should ensure, however, that children with developmental language delay have their hearing tested by a trained audiologist. If treatment with stimulant medication is planned it is important that baseline growth parameters, blood pressure and full blood count are obtained and regularly monitored.

Mental retardation and autism

Both types of disorder are dealt with in this section because autism is frequently accompanied by mental retardation (although identifiable aetiological factors are much more common in mentally retarded individuals who do not have autism). Whether child psychiatrists assess children with severe mental retardation will depend on individual working practices and expertise, but all clinicians can expect to see mildly retarded individuals, although their cognitive difficulties may not have been identified previously. The approach of the clinician, at least with respect to mental retardation, is somewhat different from that outlined above. That is because the starting assumption is that an identifiable cause for general cognitive impairment *can* be found in roughly half of all cases of mental retardation.

The overall approach to these disorders is to obtain a systematic history of potential aetiological factors, to conduct a careful and comprehensive physical examination in order to identify physical signs that might suggest specific causes or syndromes, and to choose investigations judiciously, based either on available evidence or what is known about the probability of individual factors. It is difficult to acquire this range of skills—particularly in physical examination—from reading alone and the training of child psychiatrists should include the opportunity to gain paediatric experience, particularly in developmental surveillance and genetic clinics. Often a specific aetiology will not be identifiable in individual cases, but an understanding of the most likely cause may be sufficient to answer the family's questions. Several studies suggest that a

diagnosis or cause of mental retardation can be identified in 40–60% of cases (Curry *et al.* 1997) and with advances in molecular and cytogenetics and in neuroimaging this rate is likely to increase. Nevertheless, common and distinctive syndromes, such as trisomy 21, will have been identified at birth or shortly thereafter, and the rate of identifiable aetiologies in cases presenting to most child psychiatrists is likely to be somewhat lower.

The history will often indicate probable aetiological factors and consequently needs to be particularly thorough, especially when there are no initial clues as to the most likely aetiology. Exposure to drugs, toxins and radiation during pregnancy must be asked about directly. Maternal infections should also be recorded and, even if there was no significant history during pregnancy, congenital infection should be suspected if there was intrauterine growth retardation, prematurity or a history of neonatal jaundice, hepatosplenomegaly, purpura or rashes. Congenital malformations should be noted.

Medical advances over the last decade have led to improved survival rates for extremely premature and very low birth weight babies, but there has been little change in their neurodevelopmental outcome (Hack & Fanaroff 1999). These infants are at particular risk for cerebral palsy, mental retardation and visual impairments (Lorenz *et al.* 1998). With respect to the aetiology of cerebral palsy, the current consensus is that in most cases the critical events occur in the fetus before the onset of labour or in the newborn after delivery (MacLennan 1999 for the International Cerebral Palsy Task Force). Spastic quadriplegia and, less commonly, dyskinetic cerebral palsy, are the only subtypes that appear to be associated with acute hypoxic intrapartum events. If the clinician suspects that a developmental disorder is linked to prior perinatal difficulties, reviewing the obstetric and paediatric notes may be informative, but the possibility that obstetric difficulties are a consequence of abnormal development should not be overlooked. When children are adopted or fostered it may be difficult to obtain details of pregnancy and early development, but this information will occasionally be relevant. Some internationally adopted children will have come from countries where there is an increased risk for vertical transmission of HIV and syphilis (as well as for infection with HIV by unscreened blood and its products) and in these circumstances more thorough screening investigations are warranted.

With respect to infancy and early childhood, the physician needs to obtain a detailed developmental history and not forget to enquire about signs that may have resolved, such as hypotonia (an early sign of Prader–Willi syndrome) and mild paresis. Severe postnatal infections, such as meningitis and encephalitis, seizures and any associated cognitive decline should also be documented. Children with disabilities are also at risk of secondary complications from their behaviour and any history of pica (potentially leading to lead exposure) and severe self-injury should be noted.

The family history is particularly important in identifying genetic causes of mental retardation. Relatives with psychiatric or medical disorders linked to the patient's condition should be

identified, as well as individuals who might benefit from examination, testing or possibly genetic counselling. The usual starting point is a three-generation pedigree of family members, including an enquiry about consanguinity. Attention should be paid to the presence of learning difficulties, developmental delays and mental retardation, psychiatric disorders and neurological and other medical disorders. Identifying whether the mother has had any miscarriages, stillbirths or neonatal deaths may also be pertinent, as many genetic syndromes show quite variable phenotypic expression and a congenital abnormality in another pregnancy may be related to a milder phenotype in the index child—the holoprosencephaly spectrum providing a clear example (Gorlin *et al.* 1990).

Occasionally, the physical examination may be challenging because of limited co-operation, potentially necessitating a piecemeal or opportunistic approach. With respect to measurement of growth, the association of many mental retardation syndromes with short stature has already been noted. Prader–Willi syndrome (Khan & Wood 1999) is the most common genetic mental retardation syndrome associated with obesity and physical signs include infantile hypotonia, short stature, severe obesity, hypogonadism, and small hands and feet. Microcephaly arising on the basis of *in utero* infection may also be accompanied by eye signs such as retinopathy, cataracts, corneal scarring and micophthalmia and by hearing impairment and cerebral palsy. Otherwise, obtaining newborn and postnatal head circumference measurements may help to differentiate a prenatal from postnatal (e.g. HIV, Rett syndrome) onset of microcephaly. Increased head circumference is found in some individuals with fragile X syndrome (De Vries *et al.* 1998), autism (Kanner 1943; Bailey *et al.* 1993; Woodhouse *et al.* 1996) and is characteristic of Sotos syndrome. Increased head circumference may also be secondary to much rarer conditions, such as the mucopolysaccharidoses. Delayed or incomplete puberty is a feature of Klinefelter, Prader–Willi and Turner syndromes, whereas precocious puberty is sometimes seen in children with neurofibromatosis, tuberous sclerosis, and occasionally as a sequelae of meningitis or encephalitis.

A comprehensive head-to-toe examination of individuals with mental retardation is always necessary, particularly to identify minor anomalies that might lead to specific syndrome diagnosis, or help to date the onset of a developmental problem (Curry *et al.* 1997; Battaglia *et al.* 1999). In this section, the dysmorphic features that the examiner should search for are covered in detail, as most psychiatrists have no particular training in their identification and usually they are not brought together in standard texts. There is a deliberate focus on abnormal facial structures as these provide the most frequent clues to specific syndrome diagnosis. Photographs of dysmorphic features are available in standard texts (Gorlin *et al.* 1990; Jones 1997) and computerized databases (Winter & Baraitser 2000).

The skin should be examined for evidence of phakomatoses. The earliest skin lesion in tuberous sclerosis is the depigmented, ash leaf shaped macule, which is most easily seen under a Wood ultraviolet light. Fibroangiomatic naevi occur princi-

pally in the nasolabial folds and on the cheeks but these may not be apparent until 4–7 years of age. The skin should also be examined for hypo- or hyperpigmentation and naevi, looseness or oedema, absent or excessive facial or body hair, telangiectases and haemangiomas. A malar flush is usually seen in homocystinuria and a photosensitive eruption is common in Hartnup disease.

The shape of the skull should be noted and the forehead inspected for prominent supraorbital ridges or frontal bossing. The examiner should consider whether the face is particularly round, broad, triangular or flat and note any excessive subcutaneous tissue or coarseness. Facial structure should be examined to establish whether the jaw is unusually prominent or receding and whether there is malar or maxillary hypoplasia. The ears should be inspected for signs of malformation, abnormal vertical position or posterior rotation. Inspection of the hair may reveal displacement of the parietal whorl, unusual hair loss, or altered form or brittleness of the hairs.

The examiner should assess whether the nose is particularly short, small or unusually prominent and also note whether the nostrils are properly formed, or are hypoplastic or anteverted. Whether the nasal bridge is unusually low, high or prominent should be considered as well as whether the nasal bridge and nasal root are unusually broad.

The overall size and shape of the mouth, lips and philtrum should be assessed and the possibility of hypotonia considered. The size of the tongue and any irregularities in its shape and the presence of frenula should be observed. The height and width of the palate can also be assessed and the alveolar ridges examined for hypertrophy and lead lines. The examiner should consider whether the right number of teeth are present in the right position and whether their form or size is abnormal.

Eye abnormalities are found in association with all the major chromosomal aberrations, with many inborn errors of metabolism and with congenital infections. During embryonic development the eyes move medially; many syndromes and diseases are associated with an increased distance between the orbits (hyperteleorism) or, less commonly, a decreased distance (hypoteleorism). Many facial features may produce the appearance of hyperteleorism and when the abnormality is suspected interpupillary distance can be measured and compared with published norms (Hall *et al.* 1989; Jones 1997). The slant and length of the palpebral fissures should be assessed, any prominence or retraction of the eyeballs noted, and the eyes examined for congenital ptosis. Whether the medial canthi are laterally displaced should be considered and any epicanthal folds noted. The sclera should be inspected for abnormal pigmentation and the cornea for abnormal size, clouding, opacity or deposits. Defects, unusual patterning or colouration of the iris may also be noted. Brushfield spots may be seen in both Klinefelter and Down syndrome; and Lisch nodules, pigmented hamartomas of the iris, are seen in the majority of patients with neurofibromatosis.

A thorough fundoscopic examination of the eye requires pupillary dilatation. Whether this is a worthwhile procedure must be decided on the basis of the fundal findings without my-

driasis, and the abnormalities detected in the remainder of the examination. A darkened room will normally ensure a reasonable view. Cataracts and lens dislocation may be noted and the retina should be examined for abnormal pigmentation, chorioretinitis and the macular changes seen in storage diseases, such as a cherry red spot or grey colouration. The optic nerve should be examined for atrophy.

The length of the neck should be noted and any abnormal formation of the thorax, such as pectus excavatum or carinatum. The spine should be examined for evidence of scoliosis, kyphosis, vertebral defects and sacral dimples.

The examiner should consider whether the limbs are in proportion to body size and look for fixed deformities of the joints; any joint hyperextensibility should also be recorded. The hands and feet should be carefully examined, paying attention to their overall size, absence or duplication of any fingers or toes or their partial fusion. The examiner may also assess whether the fingers or thumb are unusually long or short and whether there is metacarpal or metatarsal hypoplasia. The thumb and big toe should be inspected to determine if they are unusually broad, and the examiner should determine if any digits are either bent or permanently flexed. The pattern of creases on the fingers, palms and soles should be checked and the nails examined for unusual formation, in particular hypoplasia or hyperconvexity.

A thorough examination of the bodily systems is always necessary and particular attention paid to the presence of heart murmurs, hepatosplenomegaly and anomalies or hyper- or hypoplasia of the external genitalia. Mental retardation is frequently accompanied by sensory impairments and all affected individuals should have audiometry and a thorough assessment of visual acuity.

Sometimes the physical examination will reveal structural abnormalities of uncertain significance and then the next steps are to refer to appropriate atlases and texts and measure possible minor anomalies with reference to population norms (Hall *et al.* 1989). Consultation with clinical genetics colleagues may also be necessary; indeed many clinical genetics laboratories will not order expensive specific cytogenetic investigations unless a clinical geneticist has reviewed the child.

The approach to the investigation of a child with developmental delay varies considerably. A recent survey of consultant community paediatricians found that the typical number of investigations ordered varied from 0 to 15 (Gringras 1998) with the associated costs ranged from £0–1181. At the level of tertiary neurology/developmental paediatric services a comprehensive set of investigations may be routine (Majnemer & Shevell 1995; Battaglia *et al.* 1999) with considerable costs, particularly for neuroimaging and neurophysiological investigations. The current consensus (Curry *et al.* 1997) is that the choice of investigations should be based on the information available from the history and physical examination.

Several different types of abnormality illustrate the general approach. Children with a history or signs of prenatal infection can be tested for immunological evidence of the common aetiological agents: toxoplasmosis, rubella, cytomegalovirus, herpes

simplex and syphilis—the so-called TORCHES screen. These tests are usually most informative when conducted early in life, prior to postnatal infection or vaccination. Some individuals with congenital infections will be asymptomatic at birth, with mental retardation or neurological abnormalities, such as seizures, sensorineural hearing loss, microcephaly or motor problems, appearing at a later age. Although a TORCHES screen is still relevant in older individuals, the interpretation of positive findings is not straightforward. Unlike many causes of mental retardation, the relative importance of infectious aetiologies is subject to secular trends. There has been a recent dramatic increase in the prevalence of sexually transmitted diseases amongst young women in some countries, with the attendant risk of congenital infection. For instance, the rate of syphilis amongst girls age 15–17 years increased 126-fold in the Russian Federation between 1988 and 1996 (Tichonova *et al.* 1997). In high-risk areas a search should be made for Hutchinson teeth, interstitial keratitis, eighth nerve deafness, Clutton joints and rhagades. There is also an argument for routine screening for syphilis in children with mental retardation in endemic areas. The venereal disease reference laboratory test (VDRL) and the rapid plasma reagin flocculation test (RPR) are indirect antigen tests which are sensitive, inexpensive and easy to perform, but false positives occur in 1–2% of the general population. Accordingly, positive findings should be followed by a sensitive and specific test for treponemal antigen, such as the fluorescent treponemal antibody absorption test (FTA-ABS) and the microhaemagglutination assay for antibody to *Treponema pallidum* (MHA-TP). Similar issues with respect to screening arise when clinicians know that there has been a recent upsurge in one of the other infectious aetiologies. Because detailed local knowledge is not usually available when children are internationally adopted, children with mental retardation should routinely have a comprehensive infection screen (Hostetter 1999).

Severe kernicterus is another relatively easily identified cause of mental retardation. Rhesus incompatibility will usually have been investigated in the postnatal period, but if this was excluded the possibility of glucose-6-phosphate dehydrogenase (G6PD) deficiency should be considered, especially as further episodes of haemolysis may be precipitated by a variety of chemicals and drugs. Prolonged jaundice accompanied by feeding difficulties, a hoarse cry and subsequent hypotonia strongly suggests congenital hypothyroidism and the face should be examined for myxoedema and a protruding tongue. Affected infants will occasionally have escaped detection by newborn screening.

Some children may have dysmorphic features that suggest a syndrome that can be tested for specifically, or are strongly suggestive of a chromosomal abnormality:

- fragile X syndrome is characterized by a long face, prominent jaw, thickening of the nasal bridge and large ears;
- Prader–Willi syndrome by a narrow bifrontal diameter, almond-shaped palpebral fissures, narrow nasal bridge and downturned mouth;
- velocardiofacial syndrome by palatal anomalies, a long nar-

row face, narrow palpable fissures, flat cheeks, prominent nose, small ears and mouth and a retruded chin;

- Sotos syndrome by increased head circumference, frontal bossing, antimongoloid slant and a prominent jaw; and
- fetal alcohol syndrome by microcephaly, short palpebral fissures, a long smooth philtrum, a thin vermilion border, epicanthal folds and a flat midface.

However, these physical phenotypes often change with development, further complicating recognition:

- the typical fragile X faces may not be apparent until after childhood;
- the face in Sotos syndrome becomes longer in adolescence with disproportionate prominence of the chin; and
- fetal alcohol syndrome is difficult to recognize at birth and may also become less obvious after puberty.

Developmental changes in physical and behavioural phenotypes are one of the key reasons for comprehensive serial evaluations of individuals, as this increases the likelihood of a specific diagnosis being made. Regular photographic records of patients may be particularly helpful in aiding recognition of an emerging physical phenotype.

Children may show clinical features, such as encephalopathic or acidotic states, unusual odours, poor growth or dysmorphic features, that will suggest the need for targeted metabolic investigation (Curry *et al.* 1997). Neuroimaging is indicated in patients with micro- or macrocephaly or unusual skull shape, and when there are seizures, neurological signs or loss of psychomotor skills. Magnetic resonance imaging (MRI) is now the procedure of choice except when it is necessary to visualize intracranial calcification (e.g. in congenital toxoplasma or tuberous sclerosis) or visualization of the skull is required (as in the various craniosynostosis syndromes).

There will be many children, however, who are not dysmorphic, show no growth abnormalities, and do not have features suggesting either a metabolic abnormality or the likelihood of a central nervous system problem visualizable with neuroimaging. Traditionally, many of these children would have had a comprehensive screen for mental retardation. The current consensus (Curry *et al.* 1997) has been to move away from a routine screen, when there are no clinical indicators of particular disorders, to a more restricted approach. In part that consensus derives from the very low detection rate associated with routine administration of tests such as plasma amino acid chromatography (Curry *et al.* 1997). The current view is that, in the absence of pointers to specific disorders, children with developmental delay should routinely have a karyotype at the 500 band level. That is because chromosomal abnormalities are the single most common known cause of mental retardation and, increasingly, it has been appreciated that they may not always be associated with obvious dysmorphology (Curry *et al.* 1996).

Knight *et al.* (1999) have recently reported that 7% of children with unexplained moderate to severe mental retardation and normal routine karyotypes have subtelomeric chromosomal rearrangements detectable using a multiprobe fluorescent *in situ* hybridization (FISH) protocol. If these findings are replicated by

others, screening for submicroscopic telomeric chromosomal rearrangements should probably also become routine. Because the fragile X syndrome is such a common cause of unexplained mental retardation, laboratory testing is relatively inexpensive and the diagnosis has implications for patient management and genetic advice, *FMR1* testing should also be considered in most patients with unexplained mental retardation (Curry *et al.* 1997).

The advice to move to a limited screen in the absence of pointers to disease is geared towards clinicians with expertise in the assessment of children with mental retardation, who are expected to recognize indications for specific tests. Clinicians who do not consider themselves expert must decide whether to refer on for a more expert assessment or, in situations where this is impractical, to conduct a traditional screen. In addition to a TORCHES screen and karyotyping this would typically include a routine urine examination for unusual colour, odour or sediment; tests for protein, glucose, ketones and occult blood and measurement of specific gravity and pH. The urine should also be examined for metachromatic granules and tested for the presence of mucopolysaccharides (if the Lesch–Nyhan syndrome is suspected in boys, uric acid should also be measured) and the amino acid, organic acid and sugar composition of the sample determined. Haematological investigations include a full blood count with red cell indices, and microscopic examination of a blood film for vacuolated lymphocytes and metachromatic inclusions. Biochemical investigations on blood includes measurement of thyroxine (T_4), thyroid-stimulating hormone (TSH), calcium and phosphate; and plasma amino acid chromatography. In those areas where lead remains an environmental hazard, serum levels should routinely be estimated.

If the course of the disorder is progressive, or there is clinical evidence of a particular disorder but screening tests are negative, then further investigation should be conducted by a centre with expertise in inborn errors of metabolism and progressive neurological disorders. If an aetiology for mental retardation is eventually identified, then optimal care will be provided if the child is seen by a doctor with experience in the underlying disorder. As new aetiologies are recognized and diagnostic testing improves, clinicians should also consider re-examination and testing for young people under their care. This is especially important when disorders are genetically determined because of the potential implications for relatives.

A rather similar approach applies to the assessment of children with autism. A variety of studies suggest that an identifiable medical disorder of aetiological significance occurs in only a small minority of patients (Rutter *et al.* 1994; Barton & Volkmar 1998; Skjeldal *et al.* 1998; Fombonne 1999); chromosomal abnormalities, fragile X and tuberous sclerosis being the most frequently identified disorders. As with mental retardation, a thorough history and comprehensive head-to-toe examination of all cases—including a search for depigmented lesions with a Wood light—is necessary to identify any pointers to identifiable aetiologies. When the history and physical examination are unremarkable, routine investigation should be confined to kary-

otyping and *FMR1* testing. If there are clinical indications of seizure activity an electroencephalogram (EEG) should also be performed. Because macrocephaly is found in a minority of individuals with idiopathic autism, the finding in isolation is not an indication for neuroimaging.

Loss of skills

The extent to which children who lose skills present to child psychiatrists depends upon their age, which skills are lost and the nature of any associated symptomatology. In early childhood, development may first slow or reach a plateau before there is frank loss of skills but this pattern will only be recognized if a detailed developmental history is taken. Establishing the child's developmental trajectory may require repeat assessments of psychological and physical development.

Infants and toddlers with metabolic disorders will usually present to paediatricians with poor feeding or acute illnesses. Girls with Rett syndrome may occasionally be seen initially by child psychiatrists when there is a presumption of autism, although that confusion should now be much less common (see Lord & Bailey, Chapter 38). Some parents of children with autism are worried about their development from shortly after birth, but most are identified as showing abnormalities or delays in the second year of life. About one-quarter to one-third of children with autism lose speech in the first years of life (Rogers & DiLalla 1990) often accompanied by or preceded by changes in social behaviour. The history of uninterrupted motor development and the previous acquisition of only a very small vocabulary are important in differentiating autism from disintegrative psychosis, which usually has an onset after age 2 and involves the loss, not just of language, but also of motor and self-help skills and bowel/bladder control. The final outcome is usually indistinguishable from profound mental retardation and autism (Hill & Rosenbloom 1986), although deterioration can continue with more severe motor dysfunction and the development of seizures and localized neurological signs (Corbett *et al.* 1977). The age of onset and the usual lack of an association with seizures are also important features differentiating autism from Landau–Kleffner syndrome (see Bishop, Chapter 39), which affects previously healthy children who lose language comprehension and expression over a period of weeks or months, usually (but not always) accompanied by epileptic seizures. The peak age of onset occurs at 3–8 years.

Geography and the family and social history will usually indicate the likelihood of HIV encephalopathy rather than the other causes of early developmental slowing and loss seen by neuropsychiatrists. The pandemic of HIV has now made progressive neurological disorder a very significant presenting problem in Sub-Saharan Africa and Southeast Asia (Oleske & Czarniecki 1999). Infants acquire HIV from their mothers during pregnancy or delivery, or postnatally through breastfeeding (Giaquinto *et al.* 1998). Children with HIV-associated progressive encephalopathy usually develop neurological symptoms in the

first 2–3 years of life (see Havens *et al.*, Chapter 49). There is loss of developmental milestones or cognitive abilities and progressive symmetric motor deficits; sometimes loss or impairment of language and social adaptation skills may be the first signs of encephalopathy. Some children have a more insidious illness, with non-progressive cognitive and motor deficits and slowed developmental progression.

In children with early loss of skills the physical examination needs to be particularly comprehensive, both with respect to a search for dysmorphic features and the neurological examination. In terms of growth parameters, an important clinical sign differentiating Rett syndrome from idiopathic autism is the deceleration in head growth leading eventually to acquired microcephaly. When Rett syndrome is suspected clinically it is possible to test directly for mutations in the MECP2 gene (Amir *et al.* 1999), which are found in 75% to 90% of sporadic cases and 50% of familial cases (Shahbazian & Zoghbi 2001) as well as in male relatives with profound mental retardation (Orrico *et al.* 2000). Childhood disintegrative disorder has been linked to cerebral lipidoses, mucopolysaccharidoses, leukodystrophies and other neurological conditions (see below). These children should usually be investigated by a paediatric neurologist as screening tests may be negative and more focused specific testing indicated. Landau–Kleffner syndrome is associated with spike and wave discharges originating in auditory cortex; these abnormalities may sometimes only be seen during slow wave sleep. Often MRI will not reveal structural abnormalities.

In older children with progressive neurological disorders, loss of skills may not be the presenting complaint; rather, individuals may be seen because relatively non-specific psychiatric symptomatology or psychosis are the first signs of dementia. The early identification of affected individuals will usually rely on obtaining a detailed history of school performance, and this should be a routine part of the psychiatric history. Any decline should prompt a detailed enquiry about those neurological difficulties that may not be volunteered, particularly gait, co-ordination and visual difficulties. The extreme psychological consequences of physical or sexual abuse will occasionally need to be differentiated from somatic conditions, and this requires a thorough history and a high index of suspicion. Often observation in an inpatient setting may help to differentiate such psychological reactions from somatic disorders. Abuse may also constitute a risk factor for brain injury or infection.

Location and disorders in other relatives will often provide clues to the most likely aetiological factors underlying progressive disorders; a number of different aetiologies are outlined that illustrate some general principals. AIDS is now the leading cause of presenile dementia, characterized by cognitive impairment ranging in intensity from memory dysfunction to global dementia, motor disabilities, involuntary and slowed movements and behavioural abnormalities such as psychosis and depression. Outside endemic areas, drug-abusing adolescents, sexually abused children (Hammerschlag 1998) and individuals who may have been exposed to unscreened blood products are at most risk.

Wilson disease (Bacon & Schilsky 1999; Schaefer & Gitlin 1999) is an autosomal recessive disorder of copper metabolism for which an effective therapy is available; consequently the challenge is to make the diagnosis before end organ damage and to identify potentially at-risk siblings. Wilson disease is usually symptomatic in adolescents and young adults and the majority of patients show neurological/psychiatric disorders (Cuthbert 1998). Common psychiatric manifestations include abnormal behaviour, personality change, a schizoaffective picture, depression and cognitive impairment.

Huntington disease is an autosomal dominant disorder and so the presence of other affected family members substantially narrows the diagnostic possibilities, although psychological disturbance may be a consequence of an abnormal family environment. Juvenile onset occurs in about 5% of cases, usually via paternal inheritance. Affected individuals may first become withdrawn or show emotional disturbances or changes in personality.

X-linked adrenoleukodystrophy is a peroxisomal disorder associated with abnormal accumulation of very long chain fatty acids (VLCFA) (Smith *et al.* 1999). The commonly recognized form affects boys between 4 and 8 years of age and begins with signs and symptoms of ADHD followed by intellectual, behavioural and neurological deterioration; progression is slower with an adolescent presentation. Juvenile onset metachromatic leukodystrophy may also present with emotional or schooling difficulties.

When progressive neurological disorders are suspected, examination of the motor system is particularly critical and early gait ataxia may be detected during tandem walk. Thus, the early neurological findings in AIDS include gait ataxia (which may be mild), hyperreflexia and weakness of the lower limbs. In Wilson disease, four types of movement disorder are seen: parkinsonian, pseudosclerotic, dystonic and choreic (Cuthbert 1998). Copper is deposited in the cornea and the basal ganglia at the same time and a slit lamp examination of the cornea should be undertaken for Kayser–Fleischer rings (a brown–green discolouration in the limbic area of the cornea). Hepatomegaly or splenomegaly may also be found. The abnormal movements in Huntington disease also include chorea, akinesia and rigidity. In X-linked adrenoleukodystrophy the disease process targets the white matter of the central nervous system, the adrenal cortex and the gonads. In patients with adrenal failure increased skin pigmentation may be noted in skin folds, in addition to pyramidal and extrapyramidal signs. In metachromatic leukodystrophy the examiner may detect nystagmus, hypertonia and intention tremor as well as ataxia.

Specific investigations are available to detect these diverse disorders. In endemic areas, testing for HIV should be routine in the assessment of children with onset of cognitive difficulties, depression or psychosis. Available tests either measure antibodies to HIV-1 or HIV-2 or detect the virus directly. Enzyme-linked immunosorbent assay (ELISA) to detect antibody is readily available and cheap, but this test will not detect antibodies within 3 months of infection and is not useful in children less than 24

months of age. HIV DNA can be screened by polymerase chain reaction (PCR) and culture; but the growth characteristics of viral strains from different countries may differ and laboratories should be alerted to the country of origin of the child (Hostetter 1999). In parallel with the worldwide spread of HIV, the prevalence of other sexually transmitted diseases has increased and infected children should also be tested for syphilis. When available, baseline neuroimaging studies are usually performed as screening for encephalopathy and to detect secondary neurological complications. HIV is rapidly becoming the most common cause of basal ganglia calcifications in children (States *et al.* 1997) and is unique to vertically infected children, thus computed tomography (CT) is the imaging modality of choice for evaluating the symptomatic HIV-infected child. Both CT and MRI will reveal atrophy in 57–86% of children (States *et al.* 1997).

In Wilson disease hepatic copper is not incorporated into ceruloplasmin or excreted into bile and accumulates in the hepatocyte cytoplasm, eventually resulting in cellular necrosis and leakage of copper into plasma. A 24-h urine collection to detect elevated urinary copper levels is the most cost-effective screen. The level of ceruloplasmin-bound copper and total copper are decreased, as is ceruloplasmin oxidase activity. Serum ceruloplasmin levels are also decreased, as non-copper-containing ceruloplasmin has a shorter half-life. Measurement of hepatic copper by biopsy, together with the other tests, allows a definitive diagnosis. Molecular genetic studies enable early diagnosis of affected presymptomatic siblings and treatment with zinc salts to reduce copper absorption. Nevertheless, this is complicated because more than 60 mutations and polymorphisms in the gene have been identified (Bacon & Schilsky 1999) and many patients have different mutations in each copy of their gene: compound heterozygotes (Gasser 1997). Particular mutations are frequently found in members of a specific population or ethnic group and screening of family members by haplotype analysis is possible (Cuthbert 1998).

In Huntington disease (Huntington's Disease Collaborative Research Group 1993) a CAG expansion in a protein-coding region of the gene results in an abnormal protein. Repeat length explains about 50–60% of the variance in age at onset, with lengths of >60 or 70 CAG triplets frequently resulting in juvenile onset (Trottier *et al.* 1994). Definitive diagnosis is by detection of the expanded triplet repeat using PCR. Neuroimaging may demonstrate caudate atrophy and hypometabolism. There is also the possibility of presymptomatic genetic testing (see Simonoff, Chapter 66). In the cerebral form of leukodystrophy, cerebral demyelinating lesions usually start in the splenium of the corpus callosum and show a slow progression; symmetrical demyelinating lesions in the parieto-occipital regions can be detected by MRI. A total of 200 genetic mutations have been reported with the majority of kindreds having private mutations (Smith *et al.* 1999).

There is still much uncertainty about the scale of the problem presented by new variant Creutzfeldt–Jakob prion disease (Collinge 1999). These brain diseases are associated with accumulation of an abnormal isoform of a host encoded glycopro-

tein known as prion protein. A new variant prion protein that can be passed from cattle infected with bovine spongiform encephalitis (BSE)—mainly acquired through the consumption of feed containing animal products—to humans and other animals has been recognized since 1986, initially in the UK, but now also in mainland Europe. Infection probably occurs via the food chain and infected individuals probably also have a high innate sensitivity to BSE. In the early stages the disorder predominantly presents with psychiatric symptoms. These include particularly depression, and also anxiety, withdrawal, aggression/irritability, first rank symptoms, hallucinations, delusions, forgetfulness and suicidal ideation. There is also pain in the limbs or joints, or painful or unpleasant paraesthesia or dysaesthesia (Will *et al.* 1999). Obvious neurological symptoms subsequently develop, including gait and motor disturbance and dementia. Diagnosis usually awaits the onset of these neurological abnormalities. The prion protein can be detected in tonsils and other lymphoreticular tissue, and other tests include immunoassay for 14-3-3 protein (Will *et al.* 2000). So far all identified cases have been associated with homozygosity for methionine at codon 129 of the prion protein gene, highlighting the role of genetic influences on susceptibility. Because of the long incubation period of the prion diseases (mean of 12 years in kuru), it is unclear whether the number of cases will ever reach epidemic proportions.

Psychosis and acute behavioural change

Many children present to child psychiatrists with acute changes in their behaviour. When not obvious, an organic aetiology will need to be considered if the symptomatology is atypical, there are no psychological stressors or relevant family history or the disorder is subsequently refractory to adequate treatment. Additionally, these young people may be at increased risk for acquiring other diseases because of their behaviour. A comprehensive history is the most important part of the assessment and should establish the time course and severity of symptoms, as well as highlighting unusual features and possible aetiological factors. Depression, mania and schizophrenia are rare before puberty and a marked behavioural change in a pre-pubertal child should raise the possibility of a somatic condition or physical or sexual abuse. In addition to eliciting psychiatric symptoms, the physician will also need to gather information about the individual's overall level of functioning, including school reports and any deterioration in self-help skills. The most puzzling cases will often require admission and in these circumstances planned investigations, particularly to identify progressive neurological impairments, should usually be discussed with neurological colleagues.

Young people with an acute brain syndrome (Lishman 1998) with impairments in consciousness, thinking and memory and disturbances of perception, emotion and motor behaviour will usually be seen by paediatricians, or in the emergency department. When there are hallucinations or irrational behaviour,

however, patients may be sent initially to psychiatric services. Consequently, the mental state examination must include a cognitive assessment, and any evidence of an acute organic syndrome should lead to a focused search for underlying causes (including use of drugs). Ideally, this should be in a paediatric setting where there are the appropriate resources for rapid investigation and resuscitation.

A preliminary physical examination will need to establish whether the child is acutely unwell or pyrexial, detect any neurological impairments (which are often evident in progressive disorders) or evidence of an underlying disease process. In the absence of pyrexia and obvious pointers to underlying aetiology, a routine screen for a severe change in behaviour or psychosis should include:

- a full blood count and erythrocyte sedimentation rate (ESR);
- urea, electrolytes and glucose;
- calcium and phosphate;
- alkaline phosphatase, aspartate transaminase and albumin;
- T₄ and TSH; and
- a routine urinalysis (including porphyrins and metachromatic granules) and a urine toxicology screen.

Many clinicians will now undertake an MRI scan routinely following the first episode of psychosis. An EEG should also be performed if there is a suspicion of epilepsy. Subsequent tests should be guided by the clinical course, but clinicians should also consider the possibility of conditions such as cerebral systemic lupus erythematosus as well as the progressive disorders outlined above.

Worldwide cerebral infections may present with behavioural change or cognitive decline, and clinicians in the relevant areas will need to be alert to the key features of these disorders. A change in temperament of a child with a primary tuberculosis complex should arouse suspicion of tuberculous meningitis. Many parasitic organisms invade the central nervous system producing focal seizures, signs of space-occupying lesions, encephalopathies or behavioural change; these include: hydatid cyst disease, malaria, schistosomiasis, tapeworms, toxocariasis and trichinosis. Where measles remains endemic, the virus can also cause a progressive central nervous system disorder (subacute sclerosing panencephalitis) that begins several years after measles infection (Roos 1998).

Somatizing disorders

The tendency to experience and communicate somatic distress and symptoms in the absence of organic pathology is common in childhood. Symptoms undergo a developmental sequence and are usually monosymptomatic initially. Recurrent abdominal pain and, less frequently, headaches are the most prominent complaints prepubertally, whereas limb pain or aching muscles, fatigue and neurological symptoms increase with age (Fritz *et al.* 1997). The disorders are more common in girls and in non-Western clinical settings (Chandrasekaran *et al.* 1994; see also Rutter & Nikapota, Chapter 16). They are also associated with

childhood sexual abuse (Friedrich & Schafer 1995; Kinzl *et al.* 1995). Pain and neurological symptoms do not fit with any local anatomical or physiological process, whereas fatigue is usually present to a pathological degree and can rarely be objectively confirmed (Jordan *et al.* 1998).

The initial goal is to rule out diagnosable medical disease. The history is particularly important in differentiating physical disease from somatic symptoms and requires an accurate description of the nature and timing of the problem, direct questioning about associated symptoms that might suggest an organic condition and a wide-ranging search for precipitating or maintaining factors. The clinician should then attempt to elicit physical signs and note whether growth and pubertal status are appropriate for the child's age. The investigation of individual disorders should be undertaken by a physician with the relevant expertise, in order that any underlying pathology is not missed. The psychiatrist must search for diagnosable psychiatric disorders, particularly depression and panic disorder. All the involved professionals need to establish a collaborative therapeutic alliance with the patient, making symptom palliation, coping and rehabilitation the focus of the clinical enterprise (Barsky & Borus 1999).

Anorexia and bulimia

Anorexia and bulimia are disorders in which abnormal behaviours adversely affect the patient's physical health (see Steinhilber, Chapter 34). The history should include the patient's view about their weight and shape, details of their diet, the frequency and severity of any vomiting and purging, the amount of exercise they take, the chronology of weight change and, in females, the pattern of menstruation. The physical examination has several purposes. The patient's current weight and height should be measured and the percentage of expected body weight or body mass index (BMI; Wt/H^2) calculated. The extent of emaciation in patients with weight loss should be noted, pubertal status assessed and a search made for the complications of malnutrition, vomiting, purging and medication abuse (Becker *et al.* 1999).

Measuring endocrine and metabolic disturbances provides a means of monitoring the course of the disorder and the findings can be explained to patients and parents, who may doubt the severity of the condition. Serum potassium may be decreased and bicarbonate elevated from vomiting or diuretic abuse, whereas a non-anion gap acidosis is associated with laxative use. Decreased sodium is usually a consequence of excess water intake or inappropriate antidiuretic hormone secretion. A full blood count may reveal leucopenia, neutropenia, anaemia and thrombocytopenia. Amenorrhoea is a consequence of decreased pulsatility of gonadotrophin-releasing hormone which leads to low oestradiol/testosterone levels. Bone loss can be assessed by bone densitometry. If tricyclic antidepressants are being contemplated, an ECG should be performed as prolongation of the QT interval is a contraindication to their use.

Investigations

There have been remarkable advances in the investigation of neuropsychiatric disorders since the last edition of this textbook. Genetic testing and structural and functional neuroimaging deserve especial mention, both because of the progress to date and the potential for substantial future developments. Chromosomal abnormalities constitute the largest identifiable cause of mental retardation syndromes and are even more common in aborted fetuses and preimplantation embryos (Delhanty *et al.* 1997; Munne *et al.* 1999). There is now improved detection of some of the subtle chromosomal abnormalities linked with developmental difficulties, as typified by the microdeletion syndromes. The physical and behavioural phenotypes and the underlying genetic basis of Prader–Willi and Angelman syndromes (Khan & Wood 1999), 22q deletion syndrome (Basset & Chow 1999)—which encompasses velocardiofacial syndrome and DiGeorge syndromes—and Williams syndrome (Bellugi *et al.* 1999) nicely illustrate the complex pathways between genetic predisposition and phenotypic expression, including the role of genetic imprinting (see Skuse & Kuntsi, Chapter 13).

Improved detection of these syndromes and other chromosomal abnormalities has depended upon recent advances in cytogenetics. FISH combines molecular genetic and conventional karyotype banding approaches. It involves the binding of specific DNA probes to denatured chromosomes, hybridization being detected using fluorescently labelled molecules linked to the probes. FISH can detect deletions, duplications and translocations of specific chromosomal regions with sufficient sensitivity to detect intragenic rearrangements (Ekong & Wolfe 1998). Specific probes are now available to detect Prader–Willi, Angelman, velocardiofacial, Williams, Smith–Magenis and Dieler syndrome microdeletions, but the requesting clinician must still specify the syndrome/chromosomal region. Another important development is a multiprobe FISH protocol to detect subtelomeric microdeletions when there is no knowledge about which chromosome might be affected (Knight *et al.* 1997). A further advance is spectral karyotyping (SKY; Schröck *et al.* 1997): the colour differentiation of all chromosomes based on the simultaneous hybridization of 24 chromosome-specific painting probes. This research tool can identify subtle translocations and those that involve regions with similar traditional banding patterns.

In terms of psychopathology linked with single gene disorders, identification of the unusual patterns of inheritance associated with expansion of trinucleotide repeats represents a significant advance (Margolis *et al.* 1999). Of most relevance to child psychiatry are the mechanisms underlying the fragile X syndrome (and related conditions); an X-linked condition that is the most common genetic cause of severe cognitive deficit (De Vries *et al.* 1998; Kaufmann & Reiss 1999). The disorder arises from an expansion of a long CGG repeat in the *FMR1* gene, leading to hypermethylation of an adjacent genomic region and consequent loss of gene transcription. The CGG repeat expan-

sion can be detected by either Southern blotting or PCR. The *FMR1* protein is absent in males with a fully methylated mutation and an antibody test is a rapid and cheap means of screening in mentally retarded males and male neonates, although it will not differentiate between normal and premutation alleles (De Vries *et al.* 1998).

Recent progress in identifying genes for relevant Mendelian disorders includes tuberous sclerosis 1 (van Slechtenhorst *et al.* 1997), most cases of Rett syndrome (Amir *et al.* 1999) and Wilson disease (Bull *et al.* 1993; Tanzi *et al.* 1993; Petrukhin *et al.* 1994). Testing individuals for mutations in such disorders can be useful when symptoms or signs are equivocal, or to detect at-risk relatives when effective treatments are available. Often, however, *de novo* analysis for specific mutations is difficult if either the gene is large or there are many different mutations. In these situations, knowledge about the most frequent mutations in a particular population may be helpful, or family members can be screened using haplotype analysis (Bacon & Schilsky 1999). In the future, methodologies that screen the entire coding system of genes may make it practical to consider direct molecular genetic testing (Saugier-Weber *et al.* 1998).

For many childhood psychiatric disorders, however, a complex genetic predisposition is thought to be relevant (Rutter *et al.* 1999). Although there are promising developments in this area, none so far is useful at the individual level. In autism there is overlap in the linkage findings from several whole genome scans (see Lamb *et al.* 2000; Maestrini *et al.* 2000 for reviews), particularly on chromosome 7 (IMGSAC 1998). There has also been progress in respect to ADHD and language-related disorders (see above). The extent to which testing for individual susceptibility genes will be clinically relevant in the future will depend upon the magnitude of the gene's effect, the degree of genetic heterogeneity (whether an identified gene is implicated in a particular family), whether there is epistasis (interactions between genes), and how phenotypic expression relates to particular loci (Turner *et al.* 2000). Paradoxically, as knowledge about susceptibility loci increases, the recognition that complex genetic influences are *not* implicated in individual cases may indicate the need for further investigation. Keeping abreast of the rapid developments in genetic testing can be problematical and [HTTP://www.genetests.org](http://www.genetests.org) provides a regularly updated list of available investigations.

Neuroimaging

Over the last decade there have been considerable advances in the ability to visualize brain structure and function. The main clinical use of neuroimaging is in the detection and investigation of neurological disorders, but in the future clinical applications may extend to idiopathic childhood psychiatric disorders. The detail of the physics and practical aspects of neuroimaging are beyond the scope of this chapter and interested readers are referred to several excellent books (Orrison *et al.* 1995; Lewis & Higgins 1996; Frackowiak *et al.* 1997; Ernst & Rumsey 2000).

A brief summary of the main methodologies is included in Appendix 1. The detailed findings in child psychiatry have been frequently reviewed (Bailey & Cox 1996; Filipek 1999; Santosh 2000; Overmeyer & Taylor, in press) and the findings in individual disorders are also covered in the relevant chapters.

Neuroimaging has had most clinical impact in epileptology, investigation of mental retardation and assessment of progressive neurological disorders. The imaging of intractable epilepsy nicely illustrates the potential of multiple imaging approaches when there are neurodevelopmental and metabolic abnormalities as well as secondary pathology. Structural MRI is clinically useful in the investigation of temporal lobe epilepsy, demonstrating hippocampal sclerosis and atrophy in intractable complex partial seizures, often removing the need for invasive or expensive presurgical investigations (Cross *et al.* 1993; Cook 1994). Magnetic resonance spectroscopy (MRS) can also detect pathology by measuring the changes in *N*-acetylaspartate: creatinine + choline ratios associated with neuronal loss or damage (Gadian *et al.* 1994; Cross *et al.* 1997). In many cases of intractable epilepsy, ictal technetium-99 HMPAO single photon emission CT (SPECT) will demonstrate areas of hyperperfusion predictive of the seizure focus, whereas interictal studies can show unilateral hypoperfusion (Cross *et al.* 1997), which is also visualized using FDG-PET (Gaillard *et al.* 1995). Metabolic abnormalities may also be detectable when there are no focal cerebral structural abnormalities and ligands to benzodiazepine receptors are claimed to further increase the sensitivity of positron emission tomography (PET) studies (Muzik *et al.* 2000).

Structural MRI has also been invaluable in identifying areas of cortical dysgenesis in patients with intractable partial seizures, particularly those associated with mental retardation (Palmini *et al.* 1991; Brodtkorb *et al.* 1992; Wolf *et al.* 1995). The dysplastic lesions can be intrinsically epileptogenic, as demonstrated by electrocorticography, magnetoencephalography (MEG) and the results of surgery (Palmini *et al.* 1995; Morioka *et al.* 1999), but surgical outcome studies also indicate that structural abnormalities may extend beyond the visualized boundaries of cortical dysplasia (Palmini *et al.* 1994). Immunocytochemical studies of surgically resected tissue suggest that the epileptogenicity of these dysplastic lesions is in part a consequence of decreased numbers of gamma-aminobutyric acid (GABA)-ergic neurones (Spreafico *et al.* 1998) and recent advances in MRS editing techniques now allow non-invasive measurement of brain GABA, glutamate and glutamine levels, with some evidence that seizure frequency in patients with complex partial seizures is inversely related to brain GABA levels (Petrossian *et al.* 1999). Analyses of quantitative relationships between cortical surface areas and volumes in cerebral dysgenesis (Sisodiya & Free 1997) offers another approach to identification of presumed abnormal connectivity in the absence of visual abnormalities.

Severe and intractable cases of epilepsy sometimes benefit from surgery, but this requires establishing whether eloquent cortex is affected and clarifying language lateralization. Increasingly

functional MRI (fMRI) is being used for presurgical mapping of cortical function and language laterality (Stapleton *et al.* 1997; Bookheimer *et al.* 1999), with a reduced risk of morbidity and mortality compared to traditional methods. The excellent temporal and good spatial resolution of MEG is also useful in the presurgical evaluation of Landau-Kleffner syndrome: an acquired aphasia secondary to a focal epileptogenic lesion affecting speech cortex. MRI (and CT) are typically normal (Sobel *et al.* 2000). Spike and spike-wave discharges originate in intraperisylvian regions (Paetau *et al.* 1999; Sobel *et al.* 2000) and may be triggered by environmental sounds (Paetau *et al.* 1999). Multiple subpial transection is claimed to be an effective treatment in unilateral cases (Morrell *et al.* 1995) and MEG can identify sources precisely, and also those individuals with a unique unilateral pacemaker and spread to the opposite hemisphere (Paetau *et al.* 1999).

Structural brain abnormalities are found in a significant proportion of individuals with mental retardation (Curry *et al.* 1997). These patients often have epilepsy (see above) and MRI has revealed the full range of neuronal migration disorders and dysgenetic lesions, as well as other gross developmental abnormalities visualizable by CT. MRI is also the modality of choice for detecting lesions associated with cerebral palsy: that applies to common (Truwit *et al.* 1992) and rare (Kuzniecky *et al.* 1993) migration disorders; vascular lesions, such as periventricular leukomalacia; localized cortical necrosis; multicystic encephalomalacia; and basal ganglia injury (Krägeloh-Mann *et al.* 1995).

There are some contradictory results in the fields of epileptology and mental retardation, but the convergence of findings is impressive. This contrasts with the discrepant findings from many neuroimaging studies of childhood psychiatric disorders (see Lord & Bailey, Chapter 38). As the field matures, current methodological difficulties are likely to be overcome, but it is too soon to gauge the future role of neuroimaging in routine clinical practice. One of the aims of this work is to identify the impaired neural systems underlying complex neurodevelopmental disorders. The obstacles are the weaknesses of current explanatory models (which are largely derived from animal work and lesion studies in adults) and the limited availability of histopathological and post-mortem neurochemistry data. These findings are necessary to link genetic and molecular biology findings with the macroscopic phenomena visualized by structural and functional imaging.

Findings from several disorders illustrate the range of conceptual problems. Measuring the size of brain structures *in vivo* has a long history. Recently, for instance, the caudate nucleus has been the subject of scrutiny in ADHD (Filipek 1999; Overmeyer & Taylor, in press). Nevertheless, there are no post-mortem studies against which to judge these findings, and although these abnormal frontostriatal interactions are considered to partly underlie some behavioural abnormalities in ADHD, there is no clear consensus about whether the effects lateralize, and if so to which side. Measures of planum temporale asymmetry in individuals with specific reading difficulties are similarly contra-

dictory (Bailey & Cox 1996; Filipek 1999) and the rationale underlying this measure is uncertain when nearly 40% of the general population do not show the supposedly 'normal' pattern of asymmetry. Even in autism (for which there is some limited post-mortem data), contradictions abound. Thus, claims of specific hypoplasia of cerebellar vermal lobules VI and VII (Courchesne *et al.* 1988) have not been consistently replicated (reviewed by Filipek 1999). Also the predicted macroscopic correlates of increased cell packing density in the hippocampus and related structures (Kemper & Bauman 1998) are unclear, which complicates the interpretation of unchanged (Filipek *et al.* 1992; Piven *et al.* 1998), decreased (Aylward *et al.* 1999) and increased (Abell *et al.* 1999; Howard *et al.* 2000) measures of medial temporal structures. Although establishing age-appropriate norms for human brain development (Giedd *et al.* 1996) should aid interpretation, the underlying conceptual problem will persist: there is not a universal relationship between size of a structure and either pathology or function.

In the longer term, functional imaging is likely to transform our understanding of the brain basis of developmental psychopathology. There may also be scope for clinical applications: e.g. in complex cases in which symptomatology is compatible with several different diagnoses; when there are also severe psychosocial stressors; in clinically mild cases who may pass standard cognitive tests using alternative neural pathways; and in monitoring treatment response. For disorders such as hyperactivity, in which there are strong psychopharmacological effects, it is already possible to visualize differential responses to medication during functional imaging (Vaidya *et al.* 1998). However, it seems probable that most psychiatric disorders arise on the basis of several cognitive (and emotional) deficits, and clinically specific diagnostic approaches will likely require a heterogeneous functional test battery. Clinical utility will also demand considerable standardization of tasks, stimulus presentation parameters and data analysis.

There are also conceptual challenges in the interpretation of functional imaging data. Cognitive studies using PET and fMRI rely upon subtraction paradigms in which brain activity generated by a control task is subtracted from that evoked by the task of interest. The resulting image is a difference image, not a response to a physically presented stimulus. If the underlying disorder involves the use of qualitatively different processing strategies (Rubia *et al.* 1999), unusual processing of control stimuli will be most evident if there is also a baseline task in addition to control and probe tasks. Subtraction approaches also assume that cognition is serial and non-interactive. Cognitive processes that are interactive or which are similar in their anatomical distribution but differ in their order or time course will not be properly differentiated using subtraction methodology (see Sergent *et al.* 1992, for a fuller discussion of this issue). Consequently, complementary methods with adequate temporal resolution, such as EEG or MEG, are also necessary. However, all of these approaches assess function at the level of large populations of neurones which ultimately constrains the

neurophysiological models that can be tested. A final challenge is to understand the developmental processes that lead to abnormal localization of activation in older children and adolescents. Whereas such abnormalities may represent localized dysfunction, they may also be a consequence of abnormal input, possibly earlier in development, and while appropriate tasks may identify current input abnormalities, identifying developmental precursors will ultimately require studies of infants and young children.

Appendix 1

Computerized tomography (CT)

Computerized tomography is an X-ray technique that isolates a plane of interest in the subject by blurring out adjacent planes. It produces a series of sectional images, usually transverse to the long axis of the subject, which reflect the radiographic density of tissues in the plane of sectioning. The technique was a major innovation in modern imaging and, although now largely superseded by MRI, it remains the modality of choice for visualizing calcification and the skull.

Positron emission tomography (PET) and single photon emission computed tomography (SPECT)

Positron emission tomography and single photon emission computed tomography are techniques in which radioactive isotopes linked to tracers cross the blood-brain barrier and emit gamma radiation while decaying. PET uses isotopes of carbon, nitrogen, oxygen and fluorine which emit a positron when they decay. After travelling a few millimetres the positron collides with an electron, producing two high energy photons which travel in opposite directions. By detecting both photons outside the head their origin can be pinpointed to a within slice resolution of 5–6 mm. Depending on the property of the tracer to which the isotope is attached, it is possible to calculate increases in absolute regional cerebral blood flow or glucose metabolism associated with neuronal activity, or image neurotransmitter synthesis, the distribution and occupancy of receptors and the density of neurotransmitter transporters. The various isotopes have short half-lives necessitating manufacture on-site using expensive cyclotron or particle accelerators. The short half-life of the isotopes enables several activation studies to be conducted during one scanning session, with the administration of a series of cognitive tasks and the 'subtraction' of one image from another to identify statistically significant brain activity associated with cognitive components.

A variety of statistical techniques are available for analysing data produced by brain activation studies, but statistical parametric mapping (SPM) using the general linear model (Friston *et al.* 1995) is particularly widely used. In order to compare groups of subjects, regions of interest can be delineated, or the functional images can be co-registered with structural images

or plastically transformed (Friston *et al.* 1995) onto a standard brain shape (Talairach *et al.* 1967).

SPECT uses radioactive isotopes such as iodine and technetium, which have a comparatively long half-life (thus not requiring expensive on-site generation) and hence involve greater radiation exposure. They decay with emission of a single photon that has relatively low energy and thus the technique is less sensitive than PET. Although only relative blood flow and semi-quantitative indices of receptor binding can be calculated, these will be adequate for many purposes. The exposure to ionizing radiation largely precludes the use of PET and SPECT in children for research into the brain correlates of cognition.

Magnetic resonance imaging (MRI)

Magnetic resonance imaging is based on the capacity of organic tissue placed in a magnetic field to absorb energy from radio waves and then re-emit this energy in proportion to the mobile hydrogen ion concentration (Wolbarst 1993). The magnetic resonance image is a map of signal strengths across a defined section of tissue and the signals are influenced by the tissue environment in which the protons are situated. The technique does not involve ionizing radiation and there is a very wide choice in scanning parameters, which can emphasize the contrast between different tissue types, with new approaches being developed continuously. Diffusion tensor imaging also has the potential to identify the direction and confluence of white matter tracts (Jones *et al.* 1999). Unlike CT, MR images can be generated in any plane and spatial resolution is excellent.

Functional magnetic resonance imaging (fMRI)

Functional MRI refers to a fast imaging method for indirectly visualizing regional changes in brain activity by detecting local haemodynamic changes. Following brain activation there is a disproportionate increase in blood flow resulting in increased oxygenation of venous blood compared with the resting state. The increased MRI signal from oxygenated blood compared to the inactive state can be visualized by appropriate choice of pulse sequence (blood oxygen level dependent effect, BOLD; Kwong *et al.* 1992; Ogawa *et al.* 1992). Signal intensity is measured in arbitrary units and it is usually necessary to compare two activation states with each other. The haemodynamic response lags behind brain activity and this delay is taken into account in data analysis.

Most published studies have presented alternating blocks of contrasting stimuli and correlated measured signal intensity from each point (voxel) in the image with the time course of stimulus presentation to detect statistically significant differences in activation between the two stimulus types. It is now possible to interleave different types of stimuli and analyse the correlation between single trials and blood flow changes (event-related fMRI; Buckner *et al.* 1996) allowing new classes of behavioural paradigms to be tested.

Other methods of visualizing haemodynamic changes are also

available. fMRI data can be combined with structural MRI images to provide excellent localization of activation and fMRI data analysis techniques have built upon those developed to analyse PET data. Regardless of imaging sequence, the main practical problems are minimizing subject movement during the experiment and correction for any movements during statistical analysis. The lag between neuronal activity and haemodynamic response ultimately constrains the time resolution of fMRI approaches, but this is a rapidly developing field with continuing improvements in temporal resolution and quantification of data.

Magnetic resonance spectroscopy (MRS)

Magnetic resonance spectroscopy is a method for detecting the presence and amount of different molecules in tissue, either *in vivo* or *in vitro*. The technique detects differences in how atoms with an odd number of protons (e.g. hydrogen, carbon, fluorine, sodium, potassium, phosphorus) resonate in a magnetic resonance scanner. The resonant frequency is affected by the local magnetic field surrounding the nucleus (the chemical shift) and thus the same atom in different chemical compounds produces a distinctive peak in a frequency spectrum. In child psychiatry most interest has focused on the study of membrane phospholipids and the levels of *N*-acetylaspartate (NAA), a compound largely found in neurones.

Electroencephalopathy (EEG) and magnetoencephalography (MEG)

Electroencephalopathy and magnetoencephalography are the only currently available techniques that directly detect the activity of populations of neurones with millisecond time resolution. The primary source of signals are postsynaptic potentials in activated cortical dendrites that are generally orthogonal to the cortical surface. EEG detects the induced extracellular volume currents, regardless of their orientation, which spread passively throughout the head. MEG detects the minute magnetic fields that wrap around the currents flowing along dendrites, but only neurones in sulci (or whose dendritic fields are parallel to the skull) produce a magnetic field detectable outside the head.

The chief advantages of MEG over EEG are the lack of signal distortion by the skull and scalp and the ability to model the underlying current source. In addition to 'resting' brain activity, the potentials induced by physical stimuli or cognitive tasks can be recorded to permit computation of the underlying neural sources with no requirement for subtraction methods. The data from EEG and MEG can be combined with anatomical data from structural MRI to constraint calculations of underlying neural generators.

Introduction

As a non-invasive, inexpensive and repeatable means of assessing cerebral function, the electroencephalogram (EEG) is an invaluable diagnostic aid in child psychiatry. Nevertheless, it presents many complexities, not least because of the changes in the EEG occurring throughout childhood and adolescence as a result of maturation. The EEG is of most value in epilepsy and the various cerebral degenerative diseases. Its utility as a 'soft' sign of cerebral dysfunction in a wider range of disorders is more questionable.

Evoked potentials (EPs) elicited by sensory stimulation serve two purposes: assessment of sensory function (e.g. hearing in children with communication difficulties); and the detection, and sometimes identification of, cerebral disease involving the afferent pathways in the brainstem and white matter and projection areas.

Standard clinical neurophysiological techniques in children

Electroencephalogram (EEG)

Origins of the EEG

The EEG is a recording of cerebral electrical activity from the scalp. It mainly comprises the averaged synchronous postsynaptic potentials from radially orientated cortical neurones. The ongoing activity of the spontaneous EEG is rhythmic in character, reflecting synchronous oscillatory processes involving many neurones. Several sources of rhythmic neuronal activity are known. Individual neurones or groups of interconnected cells can display rhythmic discharge. There are also anatomically discrete pacemakers, or distributed systems of interacting neurones (see Steriade *et al.* 1990 for review). Rhythmic activity may be suppressed, e.g. by brainstem projections which desynchronize the EEG (increased frequency and reduced amplitude) during arousal. Conversely, functional deafferentation during sleep promotes synchrony, reflected in increased EEG amplitude and reduced frequency, and by an increase of synchronous transients, such as spikes.

Evoked potentials (EPs) are recorded from the scalp when a brief sequence of synchronous neuronal events is elicited by

a sudden transitory stimulus. Various other transient EEG phenomena, both normal and pathological, also owe their synchronicity to a triggering event.

Recording the EEG

Like other bioelectrical signals, such as the electrocardiogram (ECG), the EEG is picked up by electrodes and amplified to drive a display, formerly a chart recorder but nowadays usually a computer screen. The signal is smaller than the ECG, of the order of 10–200 μV . Consequently, the recording is more liable to artefacts, from biological sources such as the eyes and scalp muscles, and from electrical interference. These can be reduced by meticulous technique. Electrode preparation and application are crucial. Low stable electrode potentials and contact resistances reduce susceptibility to physical interference, and the promotion of co-operation and relaxation in the subject helps to minimize biological artefact. These may be difficult to achieve in children, especially infants and those who are mentally retarded or disturbed. The importance of skill on the part of the technologist is reflected in the difference between the technical quality of children's EEGs obtained in routine departments and those recorded in specialized paediatric units.

Sometimes it is impossible to obtain an EEG without sedation or even anaesthesia, and it is then necessary to consider whether the clinical value of the investigation justifies such measures. Preschool-age children will usually take a sedative antihistamine syrup (e.g. trimeprazine (alimemazine) 2–4 mg/kg), and older patients can be sedated with short-acting barbiturates (e.g. secobarbital 100–150 mg). Before the last resort of general anaesthesia, which precludes a waking EEG, intramuscular droperidol may be tried.

Normal EEG phenomena in childhood and adolescence

For descriptive purposes, continuous *ongoing activity* is distinguished from *transients*. Ongoing EEG activities are classified into four frequency bands:

- 1 *delta*, below 4 c/s;
- 2 *theta*, from 4 up to 8 c/s;
- 3 *alpha*, from 8 up to 14 c/s; and
- 4 *beta*, from 14 c/s upwards.

The EEG changes from birth, throughout childhood and adolescence, stabilizing as the adult pattern at about 22 years. The main feature of the waking adult EEG is usually the alpha

rhythm: α frequency activity, at about 9–10 c/s, with an amplitude of 50–100 μ V seen symmetrically at the back of the head. The *alpha rhythm* is best developed in quiet wakefulness with closed eyes; it is attenuated by eye opening and disappears in drowsiness. *Beta activity*, usually at about 18–25 c/s is of lower amplitude, usually some 10–20 μ V, again symmetrical, and most prominent over the frontal regions. *Gamma activity* describes fast components above 40 c/s. It is a term that was used early in the history of EEG, then abandoned, and more recently re-introduced because of interest in high-frequency components in intracranial recordings and also claims of significant changes in gamma activity in various psychiatric disorders. *Theta activity* may be inconspicuous but is always present, generally with a bitemporal maximum, increasing in drowsiness. Particularly in young adults, theta activity of half the alpha frequency may be seen posteriorly intermixed with the alpha rhythm and showing a similar response to eye opening (this is '*slow alpha variant*'). Delta activity is not usually obvious in the mature waking EEG.

Changes in sleep are classified into five stages, by a system described by Dement & Kleitman (1957).

- *Stage I.* In drowsiness the alpha rhythm is replaced by theta and/or beta activity; slow lateral eye movements appear. Auditory stimuli elicit sharp transients at the vertex.
- *Stage II.* Delta activity appears, beta activity increases further and spindle-shaped bursts of activity at about 14 c/s appear with a frontal preponderance (*sleep spindles*). Arousal now produces more complicated waveforms near the vertex, typically '*K-complexes*': a sharp wave, a delta wave and a spindle.
- *Stages III and IV.* These are distinguished by increasing amounts of delta activity, and a possible disappearance of spindles in stage IV.
- *REM.* After the first 90 min of sleep, episodes occur in which the EEG is of low amplitude, resembling stage I, but accompanied by rapid lateral eye movements, seen as oculographic artefacts, which give this stage the name of REM sleep. REM appears to accompany dreaming.

The EEG of the full-term waking newborn mainly consists of diffuse activity in the delta range with amplitudes of 50–100 μ V. Two sleep patterns may be distinguished: in 'quiet sleep', bursts of delta activity are separated by 6–10 periods of relatively low amplitude ('*tracé alternant*'); whereas in 'active sleep', probably corresponding to adult REM, continuous delta activity is seen with ripples of superimposed faster rhythms.

The first year of life sees a gradual increase in EEG frequency and the emergence of a responsive posterior theta rhythm which reaches about 6 c/s by 12 months and will attain a low alpha frequency of about 8 c/s by the age of 3 years. From 3 to 12 months a Rolandic rhythm of 6–7 c/s is seen. A transitional state between waking and sleep appears at about 6 months, with dominant theta activity. From this time the classical sleep stages are distinguishable and much the same criteria apply as in adults. Spindles appear at about 2 months and vertex sharp transients and K-complexes in the middle of the first year.

In early childhood the alpha rhythm gradually emerges,

increasing in frequency and responsiveness, but its frequency shows considerable variability, both between subjects and between published normative series. A dominant frequency of 8–9 c/s may be expected by the age of 5 years, but underlying the alpha rhythm large amounts of theta and delta activity remain. The theta activity takes on the characteristics of a slow alpha variant and the delta becomes intermittent and focal over the posterior temporal regions. The further evolution of the waking EEG though late childhood and adolescence involves quantitative rather than qualitative change. The slow alpha variant and posterior delta activity become more limited in extent and less in amount, the posterior slow waves usually disappearing entirely by the age of 22 years, and slow alpha variant a few years later. Drowsiness in early childhood produces an EEG dominated by theta activity with a frontal maximum, a picture which can easily be misinterpreted as abnormal if the reduced level of arousal is not recognized. Slow activity in sleep shows a posterior maximum up to 3 years of age, thereafter non-REM sleep patterns are not unlike those of adults. REM sleep is characterized by persisting slow activity to the age of 5 years but resembles the mature pattern thereafter.

The EEG changes with age and state of awareness, but a further source of intersubject variance is simply that the EEGs of individuals differ considerably one from another. EEG characteristics are genetically influenced to a major degree. The records of monozygotic twins are more similar than those of dizygotic twins, both on visual assessment (Lennox *et al.* 1945) and using quantitative measures (Düermuth 1968; Stassen *et al.* 1988). These similarities extend to changes on hyperventilation and in sleep (Vogel 1958). Various unusual or arguably abnormal EEG features (see below) are also genetically determined (Doose & Gerken 1973).

Pathological EEG phenomena

Clinical EEG interpretation is based on subjective judgements which are complicated by the difficulty of defining normality at different ages. Maturation is accompanied by a reduction of the slower components, whereas drowsiness and cerebral dysfunction both produce slowing; thus, it may be difficult to distinguish between the effects of immaturity, drowsiness and pathology. Currency has been given to statements to the effect that some 15% of normal children have abnormal EEGs. Such a statement defies logical thought. Normality is largely a statistical concept: findings that are common in health are normal. However, rare variants found mainly in healthy subjects must also be regarded as normal. Conversely, changes within the normal range may be pathological for the individual concerned. Reporting of normal maturational phenomena as abnormalities is probably the most common single cause of misinterpretation in electroencephalography. Slow alpha variants or posterior temporal slow waves are usually phase-locked to the ongoing alpha activity. Consequently, these slow components take off and end with an exaggerated sharpened alpha wave of opposite polarity. Misinterpretation of this single common normal phenomenon

results in innumerable children being misdiagnosed as suffering from epilepsy.

Another important consideration is that the EEG reflects cerebral function, and structural abnormality is manifest only in functional changes. Cerebral dysfunction produces in the EEG a rather limited range of abnormal phenomena, of uncertain pathophysiology.

Ongoing activities

Amplitude reduction. The most unequivocal sign of cerebral dysfunction is reduction in amplitude of normal activities. This may result from neuronal loss and from suppression of neuronal activity by toxic or metabolic factors. Extreme amplitude reduction is therefore found in brain death, after barbiturate overdose, during profound surgical hypothermia, in the terminal stages of various dementias, and immediately after a convulsive seizure. Amplitude reduction may also result from impaired conduction from the cortex to the scalp, e.g. because of an intervening subdural haematoma. Reduction in EEG amplitude may occur at the onset of an epileptic seizure (an 'electrodecremental event'), involving yet another mechanism, desynchronization of neuronal activity.

Some healthy adolescents constitutionally have low amplitude EEGs and other children exhibit a marked voltage reduction when anxious or hyperaroused; thus minor amplitude reduction may not be recognizable as abnormal unless also asymmetrical. An asymmetry greater than 50% in normal activities will generally reflect disease on the side where the amplitude is less.

Slowing. An increase in slower components of the EEG is seen in many cerebral disorders. Minor changes in ongoing frequencies may be recognized as pathological only if they are also asymmetrical. As low-frequency activity may reflect cerebral dysfunction, it might be expected to be of greater amplitude over the more disturbed hemisphere; however, the opposite will be found if the underlying pathology also leads to amplitude reduction. Slowing is a non-specific abnormality which can reflect various pathological processes including cerebral hypoxia, oedema, raised intracranial pressure, cerebral inflammatory or degenerative processes, and intoxications.

Excess beta activity. The amount of beta activity varies greatly between children. Beta activity is, moreover, increased in spontaneous drowsiness and by many sedative drugs, notably barbiturates and benzodiazepines. Excess beta activity is rarely pathological, but if very prominent may raise the possibility that the patient is consuming non-prescribed drugs.

Altered responsiveness. When the dominant rhythm over the postcentral region is slowed, whether or not still within the alpha range, it often shows a reduced responsiveness to eye opening or alerting. However, some normal subjects exhibit only minimal alpha blocking, and most will show reduced reac-

tivity when drowsy. Poor responsiveness cannot reliably be regarded as pathological unless it is also asymmetrical (less response on the more abnormal side), or is seen in a subject whose EEG was previously responsive in the same behavioural state.

Localized abnormalities

Amplitude reduction and slowing may be bilateral or asymmetrical. Essentially similar disturbances can be more localized. Amplitude reduction over a small area may involve all components of the EEG, or the higher frequencies selectively. Global reduction of amplitude generally reflects gross hypofunction or destruction of underlying cortical neurones.

Localized slow activities apart from so-called 'rhythms at a distance' (see below) generally reflect structural abnormality in the underlying cortex. Note that it is not cerebral lesions but dysfunctional neurones that generate abnormal EEG activity, so slowing may be seen around the periphery of a space-occupying lesion but not over its centre where amplitude reduction may be detected. Localized slowing may present as abnormal activity in the lower alpha, theta or delta ranges, or combinations of these.

Another important category of abnormal phenomena which may be localized, epileptiform activity, is considered in a later section.

Rhythms at a distance

Structurally normal cortex may generate abnormal activities in response to altered afferents from deep structures; these are termed 'rhythms at a distance'.

Frontal intermittent rhythmic delta activity. Frontal intermittent rhythmic delta activity (FIRDA) occurs over the frontal regions, usually bilateral and synchronous. The frequency is 1.5–2.5 c/s, and the waveform typically sinusoidal or saw-toothed. The rhythmic bursts typically last 2–5 s. It is dependent on arousal level, being absent in the fully alert subject and below stage I of sleep. FIRDA can occur in metabolic and toxic disorders, status epilepticus, and occasionally postictally, and in association with abnormalities of the diencephalon. It may occur with thalamic tumours and with obstruction of the aqueduct. However, the most common pathological correlate of FIRDA is diffuse disease involving grey and white matter (Gloor *et al.* 1968).

Bitemporal theta activity. In early drowsiness theta activity may increase over the temporal regions but in various states causing pathological drowsiness bilateral rhythmic temporal or frontotemporal theta activity occurs. It occurs under much the same circumstances as FIRDA. It must not be confused with the very prominent frontotemporal theta activity of drowsiness seen in preschool-age children.

Posterior slow activity. As noted above, posterior temporal slow activity is a normal finding in the young, disappearing in the

early twenties. Posterior temporal slow waves may exceed the norm for the child's age, as a non-specific abnormality after such cerebral insults as trauma, cerebrovascular accidents and severe hypoglycaemia. The slow activity may be of greater amplitude on the side of greater cerebral abnormality, but in general it shares with maturational posterior temporal slow activity a tendency to predominate over the non-dominant hemisphere. Sometimes there is evidence of brainstem dysfunction as the immediate cause of posterior slow activity.

Very slow delta waves (>1 s duration) are sometimes seen over the occipital regions, particularly in children, in association with mass lesions in the posterior fossa, and also with haemorrhage from the vertebrobasilar system.

Rhythmic, usually bilateral, posterior slow activity at about 3/s is seen in some children with absence seizures. It may represent a variant of spike-and-wave activity (see below), as on overbreathing it often acquires a notched waveform and spreads more widely before being replaced by typical generalized spike-and-wave discharges.

Epileptiform activity

Cerebral electrical activity changes during epileptic seizures and becomes characteristically spiky. Waves of sharp outline standing out from the background rhythms and lasting less than 70 ms are 'spikes'. Those lasting 70–200 ms are termed 'sharp waves'. Spikes are often followed by delta waves to form 'spike-and-wave' complexes, which may occur in runs as 'spike-and-wave activity'. Any of these can be generalized or focal. Spikes and sharp waves are, according to the latest approved terminology of the International Federation of Societies for Clinical Neurophysiology (Noachtar *et al.* 1999) 'clearly distinguished from background activity, with a pointed peak', which makes sense to experienced electroencephalographers but clearly lacks objectivity. In practice, an epileptiform pattern is whatever an experienced electroencephalographer says it is—not a satisfactory criterion.

Sharp waveforms occur in the interictal state (between overt seizures) in most people with epilepsy. Similar phenomena are also found in some patients with other cerebral disorders without seizures. There is no agreement as to a suitable collective term to describe this category of phenomena, but 'epileptiform activity', used here, acknowledges the association with epilepsy underlying the concept, while stressing that the term refers to the waveform, not a diagnosis.

Interpretative difficulties are increased by the occurrence in normal subjects of various sharp waveforms, unrelated to epilepsy. The most important of these in paediatrics are 6 and 14/s positive spikes which occur in short bursts at these two distinctive frequencies. At the focus the spike components are positive, a distinctive feature as most spikes are negative. Positive spikes occur in 20–30% of adolescents and young adults during drowsiness and light sleep. An increased incidence has been claimed in conditions ranging from behaviour disorders to allergies, but they contribute nothing to the diagnosis of epilepsy.

These and other spiky phenomena which are normal or of little diagnostic significance are distinguishable by characteristic morphology, topography or circumstances of occurrence.

'Periodicity'

Various pathological EEG phenomena occur at more or less constant intervals. The most dramatic example is provided by stereotyped complexes of slow waves, spikes, and sharp waves occurring every 10–20 s in subacute sclerosing panencephalitis. Periodic phenomena appear in various conditions; if these have any common feature, it is probably diffuse dysfunction of both white and grey matter.

Other transients

Triphasic complexes comprise three waves of alternating polarity, some or all of which lie in the delta range. Typically, the first and third components are frontonegative but the whole complex spreads across the head from front to back with a small time lag. This phenomenon is a sign of severe diffuse cerebral dysfunction, usually associated with metabolic disorder and typically with hepatic encephalopathy.

Paroxysmal lateralized epileptiform discharges (PLEDS) are stereotyped sharp waves or complexes of sharp waves repeating at intervals of about 1 s. They generally show a localized maximum but appear widely over one hemisphere. Occasionally, the phenomenon is bilateral, although usually asynchronous. PLEDS are seen in a variety of conditions, both acute and chronic, but always associated with localized structural disease and possibly more generalized cerebral dysfunction; examples include rapidly growing tumours, cerebrovascular accidents, herpes simplex encephalitis, cerebral abscess and following head injury.

Activation procedures

Various measures may be used to 'activate' the EEG to increase the yield of clinically significant findings. Hyperventilation, probably by reducing cerebral blood flow, slows the EEG especially in the young. Children from the age of 3 years can be persuaded to overbreathe, if necessary with the help of a toy windmill. Background rhythms are slowed, posterior slow activity increases, and rhythmic bifrontal delta activity appears. Various abnormalities may be increased, epileptiform activity in particular, and generalized spike-and-wave discharges may occur, notably in children with absences. Bifrontal delta activity on overbreathing in young people is normal, but often misinterpreted, sometimes resulting in unnecessary administration of antiepileptic drugs or neuroimaging investigations.

Photic stimulation by discrete flashes elicits visual evoked potentials (see below). Repetitive flashes at 4–30/s or more produce a rhythmic response at the back of the head, termed photic following. In some people, most of whom have epilepsy, generalized epileptiform discharges are elicited by flicker at certain

frequencies, most readily at 18/s. Between these extremes, other anomalous responses may be observed, some of which are genetically determined but of little clinical significance.

Some confusion has resulted in the literature from some authors attaching the term 'photosensitivity' to all anomalous photic responses, and others confining it to the triggering of generalized spike-and-wave activity (the 'photoconvulsive response' of Bickford *et al.* 1952). Generally accepted current terminology follows that of Waltz *et al.* 1992 who distinguished four grades of 'photoparoxysmal response', of which only type 4, generalized spikes or spike-and-wave activity, is strongly associated with epilepsy. However defined, photosensitivity is considerably more common in children than in adults. Some 20% of children with epilepsy show a type 4 photoparoxysmal response. The diagnostic specificity of this phenomenon is disputed. Various authors have reported photosensitivity in as many as 15% of normal children but have generally failed to distinguish clearly between the different types of anomalous responses.

Photosensitivity in a child with epilepsy has practical significance. In most cases it lends support to the classification of the epilepsy as idiopathic. However, various non-idiopathic conditions which may be accompanied by photosensitivity should be ruled out (severe myoclonic epilepsy, late-infantile ceroid lipofuscinosis). More importantly, some 40% of photosensitive patients with epilepsy have no spontaneous seizures, all attacks being precipitated by visual stimuli. Thus, seizure control may be achieved without drugs, by practical measures to avoid provocative stimuli. Further, some 30% of children with photosensitive epilepsy use visual stimuli to induce seizures. The most easily recognized manoeuvre is to wave the outspread fingers of one hand in front of the eyes while staring at a bright light. However, the majority of children use a more subtle method involving a slow eye-closure with lid fluttering, itself easily mistaken for a seizure or a tic. EEG and video may be required to establish the occurrence of self-induction, and should be considered in any therapy-resistant photosensitive child. Monitoring in a well-lighted environment may facilitate self-induction, whereas recording in a dark environment will be accompanied by cessation of both the self-inducing behaviour and its EEG correlates.

Sleep has a profound effect on epilepsy, and many seizure types show a marked dependence on the sleep-wake cycle. In general, epileptiform activity occurs more readily in sleep than in waking, particularly focal discharges. Recording of the EEG during sleep, induced if necessary by sedative drugs, therefore plays an important part in the diagnostic EEG investigation of epilepsy.

Evoked potentials

Evoked potentials are responses to stimulation. An abrupt stimulus, such as a click, produces a synchronous volley in the afferent pathways of the cord and/or brainstem and thalamic radiations, followed by a more complex sequence of events

when the signal reaches the specific and non-specific cortical projection areas. These phenomena have a fairly constant time course following each stimulus, whereas the waves of the ongoing EEG occur randomly in time. Therefore if the average of the signals following repeated stimulus presentations is calculated, the random activity tends to zero and the constant response to the stimulus is unmasked. Registration of EPs thus requires a special recorder containing a computer to average signals, and control the stimulators.

EPs consist of a sequence of waves, or 'components', identified by their latency and polarity. Normative values are published, but minor differences in technique and instrumentation result in substantial differences between laboratories; every department should obtain its own local reference data, a difficult achievement in paediatric practice as different norms apply to each age group.

Auditory evoked potentials

Auditory EPs are divided into early, middle latency and late. The early components, arising from the VIIIth nerve, cochlear nucleus and brainstem pathways, are termed brainstem auditory EPs (BAEPs). They are elicited by a click and, being of low amplitude, may be detected only after many stimuli; difficult children will often need sedation. The BAEPs are designated by the roman numerals I–VII and occur within 10 μ s after the stimulus. BAEPs are recorded between bilateral mastoid or earlobe electrodes and the vertex. Wave I arises from the peripheral part of the ipsilateral cochlear nerve and may persist even when the brainstem or the proximal part of the nerve is damaged. Wave II is often inconspicuous and originates in the proximal part of the nerve and the cochlear nucleus. The other components arise in the brainstem and are recorded remotely from the vertex. The most robust is wave V which persists close to the subjective auditory threshold and can be used for audiometry. Waves I, III and V are present at birth. The latencies of BAEPs are the most stable of all EPs within and between subjects but diminish with maturation, virtually attaining the adult values by 3 years of age. Conduction velocity in the brainstem is assessed by measurement of the peak to peak latencies of waves I–III or I–V (the latter is typically about 4 μ s).

Middle latency auditory evoked potentials (MLAEPs) occur in the 10–50 μ s after the stimulus. Five waves are distinguished, of which only those at 16–20 μ s and 27–33 μ s are sufficiently consistent to be of clinical value. Asymmetries may provide evidence of hemisphere lesions.

Long latency auditory evoked potentials (LLAEPs) comprise a negative wave at about 100 μ s and a 180- μ s latency positive component. Their amplitude and latency are unstable, as they are influenced by vigilance, cognitive processes and drugs. Formerly they were used for audiometric testing, but have been superseded by BAEPs. However, abnormal or absent LLAEPs may offer evidence of hemispheric lesions.

Visual evoked potentials

Visual stimuli, flashes of light or reversing black and white patterns, elicit potentials both from the retina (the electroretinogram; ERG) and from the cortex (visual evoked potentials; VEPs).

The ERG to white flash is characterized by two waves: a and b. The a-wave arises from the receptor layers of the retina, and is followed by the b-wave which probably originates in the Müller cells. Some small faster waves appear superimposed upon the b-wave: the oscillatory potentials. Later components, the c- and d-waves, are of little clinical significance. By changing the intensity and colour of the flash or the state of light adaptation, it is possible to distinguish rod and cone components of the ERG. Ideally, electroretinography requires corneal electrodes; these are not tolerated by children, so supraorbital electrodes are used. Paediatric ERG is therefore rather crude, and may be limited to establishing whether a response is present, as a check on retinal function which greatly aids the interpretation of abnormal VEPs. If necessary, the examination can be performed under general anaesthesia. The flash ERG is detectable after the first week of life, but is smaller and of greater latency than in adults. The mature pattern is attained by the age of 1–2 years.

The VEPs to a diffuse flash of light comprise up to seven waves, within 250 μ s of the stimulus, of which the most consistent are N70, P100 and P160. The intersubject variation of latency and amplitude is considerable. For clinical purposes, absence of response and interocular asymmetries of latency or amplitude are considered. In infants the earliest wave is positive at 170–190 μ s, followed by a negative at 220–240 μ s. An adult waveform is attained by 4–6 years but the P100 still has a latency of 110–130 μ s.

Responses to patterned stimuli may appear more physiological than those elicited by diffuse flash, and indeed pattern VEPs generally prove of greater clinical value. For routine purposes the stimulus used is the sudden reversal of the black and white squares of a checkerboard. The pattern VEPs comprise three main waves: N75, P100 and N145, of which P100 is the most prominent. Pattern VEP studies require good co-operation and ocular fixation by the subject and are difficult before the age of 6 years, by which time the potentials resemble those of adults. Only limited normative data are available for infancy and early childhood. Latencies are much greater than in adults.

Somatosensory evoked potentials

Somatosensory evoked potentials (SEPs) are elicited by electrical shocks applied to peripheral nerves. The ascending impulses can be traced along the limbs, the brachial plexus and spinal cord, to the cortex. In the present context only cortical potentials are relevant, and for simplicity only latencies from median nerve stimulation will be cited.

The first short latency cortical potentials comprise a parietal N20–P27 complex, and the frontocentral P22 and N30 potentials; all are recorded contralateral to the stimulus, but the N30

often extends to the ipsilateral frontal area. Responses to right- or left-sided stimuli are of equal amplitude and latency, and asymmetries reflect pathology of the underlying pathways. The short latency SEPs include two later components: the P45 and N60 potentials, neither of which is studied for clinical purposes.

Auditory and visual EPs show a reduction in latency from infancy to adulthood, with increasing conduction velocity caused by myelination and increase in fibre diameter. However, in the case of SEPs a second factor comes into play; the lengthening of the neural pathways with growth, delaying and desynchronizing the afferent volleys. In the preschool period the net effect is a reduction in latency, thereafter latencies again increase and the waveforms are widened. Comparison of the findings to normative values is simplified by correcting latencies for limb length or height, but again it is essential that each laboratory collects its own set of reference data.

Event-related potentials

The EPs described above are generated as a direct consequence of a stimulus. However, there are some, termed event-related potentials (ERPs), that are associated with endogenous or cognitive events. These include potentials preceding a voluntary movement, the Bereitschaftspotential (BP), and potentials ‘evoked’ when a stimulus is omitted from a regular series of stimuli. In psychiatry special attention has been directed to the P300, a positive wave with a latency of 250–450 μ s, related to decision-making or recognition of a stimulus relevant to a particular task (for a review see Picton 1988; and for details of maturation of ERPs Picton *et al.* 1984).

Selection and interpretation of clinical neurophysiological results in a clinical setting

Clinical neurophysiological investigations have been used in psychiatric disorders ever since the introduction of EEG, although clinicians have often found it difficult to relate the findings to the specific clinical context. However, with a better understanding of the significance of particular EEG findings and the development of newer techniques, such as EPs, combined neurophysiological investigations now offer improved prospects of obtaining clinically meaningful data. Nevertheless, it is important to understand the strengths and limitations of particular investigations. For example, many clinicians request visual or auditory EPs in the expectation that they will reveal whether the child ‘sees’ or ‘hears’. Although conventional EP testing can indicate whether the pathways are functioning appropriately, it will not determine what use the child is able to make of the sensory information. To take two extreme cases, an infant may have normal short-latency EP findings yet not respond normally as a result of severe impairment of cortical activity, while a bright child with a severe visual pathway problem and grossly impaired EP findings may have learned ploys of head movement, etc. that allow the child to use residual visual function to the full.

Table 11.1 Stages in the selection and interpretation of clinical neurophysiological investigations.

What is the clinical question?
Can it be addressed by clinical neurophysiological investigation and if so which procedure is most likely to be useful?
Are the findings normal or abnormal?
What does this mean in the clinical context?
What further investigations might be helpful?
Does the combination of neurophysiological and other findings suggest a specific diagnosis or process?
Are repeat investigations likely to be helpful and after what interval?

Clinical neurophysiological investigations in paediatric psychiatry have been used in two ways.

- 1** As additional ‘clinical signs’, evaluated as components of a pattern of signs in a particular clinical context. For a neurophysiological finding to be useful clinically, it should fulfil the criteria that it is a definite abnormality, and found consistently in a large proportion of cases with a particular condition, allowing patients to be clearly distinguished. They may also be used to check on the presence or absence of known complications of a particular condition (e.g. infantile spasms in Down syndrome).
- 2** As tools to elucidate specific underlying mechanisms of ‘mental retardation’ or ‘psychiatric disease’. Before a finding can be used to illustrate some more fundamental aspect of disordered function, there should be supporting evidence that it is likely to be relevant.

Discussion in this chapter focuses on conventional clinical neurophysiological investigations because quantitative methods have often failed to fulfil their promise and have not entered routine practice (Nuwer 1988a,b). Some research techniques offer particular insights into psychophysiological processes and are reviewed in the appropriate specialist chapters. Selection and interpretation of such investigations should be considered as a continuing clinical process of reappraisal between clinicians and neurophysiologists (Table 11.1).

If the diagnosis is secure, then neurophysiological investigations are not usually relevant, but may be helpful in the management and understanding of the cases. When there are specific questions relating to aspects of management, such as episodic alterations in behaviour, then appropriately selected neurophysiological investigations may help clarify the nature of the problem, within the limitations of the tests as described above. Prior discussion with the clinical neurophysiologist will facilitate the selection of relevant tests.

When the diagnosis is in doubt, and particularly where there is concern about progressive organic disorder, then investigations at an early stage may suggest the nature of the problem. Investigations in clinical neurophysiology should not be undertaken on a purely speculative basis, but there may be clinical hints which will repay further consideration if supported by neurophysiological findings. As Batten disease (see below) is the

most common neurodegenerative (central nervous system) disease, it is useful to combine flash ERG/VEP studies with EEG recording.

If there is continuing clinical uncertainty, then repeating the investigations after an interval, determined by the tempo of the clinical condition, may indicate whether the process is progressive.

Special techniques

Polygraphic recordings

The term ‘polygraphy’ is used to refer to the simultaneous recording of several physiological signals. This technique provides very useful information on the relationships between behavioural phenomena and physiological variables (Tassinari & Rubboli 1997). To exploit effectively the possibilities of polygraphy, recordings must be tailored to the patient’s clinical presentation. The main points of polygraphic semiology consist in the correlations of EEG events with the other physiological functions monitored and their temporal relationship. Polygraphic recordings are usually carried out using an EEG apparatus with some channels used for other biological signals. The two main clinical applications in children are seizures and sleep disorders. Polygraphic recordings of the sleep–wake cycle is termed ‘polysomnography’ and is particularly important in studying the relationship between sleep and epilepsy. The main variables that can be monitored are EEG, electromyographic activity, electro-oculogram, ECG, respirogram, blood pressure, movement and micturition. Recordings with simultaneous surface EMG acquisition from multiple muscles are of particular interest for studying the various epileptic motor manifestations in children, including myoclonus, spasms, tonic seizures, atonic phenomena and tonic–clonic activity, all easily misdiagnosed on the basis of clinical evidence only.

Jerk-locked computerized EEG averaging is a special technique which is used to detect the cortical potentials associated with EMG activity. EEG averaging triggered by the EMG potential permits extraction of low-voltage cortical potentials from the background EEG activity. This technique allows characterization of different types of myoclonus, according to the presence or absence of a cortical potential and to its temporal relationships with the EMG activity. Non-epileptic disorders that may be diagnosed with the help of polysomnography or other prolonged nocturnal recordings include sleep apnoea, with oxygen desaturation and cessation of airflow, and night terrors arising from deep sleep.

Long-term EEG monitoring

There are serious limitations to the routine EEG investigation of known or possible epilepsy. The clinical and electrophysiological manifestations of epilepsy are intermittent; a single routine recording may fail to show epileptiform activity, which may in-

deed occur only during seizures. The relevance of interictal discharges to specific clinical events may be uncertain; spikes in the EEG of a mentally retarded child with episodes of aggressive behaviour do not indicate that these attacks are epileptic. Finally, clinical and electrophysiological observations of seizures in the EEG laboratory offer little guide as to their frequency and significance in daily life. These problems can be addressed by long-term monitoring of EEG and behaviour. Two methods are available: continuous EEG recording by telemetry with behavioural observation by video recording, and ambulatory monitoring of the EEG in the patient's everyday environment with a portable recorder. These technologies are not alternatives and have different applications.

Telemetry

Routine EEG recording limits the patient's activity and will not be tolerated by a lively child for much more than an hour. Moreover, limiting activity may prevent the observation of subtle ictal phenomena, or the effects of behaviour and environment on seizures. Greater mobility is achieved by telemetering the EEG through a long flexible cable, or by a radio link.

Simultaneous video recording is important. Subtle clinical and electrophysiological ictal events are often identifiable only by comparison of EEG and behaviour. Thus, a momentary arrest of activity may be shown to be a seizure because it consistently coincides with an EEG change. Conversely, apparent subclinical discharges may prove to be ictal because of associated but inconspicuous clinical events.

Some misunderstanding surrounds the significance of the 'negative ictal EEG'. All epileptic seizures involve abnormal neuronal discharge, but this may not be recorded from the scalp. Ictal EEG changes may be entirely absent or consist not of 'epileptiform activity', but rather of a minor change in ongoing rhythms. Some seizure types, such as absences, are consistently accompanied by epileptiform activity. Some are usually associated with other changes, such as bitemporal theta activity during a complex partial seizure. Simple partial seizures, particularly with psychic or viscerosensory symptoms, often produce no EEG change. Interpretation of an apparently negative ictal EEG depends on the nature of the seizure and correlation in time of EEG and behaviour to detect subtle changes.

Ambulatory monitoring

Ambulatory recorders permit recording outside the EEG laboratory. Formerly, audio cassettes were used as the recording medium but these have been superseded by solid state digital devices, such as flash cards. Each runs for 24 h between technical checks. Recording quality of cassettes was inferior to that of telemetry, and this increased the difficulty of distinguishing EEG activity from artefact, which may be abundant in an actively moving child. Solid state devices are more satisfactory, but there remain difficulties in correlating the EEG findings with behaviour in the absence of synchronized video registration.

Ambulatory monitoring is no substitute for video EEG telemetry, e.g. for detecting subtle seizures or deciding whether particular events are epileptic. However, it is invaluable for investigating a known EEG phenomenon in a particular situation, e.g. to determine the frequency of absence seizures during school.

Brain mapping and dipole modelling

As the EEG and EPs are distributed over a three-dimensional surface and change with time, ideally they should be presented using a five-dimensional display system. As this is not practical they are usually demonstrated in two dimensions as voltage–time curves. However, by adopting a stylized two-dimensional scalp outline and sacrificing information about changes in time, the distribution of the electrical field can be displayed as an isopotential contour map. This can highlight features of both EEGs and EPs which are not easily recognized in conventional displays. Mapping has, for instance, shown that the negative Rolandic spike of benign childhood epilepsy is typically accompanied by a mid-frontal positive wave—an unusual distribution, as dipolar fields with simultaneous positive and negative foci are rarely recognizable in the scalp EEG. Minor variations in the topography of this phenomenon appear to be clinically significant. The technique depends critically on the skill of the user who must first identify those momentary salient features of field distribution which justify closer inspection.

Mapping is also applied to quantitative results of EEG analysis, e.g. the total electrical power or the ratio between the amounts of activities in two frequency bands. Temporal information is again lost, as the analysis presents a time average of some EEG feature over one or more epochs, typically of many seconds. This user-friendly way of presenting quantitative information is fraught with problems. The values plotted at each site represent, not the cerebral activity of that region, but the difference between the electrode and a reference. For instance, if the reference is obtained jointly from both ears and the patient has a temporal delta focus, a map may show maximum delta power in the contralateral central region. Any but the most sophisticated user, who hardly needs the help of mapping, is likely to interpret the map as showing an abnormality incorrectly localized and over the wrong hemisphere.

Interest in this long-established technique has been recently increased by developments in computer graphics. There is great appeal in the apparent demystification of the EEG and EPs by the substitution of simple coloured maps for long and complex chart tracings. It must be hoped that the present misuse of this potentially valuable technique will prove a temporary aberration (Binnie & MacGillivray 1992).

Another approach to display of EEG topography, of equal potential value and no less open to abuse, is equivalent dipole modelling. A source generating an electrical field must produce one site, or pole, that is maximally negative and another that is most positive (a dipole). A dipole may be described by its location, orientation, and the changing potential difference it generates be-

tween its two poles as a function of time. If such a generator were present within the brain it is possible from considerations of biophysics to predict the field that it would produce on the scalp (the so-called 'forward solution'). The electrical field over the scalp at any instant in time will be maximally negative at one site and most positive at another; it is possible by means of suitable computer programs to estimate with greater or less reliability the characteristics of a hypothetical dipole, or dipoles that could produce such a field (the 'inverse solution'). When the EEG field is strikingly dipolar, the Rolandic spike providing a good example, such a dipole or dipoles may usefully summarize the electrical field. The danger in the use of dipole modelling is the belief that because a particular dipole or group of dipoles could produce the observed field, such dipole generators actually exist. This misconception is seen particularly in studies of temporal lobe epilepsy. Interictal discharges from mesial temporal structures propagate to involve lateral temporal neocortex. The resulting widespread field can be represented by a deep temporal dipole which, almost inevitably, will be located in or somewhere adjacent to mesial temporal structures, notably the hippocampus. It may then be claimed that dipole modelling has identified a mesial temporal source of the discharges—erroneously of course, as even if the epilepsy is in fact of mesial temporal origin, the signals used for the modelling arise from lateral neocortex. The more sophisticated workers recognize that dipole modelling merely provides a useful method of synoptic representation of complex electrical fields, the more naïve persist in the belief that they are identifying physiological generators and that dipole modelling is useful for locating such sources, e.g. in pre-surgical assessment of epilepsy.

EEG findings in psychiatric disorders

Pervasive developmental disorders

Autism

Clinical neurophysiological abnormalities have been reported more often in autism than in any other psychiatric condition in childhood (Small 1987), but usually simply as evidence of an organic basis for the condition. The criteria for definition of autism, degrees of severity at the time of testing, EEG recording conditions (sleep or wakefulness), and the EEG abnormalities described have all varied widely (Tuchman 1994). This complicates interpretation of the findings, but slow activity or discharges, generalized or in a variable focal distribution, will be found in around 30–45% in single recordings (Small 1975; Tsai *et al.* 1985). The percentage was much higher when multiple recordings and sleep recordings were used. There is a relationship between IQ and the likelihood of finding EEG abnormalities, the more severely affected children being more likely to show changes (Small 1975).

Epilepsy is quite frequent in children with autism (see Lord & Bailey, Chapter 38). Major attacks are the most common seizure

type but complex partial seizures also occur. In cases where there is doubt over whether a particular behaviour is ictal, evidence of persistent EEG foci with changes during the episodic behaviour should identify children who might respond to anticonvulsants.

Lewine *et al.* (1999) suggested that epileptiform discharges in children with autism spectrum disorders might be clinically relevant, even in the absence of manifest seizures. They performed a magnetoencephalographic (MEG) study in 50 children with an autism spectrum disorder involving regression after 30 months. Only 16 of the 50 children had been diagnosed as having autism as such, and 15 had experienced epileptic seizures; 41 had epileptiform abnormalities during sleep (simultaneous surface EEG could detect abnormalities in only 34 of them). Multiple subpial transections (Morrell *et al.* 1989) with or without small topectomies, aimed at reducing the amount of discharges, were claimed to lead to a reduction of autistic features and improvement in language skills in 12 of 18 cases, despite the multifocal origin of the EEG abnormalities. However, the authors pointed out that surgery was not the only option, as steroid treatment led to an improvement in autistic features in some cases. Also, surgery was accompanied by speech and behaviour therapy.

Performing an EEG recording including at least the transition from wakefulness to sleep and at least 15–20 min of slow wave sleep is strongly advised. Epilepsy with continuous spike-wave during slow-wave sleep (CSWS; Patry *et al.* 1971) may be ruled out if the initial sleep is not accompanied by activation of frequent epileptiform discharges. However, there is evidence that discharges vary from night to night so that a single sleep recording cannot definitely rule out CSWS or atypical benign partial epilepsy (Deonna 1991; Tuchman *et al.* 1991).

EP studies, particularly of the auditory system, have been widely used to test various hypotheses concerning putative defects in acquisition and/or processing of sensory information. Between one-third and one-half of autistic patients show impairment of function in the auditory pathways, particularly through the upper brainstem (Thivierge *et al.* 1990; Wisniewski *et al.* 1991). However, it remains difficult to assess the clinical relevance of this finding and routine BAEP studies are not indicated.

Rett syndrome

There is a clustering of EEG features in Rett syndrome which may evolve with the clinical stages of the disease (Glaze & Frost 1985). EEG development is normal until about 18 months of age, when there is often loss of sleep spindles and normal rhythmic activities. Discharges appear, solely or especially during sleep (Hagberg *et al.* 1983), mostly over the parasagittal and centrottemporal regions whether or not clinical seizures have occurred (Robb *et al.* 1989; Aldrich *et al.* 1990). In the later stages, repetitive bursts of slow components are seen during sleep (Hagne *et al.* 1989) but, in our own experience, this is rather variable. In some girls, discharges are related to obsessive finger tapping and can also be elicited by passive finger tapping by the EEG technician during recording; it was found in one-third of

the cases seen by Robb *et al.* (1989). In fact, these EEG discharges appear to be giant SEPs which originate from a hyperexcitable sensorimotor cortex. Studies of the C-reflex at rest show that stimulation of the median nerve produces a giant SEP and a cortical reflex myoclonic jerk (Guerrini *et al.* 1998a).

Episodic hyperventilation and apnoea during waking, sometimes leading to cyanosis or even to loss of consciousness (Lugaresi *et al.* 1985), has also been studied. Elian & Rudolf (1991) found bursts of high-amplitude slow waves associated with apnoea and faster activities during hyperventilation or normal breathing. Although the breathing pattern is normal during sleep, Nomura *et al.* (1984) found abnormalities of tonic and phasic components of sleep and of incremental increase in percentage REM sleep with increasing age. Evoked potentials showed variable abnormalities in nine girls aged 10–12 years investigated by Bader *et al.* (1989a,b).

Other disorders

EEG abnormalities have been found in about 35% of children with symptoms of hyperactivity, impulsive behaviour and inattention (Cantwell 1980). These include diffuse non-specific changes, excessive slow activity and epileptiform activity (Satterfield *et al.* 1974); also reduced amounts of well-organized alpha waves (Shetty 1973). However, the interpretation of neurophysiological findings in these disorders is complicated by differences in both clinical classification and methodology. There are no specific clinical implications.

Young people with depression may have reduced REM latency and increased REM time, similar to depressed adults (Emslie *et al.* 1990). However, it has been suggested that this may be accounted for, in part, by methodological problems and the effects of treatment (Thaker *et al.* 1990). The abnormalities associated with depression seem to occur less frequently in prepubertal patients, but may be expressed at a younger age when there is familial evidence for depression and abnormal sleep in a parent (Dahl *et al.* 1991; Giles *et al.* 1992).

In children with, or at high risk of, schizophrenia, non-specific EEG changes (Waldo *et al.* 1978), excessive fast activity and lack of alpha waves (Itil *et al.* 1974, 1976) and abnormalities in event-related potentials (Strandburg *et al.* 1991) have been reported. Abnormalities in these disorders are mainly of academic interest and there are no indications for routine clinical neurophysiological studies.

Mental retardation

Associations between particular conditions and neurophysiological findings have usually been of more immediate clinical assistance than efforts to define the nature of changes related to 'mental retardation'. Many children with mental retardation have normal EEGs; in most others, abnormalities are non-specific and inconstant. In a small number of conditions, neurophysiological findings are sufficiently distinctive and consistently associated to suggest the diagnosis. Unusual neuro-

physiological features shared by retarded siblings can also be used to help delineate a recognizable syndrome (Baraitser & Winter 1992).

Down syndrome

Infantile spasms are not uncommon in Down syndrome (Gregoriades & Pampiglione 1966) and the EEG features are similar to those associated with other conditions. The notion that other forms of seizures are rare in children with Down syndrome has been discarded. Guerrini *et al.* (1990) suggested that reflex seizures are common (20% of their series) in children with Down syndrome and epilepsy, and speculated that this might be related to increased cortical excitability. The risks of neurological deficit resulting from cervicomedullary compression seem to be less than originally feared, but in those cases where further investigation seems warranted, SEPs are a useful component of the assessment (Pueschel *et al.* 1987).

Angelman syndrome

The EEG in Angelman syndrome shows a distinctive pattern consisting of three different elements each comprising high-amplitude rhythmic activities of delta and theta frequencies, with other sharp theta components appearing over the occipital region, usually enhanced by, or only seen on, eye closure. They are found in variable proportions in the same or in serial records (Boyd *et al.* 1988). These EEG changes are not present at birth but develop in the first year of life (Bower & Jeavons 1967) and are seen during both wakefulness and sleep. The abnormalities are most striking in younger children and the amplitude of these changes tends to decrease with age, although this is not invariable.

Many patients present with episodes of decreased alertness with hypotonia and mild jerking lasting days or weeks, described as non-convulsive status epilepticus with diffuse slow spike-and-wave complexes (Viani *et al.* 1995). Almost all patients with Angelman syndrome also exhibit quasi-continuous multifocal rhythmic cortical myoclonus at about 11 Hz, mainly involving the hands (Guerrini *et al.* 1996).

Severity of epilepsy, but not the EEG pattern, appears to vary according to the genetic classes of Angelman syndrome (Minassian *et al.* 1998). Whereas slow spike-and-wave complexes or notched slow waves are present irrespective of the genetic mechanism involved, patients with large deletions have much more severe epilepsies, in which generalized seizure types are largely predominant. The epilepsy phenotype is relatively milder in patients with loss-of-function mutations or methylation imprint abnormalities.

By contrast, no striking EEG changes are seen in Prader–Willi syndrome, the other condition associated with mental retardation and the same chromosome deletion, but of the paternal inherited 15q region (see Skuse & Kuntsi, Chapter 13). Conventional clinical EP investigations have not shown clinically useful changes in either condition.

Malformations of the cerebral cortex

Abnormal cortical development is increasingly recognized as a cause of human epilepsy and mental retardation (Guerrini *et al.* 1996). Abnormal neuronal proliferation and differentiation can result in hemimegalencephaly (HME) and the focal dysplasia of cerebral cortex described by Taylor *et al.* 1971. In HME one cerebral hemisphere is enlarged and structurally abnormal. The clinical spectrum is wide, ranging from early onset epileptic encephalopathies to patients with normal cognitive level and mild epilepsy. Several EEG patterns have been described in children with refractory seizures in infancy, including 'burst-suppression' (Paladin *et al.* 1989). The abnormalities may be bilateral but this does not affect outcome following hemispherectomy (Doering *et al.* 1999). In focal dysplasia, histological abnormalities involve a smaller area. Patients usually develop intractable partial epilepsy. Focal status epilepticus or *epilepsia partialis continua* are relatively frequent. The interictal EEG often shows focal rhythmic epileptiform discharges but epileptiform discharges may be totally absent from the scalp EEG.

Disorders affecting neuronal migration are characterized by abnormal neuronal positioning. Horizontal lamination is impaired, while radial organization is still recognizable. Several malformations, almost all highly epileptogenic, belong to this category, including the syndrome of X-linked bilateral periventricular nodular heterotopia (BPNH) and the so-called agyria-pachygyria band spectrum. The latter designates a subgroup of migration abnormalities for which the genetic basis is beginning to be elucidated. Classical lissencephaly is characterized by absent (agyria) or decreased (pachygyria) convolutions. All patients have early developmental delay and severe mental retardation; several syndromes have been described, of which the Miller-Dieker syndrome is the best known. About 80% of affected children have infantile spasms. Lissencephaly has been shown to be associated with striking patterns of high-amplitude rhythmic activity in the EEG (Gastaut *et al.* 1987). In older children, widespread slow activity may be the only feature (Hakamada *et al.* 1979). In subcortical band heterotopia a thin band of white matter separates the cortex from the heterotopic grey matter; cognitive impairment and epilepsy are again the major manifestations. There appears to be a close correlation between the thickness of the heterotopic band and the degree of pachygyria and the likelihood of developing Lennox-Gastaut syndrome (Barkovich *et al.* 1994). A malformation originating during late neuronal migration is Aicardi syndrome, which is thought to be caused by an X-linked gene with lethality in the hemizygous male. In this highly epileptogenic malformation, specific electroclinical features change little, if at all, over time and include early onset of intractable infantile spasms and partial seizures. A typical EEG feature of Aicardi syndrome, attributable to agenesis of the corpus callosum and multiple epileptogenic cortical areas, is the so-called 'split brain pattern' consisting of bilateral asynchronous hemispheric discharges.

The best-known cortical malformation originating after com-

pletion of neuronal migration is four-layered polymicrogyria, in which horizontal neuronal lamination usually persists. Seizures, poorly controlled in about 65% of patients, often occur as Lennox-Gastaut-like syndromes. Polymicrogyria may be unilateral, producing a syndrome of hemiparesis, mild mental retardation and epilepsy. Almost all seizure types and several epileptic syndromes may be observed, including sleep-related electrical status epilepticus, evolving towards spontaneous remission (Guerrini *et al.* 1998b).

Reading disorders

Clinical neurophysiological findings have been used by various groups to support organic models of dyslexia and other less well-defined disorders. Conners (1978) noted that whereas many studies had reported EEG abnormalities in dyslexic children, the nature of these abnormalities varied between the different studies and that strict definitions of dyslexia were not used. It is worth bearing these strictures in mind when considering subsequent claims for more subtle abnormalities which often depend on finding differences between the patient and normal populations using increasingly complex statistical measures. Some studies have used small numbers of subjects and a few have not incorporated a control group. There is as yet no consensus despite numerous studies of dyslexics as to whether there are characteristic features in the EEG. For example, many EEG investigations of dyslexia have shown coherence differences between the two hemispheres, but methodological difficulties (French & Beaumont 1984) were not always appreciated in the older studies. Galin *et al.* (1992) have reviewed criteria for selection and methods in this difficult area of research, stressing the importance of examining dyslexic and normal readers during both silent and oral reading.

Language disorders

Acquired dysphasia (Landau-Kleffner syndrome)

Landau & Kleffner (1957) described six children (including siblings) with acquired dysphasia who had discharges in their EEGs and who improved with anticonvulsant treatment. An association between a prompt improvement in the EEG with treatment and a satisfactory clinical outcome continues to be reported (Lerman *et al.* 1991), but individual cases may be left with severe language deficits (van Dongen *et al.* 1989).

The nature of the relationship between the discharges and the dysphasia is much debated. The two main hypotheses are that the discharges and the dysphasia are epiphenomena related to a single underlying cause, or that the dysphasia is a direct consequence of focal discharges. On reviewing the condition, Deonna (1991) cited the absence of structural pathology and improvement with anticonvulsant treatment in favour of the latter explanation, a view supported by MEG studies (Paetau *et al.* 1991). The elegant study of Seri *et al.* (1998) has added solid evidence to this pathophysiological interpretation. These authors

studied spike-triggered auditory evoked responses in a group of children with Landau–Kleffner syndrome and observed that spikes over the left hemisphere were associated with a greater reduction in the amplitude and increased latency of the N1 component than spikes occurring in the contralateral hemisphere. Spike-related abnormal processing of the auditory information may therefore play a substantial part in the language dysfunction of Landau–Kleffner syndrome. Cole *et al.* (1988) reported that EEG discharges were generalized, bilateral, multifocal or with shifting predominance, but with a mainly temporal distribution in 85% of cases, and unilateral and again predominantly temporal in the remaining 15%.

Although Landau & Kleffner defined the eponymous syndrome as one of acquired dysphasia, other evidence (Maccario *et al.* 1982) suggested that it may also present as a developmental language disorder.

Developmental language disorder

In common with many disorders, estimates of the prevalence of EEG abnormalities in children with developmental language disorder (DLD) is complicated by the fact that the condition is heterogeneous and that children are much more likely to have an EEG if seizures are suspected. In a survey of 237 DLD children without evidence of autism, Tuchman *et al.* (1991) found that EEGs had been carried out on all 19 with epilepsy but on only 66 (30%) without seizures. EEG abnormalities, mainly epileptiform changes, were found in 63% of those with seizures and 20% of those without. Both the proportion and the type of EEG changes were similar to those seen in a comparison group of 314 children with autism, but they were very variable.

Such findings make it difficult to devise definitive guidelines for identifying children with dysphasia who might benefit from anticonvulsant medication. However, most patients with the Landau–Kleffner syndrome show continuous temporal or bitemporal discharges during sleep at some stage. It would therefore seem reasonable to consider the diagnosis in those children where the EEG during sleep shows frequent or continuous discharges predominantly in the temporal regions, and to adopt a more sceptical approach when the discharges are only sporadic and mainly extratemporal. In patients in whom speech disturbance is clearly episodic (and occurring several times per week), ictal recording may be warranted.

Neurological disorders with psychiatric consequences

Epilepsy

EEG and the classification of the epilepsies

Epileptic disorders are described in terms of syndromes, and within the general framework of a classification of the epilepsies (Commission on Classification & Terminology of the Inter-

national League Against Epilepsy 1989). The classification distinguishes generalized epilepsies, in which seizures apparently arise in both hemispheres, and partial (or ‘localization-related’) epilepsies in which seizure onset is in a circumscribed cortical area. A division is also made between symptomatic epilepsies in patients with structural brain disease, cryptogenic epilepsies in which the pathology is presumed but unproven, and idiopathic epilepsies arising in an intact brain. These criteria are reflected in the EEG.

In idiopathic generalized epilepsies, both ictal and interictal discharges are generalized often with a frontal emphasis, as typified by the bilateral spike-and-wave activity in absences. Partial epilepsies are accompanied by focal discharges, both at seizure onset and in the interictal state. These are not, however, necessarily detectable in the scalp EEG (see above). Both partial seizures and focal discharges may spread to surrounding cortical areas, involve homologous regions of both hemispheres, or become generalized. In some patients the secondarily generalized phenomena may dominate the picture and the underlying focal elements pass undetected. In symptomatic generalized epilepsies, both multifocal and generalized interictal discharges are usually found, against a diffusely abnormal background, reflecting the generalized cerebral pathology.

EEG features of epilepsy syndromes of childhood and adolescence

Many epileptic syndromes are described in childhood and all present characteristic EEG features. Those seen in the neonatal period will not be considered here.

The association of epileptic spasms with the EEG pattern termed ‘hypsarrhythmia’ characterized by diffuse high-voltage irregular slow waves with multifocal sharp waves and spikes has been called either West syndrome or infantile spasms. However, spasms *per se* only represent a special type of epileptic seizure and although in infants they are usually associated with the hypsarrhythmic EEG pattern to form a syndrome, they may also occur well beyond infancy. The current view (Commission on Paediatric Epilepsy of the International League against Epilepsy 1992) is that West syndrome results from the association of the hypsarrhythmic EEG pattern and epileptic spasms, therefore representing a subgroup of infantile spasms. In this sense, the term ‘epileptic spasms’ only applies to a type of seizures, irrespective from the age at which they occur. During spasms of West syndrome there is usually a reduction of amplitude often with the appearance of fast activity, preceded by an initial high-voltage slow wave with or without a spike. In some instances the ictal EEG consists of high-amplitude slow waves and spikes. In many patients this condition subsequently evolves into the Lennox–Gastaut syndrome. Although epileptic spasms beyond the nosological limits of West syndrome may have several different underlying aetiologies, they are likewise associated with brain malformations (Dulac *et al.* 1994).

Febrile convulsions are seizures, usually tonic–clonic, occurring with fever. Postictal slowing of background activity reflects

the length of the seizure, but except where gross cerebral pathology is present, the EEG is of little value for predicting the subsequent development of epilepsy.

The Lennox–Gastaut syndrome is a form of symptomatic or cryptogenic generalized epilepsy presenting in mid-childhood and characterized by atonic and axial tonic seizures, atypical absences, myoclonic jerks and generalized tonic–clonic as well as partial seizures. The EEG is grossly abnormal with features of symptomatic generalized epilepsy but, in particular, slow spike-and-wave EEG activity (at less than 2.5/s) is among the diagnostic criteria of the syndrome.

Benign myoclonic epilepsy in infancy presents after 6 months of age with single generalized myoclonic seizures. The waking EEG contains occasional spike-and-wave discharges, increasing during sleep. By contrast, severe myoclonic epilepsy in infancy (Dravet *et al.* 1992) is characterized by generalized or unilateral febrile clonic attacks beginning in the first year of life with subsequent appearance of myoclonic and partial seizures. The EEG is normal initially but later develops fast generalized spike-and-wave discharges, often early photosensitivity and focal abnormalities.

Myoclonic astatic epilepsy of early childhood is included amongst the generalized epilepsy syndromes which may be either symptomatic or cryptogenic (Commission on Classification & Terminology of the International League Against Epilepsy 1989) in that a subset of children present with developmental delay and resistant seizures. However, recent studies have shown that the clinical and EEG pattern and outcome presented by some children is consistent with a specific form of idiopathic generalized epilepsy (Guerrini *et al.* 1994). Epilepsy onset is in, or soon after, late infancy, usually with generalized tonic–clonic seizures. Children later develop additional seizure types including violent myoclonic jerks causing drop attacks, and episodes of absence status with mild erratic myoclonus. The interictal EEG is initially normal or contains excess theta activity. Subsequently, irregular fast spike-and-wave activity appears. Many patients are photosensitive.

Absence seizures occur in various forms of idiopathic generalized epilepsy. Childhood absence epilepsy appears at 6–7 years, with typical absence seizures but without myoclonus. The EEG shows classical 3/s spike-and-wave activity against a normal background. Despite very frequent seizures, prognosis is good; three-quarters of the patients become seizure-free, but the remainder continue to suffer absences or develop tonic–clonic seizures at puberty or in early adult life. Patients who are at risk of persisting seizures usually have atypical features, including slow spike-and-wave discharges, slow background activity or mental retardation. Their inclusion in the category of idiopathic childhood absence epilepsy is questionable.

Epilepsy with myoclonic absences differs from the above in that the seizures are accompanied by rhythmic myoclonic jerks which are synchronous with the spike component of spike-and-wave discharges. The prognosis is less favourable with respect to response to treatment, subsequent development of other seizure types and cognitive level. The EEG findings are similar to those

in childhood absence epilepsy; however, absences are of longer duration.

Juvenile absence epilepsy presents at puberty. The seizures are generally less frequent than in the childhood syndrome, but most of the patients also develop tonic–clonic seizures. All types of absence seizure occur. The EEG shows spike-and-wave activity typically slightly faster than 3/s.

Benign partial epilepsy of childhood with centrotemporal spikes (also called Rolandic epilepsy) is characterized by focal seizures with somatosensory symptoms often starting in the face or mouth, mainly during sleep. Prognosis for seizure control is good, and the condition usually remits at an age of about 16 years. The EEG shows frequent centrotemporal spikes or sharp waves of high amplitude (sometimes exceeding 300 μ V) often followed by a slow wave. Twenty per cent of patients also show generalized spikes and waves or multiple spikes and waves which are activated during slow wave and REM sleep. Typically, the discharges have a dipolar distribution, being negative in the central region with a positivity in the mid-frontal area. A liability to Rolandic spikes is genetically determined, and many children with this EEG abnormality have no overt seizures. Rolandic epilepsy is traditionally not considered to be associated with any neuropsychological deficits. However, several studies have reported impaired visuomotor co-ordination (Heijbel & Bohman 1975), attention problems (Piccirilli *et al.* 1994), auditory–verbal memory (Croona *et al.* 1999), deficits in performance IQ, visual perception, short-term memory and behavioural problems (Weglage *et al.* 1997). Weglage *et al.* (1997) assessed the behavioural status of 40 children with centrotemporal spikes with and without obvious seizures and compared them with 20 matched controls. Patients had significantly more problems in the subscales social problems, delinquent behaviour and compulsive behaviour. Cognitive deficits may be closely related to psychological impairments occurring in association with the frequent, but apparently subclinical, discharges (Binnie *et al.* 1992; see below).

Benign partial epilepsy of childhood with occipital foci is accompanied by interictal posterior–temporal–occipital spike-and-wave activity or sharp waves. The seizures are characterized by visual symptoms in older children (Gastaut 1982) and by version with vomiting and occasionally hemiconvulsions in smaller children (Ferrie *et al.* 1997). Prognosis of this type of epilepsy appears to be invariably good in early onset cases but less uniformly good when onset is in late childhood.

Epilepsy with continuous spike waves during slow-wave sleep is probably underdiagnosed, presenting as a progressive neuropsychological deterioration, affecting language, memory and attention span. This condition may appear in children with brain damage or be cryptogenic. The typical features are onset of rare nocturnal partial motor seizures at preschool age, followed by the appearance of intractable atypical or atonic absences at school age. Prolonged sleep EEG recording is required to recognize the syndrome: spike-and-wave activity present during the greater part of slow-wave sleep. The condition is self-limiting,

remitting by the age of 10 years but the prognosis for cognitive function is often poor, especially if the sleep-related electrographic abnormalities have persisted for a long time. Several discrete mild subsyndromes with deterioration of specific neuropsychological functions may sometimes be recognized upon thorough clinical observation or neuropsychological assessment (Veggiotti *et al.* 1999). Ongoing diurnal cognitive effects of discharges occurring during sleep should be distinguished from instantaneous disruption of cognition at the time of the abnormal EEG activity, known as transitory cognitive impairment (TCI; see below).

A specific condition often accompanied by CSWS is the Landau–Kleffner syndrome. Again there is cognitive deterioration, particularly affecting language, but epilepsy occurs in only two-thirds of the patients and is rarely severe. The EEG shows diffuse, or focal, usually bilateral spike-and-wave discharges, in waking and marked activation during sleep. This syndrome is considered more fully below.

Chronic progressive epilepsia continua of childhood may be caused either by a discrete cerebral lesion or by more diffuse Rasmussen encephalitis. In the former case, focal EEG discharges usually occur against a normal background. In Rasmussen syndrome the picture is variable but typically there is a marked diffuse abnormality of background activity and often bilateral discharges. The encephalitic process is usually unilateral and the EEG is asymmetrical, but progressive destruction of one hemisphere may reduce all EEG activities, so that the discharges are paradoxically of greater amplitude on the unaffected side.

Juvenile myoclonic epilepsy is a syndrome with a strong genetic background, with irregular bilateral myoclonic jerks generally worse within an hour of waking. The EEG shows both ictal and interictal irregular fast multiple spike-and-wave discharges and many patients are photosensitive. Later tonic–clonic seizures may appear, especially upon sleep deprivation. Medication is effective but often needs to be lifelong.

Another syndrome of adolescence continuing into adulthood is ‘epilepsy with tonic–clonic seizures on awakening’. It is debatable whether this is an independent syndrome or just part of the same spectrum as juvenile myoclonic epilepsy. The background EEG activity is often abnormal and various types of generalized spike-and-wave discharges occur. Despite the name, the distinguishing characteristic is a marked dependence of seizure occurrence on wake–sleep rhythms and disturbances of sleep. Some patients do indeed have seizures on awakening; in others attacks occur in the late evening or after sleep deprivation.

A recently defined epilepsy syndrome which is at particular risk of being misdiagnosed as a parasomnia, a psychiatric disorder or a form of sleep-related paroxysmal dystonia is nocturnal frontal lobe epilepsy (see also section on sleep disorders). This condition may occur in isolated patients or show an autosomal dominant pattern of inheritance (Scheffer *et al.* 1994). Mutations of the neuronal nicotinic acetylcholine receptor alpha-4 subunit gene has been identified in some families (Steinlein *et al.* 1995). The disorder, usually beginning in childhood, is charac-

terized by clusters of brief nocturnal motor seizures with tonic and hyperkinetic manifestations, typically appearing during drowsiness or upon awakening. Interictal EEGs are usually unhelpful. Good control is achievable with drug treatment. Behaviour disorders and epilepsy are also prominent in an apparently unrelated condition where there is ring formation of chromosome 20. Interictal EEG abnormalities are usually prominent and often frontal, and prolonged episodes resembling non-convulsive status are associated with EEG abnormalities which some authors consider distinctive (Inoue *et al.* 1997; Kobayashi *et al.* 1998).

The progressive myoclonic epilepsies of childhood and adolescence include various unrelated disorders with the common clinical features of myoclonus, other types of seizure, progressive mental deterioration and variable neurological symptoms. Various specific neurodegenerative conditions fall in this group, and some have characteristic EEG features. However, in general the EEG shows bursts of spikes, spike-and-wave activity and multiple spikes and slow waves, with slowing of ongoing activity and disruption of sleep patterns.

EEG investigation of children with epilepsy

It is a truism that epilepsy is a clinical diagnosis, to which the EEG can add only confirmatory evidence. In general the EEG is of greater value in identifying syndromes than for establishing, or excluding, epilepsy. Thus, slow spike-and-wave activity is among the diagnostic criteria of the Lennox–Gastaut syndrome, and (without an adequate history) benign childhood epilepsy is often first identified by the EEG finding of Rolandic spikes. If in a particular clinical context the EEG excludes the only plausible syndrome, another diagnosis should be considered. For instance, if a child reported to be inattentive overbreathes for 3 mins hard enough to produce EEG slowing, and does not exhibit spike-and-wave activity, active absence epilepsy can be excluded, and some other explanation should be sought.

Using the EEG as a screening test for epilepsy without adequate clinical evidence is rarely helpful, particularly in children with ‘soft signs’ of organic cerebral disease. Thus, only an ictal EEG will establish an epileptic basis for episodic behavioural disturbances in a disabled, presumably brain-damaged child; interictal epileptiform discharges are without diagnostic significance in this context. Some scenarios will be briefly considered.

‘Routine’ investigation of newly diagnosed epilepsy

The EEG may help to identify the syndrome, with implications for management and prognosis. Significant unexpected findings sometimes arise, e.g. photosensitivity or frequent unrecognized seizures. If a waking record does not provide the information required, a sleep tracing should always be obtained; this increases the yield of abnormal findings, especially in partial epilepsies, and may be crucial to early identification of benign childhood epilepsy, or CSWS.

Screening of children with an increased risk or doubtful evidence of epilepsy

Abnormal findings should be interpreted cautiously. Spiky EEG phenomena unrelated to epilepsy (6 and 14/s positive spikes, for instance) should be ignored. Rolandic spikes, photosensitivity and generalized spike-and-wave activity may reflect a genetic liability, rather than an active seizure disorder. However, such findings justify further enquiry, which may reveal previously unrecognized ictal events related to visual stimuli: myoclonus in proximity to a television set, self-inducing behaviour, etc.

During apparently subclinical EEG discharges, unexpected ictal events may be detected. If the child sits upright with outstretched arms during recording, momentary loss of muscle tone may be shown to accompany the discharges. Psychological tests administered under EEG monitoring often detect TCI associated with seemingly subclinical discharges. TCI has been found in about 50% of patients with epilepsy during both generalized and focal discharges (Aarts *et al.* 1984; Binnie *et al.* 1990). These findings may have clinical implications in a child with psychiatric manifestations or learning difficulties as TCI can impair day-to-day psychosocial function, such as school performance (Kasteleijn-Nolst Trenité *et al.* 1988), driving a car (Kasteleijn-Nolst Trenité *et al.* 1987) and behaviour (Binnie *et al.* 1992; Marston *et al.* 1993). Technically, such events are epileptic seizures and they are subclinical only in the sense that conventional methods of observation fail to detect the clinical manifestations.

Investigation of episodic abnormal behaviour

The only reliable method of establishing that a particular episodic behaviour is epileptic is by demonstrating ictal EEG changes. This applies equally to children with known epilepsy and to those without. The dangers of misinterpreting an interictal EEG abnormality in this context were noted above. The practicalities of capturing an ictal EEG depend on the frequency, nature and circumstances of occurrence of the episodes (see section on long-term EEG monitoring). It must be recognized, however, that even intensive monitoring may not solve the problem. If the seizures are infrequent they are unlikely to be captured at all and, if of certain types, may not produce ictal EEG changes. Referral for EEG investigation of episodic behavioural disorder should be selective and not viewed as a panacea for this common problem. Equally, it is important that every effort be made to distinguish epileptic from non-epileptic seizures, bearing in mind that these may coexist. 'Uncertainty or equivocation on the physician's part can be disabling' (Stores 1999). A relaxed pragmatic approach, suggesting that the nature of the attacks is unimportant will not lead to effective management, as the recognition and specific treatment both of epilepsy and of non-epileptic attacks are equally essential.

Neurodegenerative disease

Clinical neurophysiological findings can help identify individuals who may be suffering from a neurodegenerative disease, as a number of distinctive patterns have been associated with various conditions (Boyd & Harden 1997). They may also suggest that the child does *not* have a neurodegenerative disorder by demonstrating some other process leading to a decline in behaviour or performance, notably non-convulsive status epilepticus.

Subacute sclerosing panencephalitis

The association between subacute sclerosing panencephalitis and periodic complexes in the EEG is probably one of the best-known electroclinical associations. Despite this, cases are still missed, often because of a failure to consider the condition. This may be because of an unusual presentation such as visual disturbance (8.75% of a series of 80 children, Pampiglione & Harden 1986) or because behavioural disturbances or fits initially suggest other conditions. The EEG complexes themselves may not be striking or their significance may be dismissed because of the presence of normal activities, including alpha rhythm.

Batten disease

Distinctive neurophysiological findings in the different forms have been useful in helping to identify affected children. In the juvenile form, the child presents at around 5–6 years of age with visual symptoms and may be referred to the psychiatrist if no ophthalmic cause is found. By this time the ERG is usually absent and the flash VEP is poorly formed or absent. The EEG shows runs of sharp waves and slower components at around 2/s in about 50% of cases.

Variant forms of this group of disorders are not infrequent and Santavuori *et al.* (1991) has emphasized the wider spectrum of clinical presentation. In one case, a girl presenting with a progressive dementia without any other clinical features was eventually shown to have Batten disease on biopsy following the unexpected finding of a small ERG.

Sleep disorders

Sleep disorders in children have been characterized as both underdiagnosed and undertreated (Stores 1990). A comprehensive classification of diagnostic criteria, including neurophysiological findings, was published in 1990 (Thorpy 1990). Technical aspects of making polysomnographic recordings in infants, children and adolescents have also been reviewed (Guilleminault & Philip 1992; Hoppenbrouwers 1992; Keenan 1992). However, most of these disorders, including night terrors (Guilleminault & Silvestri 1982), are rarely associated with seizures or with EEG abnormalities. Different disorders may be associated with particular phases of sleep (Table 11.2).

Epileptic disorders manifesting as abnormal movements during sleep, especially frontal lobe seizures, are also difficult to

Table 11.2 Electroencephalogram (EEG) and polysomnographic features in some sleep disorders of infancy, childhood and adolescence. (After Thorpy 1990; see text for epileptic and mental disorders.)

Disorder	Typical age of onset	Polysomnographic features	EEG features
<i>Dyssomnias</i>			
<i>Intrinsic sleep disorders</i>			
Idiopathic insomnia (childhood-onset insomnia)	Birth	Sleep spindles may be poorly formed. and somnograms difficult to score. Long periods of REM sleep without eye movements	Varied, minor non-specific abnormalities are common
Narcolepsy	Second decade. Peak incidence 14 years	Short sleep latency. Sleep-onset REM can be associated with hypnagogic hallucinations	Often features of drowsiness. Eye opening may increase alpha activity
Recurrent hypersomnia (Kleine–Levin syndrome)	Adolescence	High sleep efficiency. Reduced stage III and IV sleep	Low-voltage slow activity or diffuse alpha activity
Idiopathic hypersomnia (NREM narcolepsy)	Adolescence	Normal	Normal
Obstructive sleep apnoea	Any age	Complex and varied. Some have initial central apnoea followed by obstruction (mixed type). Short sleep latency; occasionally sleep-onset REM	Normal
Central alveolar hypoventilation	Idiopathic: adolescence Acquired: any age	Periods of oxygen desaturation worse in REM sleep. Frequent arousals, body movements	Normal
Restless legs syndrome	Any age (mostly in middle age)	Sustained tonic EMG activity alternates between legs, occurs in antagonistic muscles during flexion and extension of legs	Normal (wake) EMG and nerve conduction studies usual in young subjects
<i>Extrinsic sleep disorders</i>			
Adjustment sleep disorder (transient psychological insomnia)	Any age	Very variable	Normal
Limit-setting sleep disorder (childhood insomnia)	2–3 years variable	Normal	Normal
Sleep-onset association disorder	6 months	Normal	Normal
Food allergy insomnia (food intolerance)	In first to second year	Frequent arousals. No preceding EEG change	Normal
Nocturnal eating (drinking) syndrome	6 months	Normal except for increased waking	Normal
Stimulant-dependent sleep disorder (stimulant sleep suppression)	Adolescence	↑ Sleep and REM latency. ↓ Total sleep and REM time. Rebound on stimulant withdrawal; MSLT may then resemble narcolepsy	Normal
Circadian rhythm sleep disorders. Irregular sleep–wake pattern	Variable	Paucity of information	↓ Sleep spindles and K-complexes ± changes associated with underlying cerebral condition
Delayed sleep phase syndrome	Adolescence	↑ Sleep latency. Some ↓ REM latency	Normal
Non-24-h sleep–wake syndrome	Variable. Usually blind infant/child	Paucity of information	↓ Sleep spindles and K-complexes ± changes associated with any underlying cerebral problem

Table 11.2 *continued*

Disorder	Typical age of onset	Polysomnographic features	EEG features
<i>Parasomnias</i>			
<i>Arousal disorders</i>			
Confusional arousals (sleep drunkenness)	<5 years	Arousals from slow wave sleep, especially first third of night	Slow activity during episode, otherwise normal
Sleepwalking	4–8 years	Begins in stage III or IV sleep	Normal*
Sleep terrors (night terrors)	Childhood	Especially in stage III or IV sleep	Normal*
<i>Sleep–wake transition disorders</i>			
Rhythmic movement disorder (head-banging, body-rocking)	Usually <1 year	Episodes in drowsiness or (mainly) light sleep	Normal*
<i>Parasomnias usually associated with REM sleep</i>			
Nightmares	Any age 3–6 years	Abrupt awakening from REM sleep, ↑REM duration and density	Normal
Sleep paralysis	Adolescence	Loss of tone, ↓EMG activity, H reflex studies; ↓anterior horn cell excitability as in REM sleep	Slow activity and/or pendular eye movements during episode
<i>Other parasomnias</i>			
Bruxism (tooth grinding)	10–20 years	↑Masseter and temporalis activity; stage II sleep	Normal
Sleep enuresis	Primary from infancy. Secondary any age	Episodes in all sleep stages, also wakefulness	Occasionally associated with epilepsy, discharges may be found
Nocturnal paroxysmal dystonia	Variable	Episodes mainly in stage II, but also in stage III or 4 sleep. EEG desynchronization; no discharges	Normal*
Infant sleep apnoea (apparent life-threatening event)	First days to weeks of life	Usually no abnormalities. Prematures; AS>QS	Rarely associated with localized discharges†
Benign neonatal sleep myoclonus	First week of life	EMG bursts lasting 40–30 μs, usually in QS	Normal*
<i>Psychiatric sleep disorders</i>			
Psychosis	Adolescence	Very variable	(See text)
Mood disorders (depressive disorder)	Childhood and adolescence	Typically ↓delta and ↑REM sleep. Short REM latency. ↑density REM. Findings in children and adolescents less marked, cf. adults	Normal
Anxiety disorder	Any age	Mild changes. ↑Sleep latency, ↑stage I and II sleep	Normal

Abbreviations: AS, active sleep; EMG, electromyogram; MSLT, multiple sleep latency test; NREM, non-rapid eye movement; QS, quiet sleep; REM, rapid eye movement.

* Normal: Useful contribution by excluding other conditions in differential diagnosis.

† Watanabe *et al.* (1982).

recognize (Stores *et al.* 1991) and often have to be considered in the differential diagnosis (Fish & Marsden 1994).

A summary of polysomnographic and EEG findings in sleep disorders seen mainly in childhood and adolescence is shown in Table 11.2.

Future developments

The history of clinical neurophysiological investigations in psychiatry and psychology has been one of high hopes succeeded by disappointment as each technique in turn proved unable to sustain the expectations placed upon it. It is to be hoped that some of the lessons have now been learnt, and that the importance of careful definition of the type of disorder being investigated and equally careful patient selection will lead to much greater progress. The experience with EEG and latterly EPs should be borne in mind when considering the claims of topographic mapping and ERPs. The need to establish reliable norms, and proper caution in establishing the limits and strengths of any new technique, are fundamental, as is the need to discriminate between individual and group differences from 'normal'. Despite this need for caution, there has been some progress in developing relevant clinical protocols (Byrne *et al.* 1999).

Conventional techniques, used carefully and in combination both with each other and with other methods of investigation are still capable of providing valuable insights into psychological processes both in normal children and in those with psychiatric disease. This is likely to be enhanced by improved applications of the powerful mathematical tools provided by digital signal processing, although the importance of ensuring that the signals obtained from the patient are of the highest quality must never be forgotten. Current interest in high-frequency components of EEG signals may lead to striking new insights into how different regions of the brain communicate, particularly when combined with other techniques, such as transcranial magnetic stimulation, but as yet there are no specific clinical associations. A similar situation pertains to the use of other techniques, such as magnetoencephalography (Baumgartner 2000); despite a large literature on localization of function obtained with this technique, its place in the investigation of brain disorders remains unclear, compounded by the limited availability of the facility in many countries. While it may find a role in the non-invasive localization of epileptic foci in children undergoing presurgical evaluation (Minassian *et al.* 1999), at present it seems unlikely to supersede EEG entirely. There is also much interest in combining MRI with simultaneous MEG/EEG recording as a means of overcoming the inherent limitations of each method when used alone (Dale *et al.* 2000), but much basic research still needs to be carried out.

Rather than being superseded by other techniques, it seems more likely that clinical neurophysiological investigations will continue to provide unique information on the function of the nervous system. While new techniques of data collection and manipulation may prove useful, cross-reference to other investi-

gations and other methods of studying the nervous system are also likely to be fruitful. As a consequence, the quality and relevance of this information seems likely to improve markedly as a result of improvements in its interpretation and in our confidence concerning its clinical and biological significance.

Influences on Psychopathology

Genetics of Normal and Abnormal Development

Peter McGuffin and Michael Rutter

Introduction

The climate of opinion has changed markedly since McGuffin & Gottesman (1985) noted the comparative neglect of genetics, and in some quarters overt hostility, among child psychiatrists. Why have views changed, and will a new-found interest in genetics ultimately be of benefit to child psychiatry? The answer to the first question could lie in the major advances in the understanding of the causation of medical diseases brought about by molecular genetics. That might suggest that child psychiatry is merely following fashion, but if we ask why that fashion has become so widespread in biomedical sciences, the answers are not trivial. A genetic approach to human health is seen to offer new benefits in terms of predicting illness, refining diagnosis and classification and ultimately discovering new methods of prevention and treatment.

As a counterbalance to such optimism, it needs to be pointed out that the promise of genetics has sometimes been oversold, particularly when findings stray from the pages of scientific journals into the popular media. Thus, in addition to hearing about the discovery of ‘genes for’ particular diseases, it is now not uncommon to hear about scientists discovering ‘the gene for’ traits such as aggression, homosexuality or feminine intuition. This cannot be wholly blamed on poor journalism. Geneticists quite often use a misleading shorthand that gives a quasi-deterministic impression of what genes do. Genes, of course, are not strictly ‘for’ anything other than to replicate themselves. Furthermore, most behaviours, and indeed most common traits and disorders, involve an interplay between the environment and a collection of genes, rather than just a single locus.

Patterns of transmission

Finding that a trait or disorder is familial is a necessary first step before embarking on genetic studies. However, finding familiarity does not provide sufficient evidence that genes play a part. We resemble our relatives because of a combination of the genes that we share with them and of environmental effects that we have in common. Shared environmental effects may include socioeconomic status which may in turn be reflected in indices of social deprivation. However, other factors aggregate in families including cultural values that may be reflected in, for example, religious persuasion, substance use, hobbies and interests or even career choice. Shared environment also includes the pos-

sibility of physical contagion and exposure to the same infectious agents. Therefore, traits or disorders may be strongly familial, but mainly or entirely non-genetic. Edwards (1960) pointed out that traits resulting from a family environment may even simulate Mendelian traits; this is borne out by a study of career choice. McGuffin & Huckle (1990) showed that not only is attending medical school highly familial (a not too surprising finding) but also that the ‘trait’ passed nearly all of the tests for autosomal recessive inheritance when modern statistical techniques were applied.

The other side of the coin is that genetic effects have sometimes being overlooked when familiarity is less obvious or striking. A good example is childhood autism where some authors in the past doubted any important genetic contribution because the recurrent risks of strictly defined autism in the siblings of autistic patients was so low in absolute terms—about 3% (Rutter 1966; Hanson & Gottesman 1976). However, this has to be compared with the general population risk using the same narrow criteria, which is in the region of 5–10 per 10000 (Rutter 2000a). Hence, the relative risk of autism in siblings, sometimes denoted by the symbol λ_s (Risch 1990), is some 50–100 times that of the general population.

Another source of confusion is that clinicians and researchers sometimes attempt a straightforward separation of disorders into familial and ‘sporadic’, with the latter being those cases where no other members of the family are affected. Even with single gene disorders, this is less straightforward than it looks. A ‘sporadic’ case of autosomal dominant disorders, such as Huntington disease or tuberous sclerosis, may arise because of a fresh mutation or because the diagnosis was missed in the parental generation. For example, a parent carrying the Huntington disease mutation may have died of some other cause before developing the disorder and a parent with tuberous sclerosis may have a mild form of the disorder with just skin lesions and no epilepsy or mental retardation. In either case, the offspring of such individuals will be at the same 50% risk as they would if a family history had been detected. Similarly, a high proportion of cases of rare recessive disorders present as ‘chance isolates’ (when neither parents nor more distant relatives are affected), but where both parents turn out to be heterozygous carriers.

A further problem about using a family history positive/negative dichotomy when it comes to more complex traits and diseases is that the probability of classifying the subject as family history positive increases with the number of relatives on

which there is available information. Therefore, a common trait that affects, say, 10% of the general population, but which actually shows no true familial aggregation will, by chance, result in anyone with five relatives having a 41% probability of being classified as ‘family history positive’ (McGuffin *et al.* 1987a). Therefore, there is no substitute for carrying out family studies in which the numbers of affected and unaffected relatives are actually counted and compared with some appropriate control group.

Family study methods

Family studies have been carried out extensively in adult psychiatry but their application in child psychiatry is more recent. For most child psychiatric disorders, the precise relative risks (λ) of recurrence in siblings or other categories of relatives remain uncertain. In part, this reflects difficulties in defining *ascertainment* or the method of selecting families for inclusion in a study. Ascertainment of a family takes place via index cases or *probands*. The most common method of doing this is via a consecutive series of patients referred to a clinic or hospital. All probands fulfilling diagnostic criteria must be included in the study *independently*. That is, no consideration is given to whether there is prior information about other members of the family being affected. If a disorder is rare, it is likely that no family will be ascertained more than once (*single ascertainment*) but if a disorder is comparatively common in the same clinic or treatment facility that sees many patients, some families will only be sampled a single time whereas others will contain more than one proband and be counted more than once. This is referred to as *multiple incomplete* ascertainment. If it is possible to study an entire population and hence count every case as a proband, this is described as *complete* ascertainment.

Accurate ascertainment is important for the use of statistical methods of segregation analysis to infer the mode of transmission. In practice, diseases in humans fall into two groups: those where inferring mode of transmission is straightforward and where there is a simple regular Mendelian pattern of transmission; and those where the pattern of transmission is more complicated and where there is not a straightforward correspondence between genotype and phenotype. Most Mendelian disorders are decidedly uncommon, and sometimes exceedingly rare. Several thousands of such disorders have been listed (OMIM 2000) and hundreds of these are of relevance to psychiatry, usually because they cause mental retardation, but sometimes because they result in relatively specific behavioural phenotypes (see Skuse & Kuntsi, Chapter 13). The disorders include fragile X mental retardation (FRA-XMR1; X-linked), phenylketonuria (autosomal recessive) and tuberous sclerosis (autosomal dominant) which exists in two forms (Sampson 2000). However, taken together, such single genes affect only 1% or less of the population. By contrast, common disorders such as childhood depression, attention deficit hyperactivity disorder (ADHD) and conduct disorder show familial aggregation, but do not show simple Mendelian patterns of transmission and

almost certainly have complex inheritance in the sense of involving multiple genes as well as environmental effects. One apparent exception to the ‘rare equals simple, common equals complex’ rule is childhood autism, for which the narrowly defined form of the disorder has a population frequency of under 1 in 1000, but where the recurrence risk in relatives is far too low to invoke Mendelian mechanisms. More recently it has been found that a ‘lesser variant’ of autism is found more frequently than narrowly defined autism in the relatives of autistic probands (Bolton *et al.* 1994; Bailey *et al.* 1998) and so it may be that there is a spectrum of autistic behaviours in the general population that are far more common than was once thought (Rutter 2000a). Indeed, many psychiatric disorders that used to be considered categories may be based on dimensions that show no clear line of demarcation between disease and normality.

Models of inheritance for complex traits

At the most basic level, the problem in the inheritance of complex traits is how to reconcile irregular segregation ratios with Mendelian inheritance. The simplest way to deal with this is to invoke the notion of *penetrance*. This is defined as the probability of manifesting a trait given a certain genotype. For regular Mendelian traits, the penetrance is always either 0 or 1. For example, if we consider a trait at a locus where there are two alternative genes or alleles *a* and *A*, there are three possible genotypes:

$$aa, aA, AA.$$

Each of these is associated with a penetrance depending upon the mode of transmission. With a recessive trait where *a* is recessive with respect to *A*, the penetrances of these genotypes are 0, 0 and 1, respectively. With a dominant trait the penetrances are 0, 1 and 1, respectively. Departures from Mendelian segregation can be explained in terms of penetrances that take values between 0 and 1. Thus, suppose we are dealing with a dominant trait with incomplete penetrance, we might find that some of those who do not carry the allele *A* (those who have genotypes *aa*) manifest the trait. These are true sporadics (they show the trait but do not carry the genotype) and they have a penetrance, $0 < f_1 < 1$. Rather than everyone with genotypes *aA* and *AA* manifesting the trait, only proportions $0 < f_2 < 1$ and $0 < f_3 < 1$ can be identified as affected.

In general, genes tend to arrive at an equilibrium within the population as dictated by the Hardy–Weinberg law. This means that if *a* has a frequency of *p* and *A* has a frequency of *q* ($= 1 - p$), the population tends to a steady state where the total population frequency is:

$$p^2 + 2pq + q^2.$$

This means that we are dealing with a disease or complex trait with penetrances as described above of f_1 , f_2 and f_3 , the total population frequency of the trait (Kp) is given by:

$$Kp = f_1 p^2 + f_2 2pq + f_3 q^2.$$

This is sometimes called the *general* single major locus (SML) model. It has the obvious attractions of relative economy and simplicity, and a good deal of effort has been expended with adult psychiatric disorders, such as schizophrenia and bipolar affective disorder, in exploring models of this type. It turns out that neither schizophrenia (McGue *et al.* 1983) nor bipolar disorder (Craddock *et al.* 1996) can adequately have their inheritance explained by SML models. The general SML model remains of both theoretical and practical importance in the application of linkage analysis (see below) to complex traits, but the inheritance of most psychiatric disorders is more plausibly explained by models involving multiple genes.

As we have noted earlier, there are two types of phenotypic variation, quantitative and categorical. Traditionally, psychiatrists like other medical practitioners have attempted to classify disorders as present or absent. Thus, a child psychiatrist may categorize a child as being affected or unaffected by a particular disorder. However, with many common disorders, such as those categorized by symptoms of anxiety, depression or antisocial behaviour, symptoms of at least a mild degree are highly prevalent, and it may be difficult to define a clear-cut point at which the level or intensity of symptoms differentiate those who are 'affected' from those who are 'unaffected'. Current classification schemes, such as DSM-IV (American Psychiatric Association 1994) or ICD-10 (World Health Organization 1993) have sought to deal with the difficulty by producing explicit definitions in the form of operational criteria. These facilitate good interrater agreement, but may give an overoptimistic view of the ease with which we can distinguish between children who are 'ill' and those who (despite having some symptoms) are 'well'.

In fact, the value of taking both a dimensional and a categorical approach has well-been recognized in epidemiological research in child psychiatry (Rutter & Garmezy 1983). This is not peculiar to child psychiatry. The notion of an underlying continuum of *liability* to disorder has long been recognized by geneticists attempting to study other common complex diseases (Falconer 1965; Reich *et al.* 1972). Where a disorder is contributed to by several (or perhaps many) genetic loci, as well as environmental factors acting additively, it can be reasonably assumed that liability follows a normal distribution, where only those individuals whose liability at sometime exceeds a certain threshold can be classified as affected. Relatives of affected individuals will tend to have an increased mean liability compared with the general population and hence a high proportion of relatives will lie beyond the threshold.

The first application of a model of this type in psychiatry was for schizophrenia (Gottesman & Shields 1967). Here the model helped explain certain phenomena that were not explained by earlier attempts to apply SML models, e.g. why the risk in relatives increases with the severity of the disorder in the proband as well as increasing with the number of relatives already affected. This is because more severe cases or individuals from families containing several affected individuals will tend to be at more extreme positions on the continuum of liability. The threshold

model approach also allows the calculation of a useful index of how familial a disorder is. If we know the frequency of a disorder in the general population and the frequency in a particular category of relatives it is possible to estimate the *correlation in liability*. (The statistically minded reader may be aware that this is effectively the same thing as a tetrachoric correlation.)

The relationship between severity and liability can be extended further to include the idea of multiple thresholds (Reich *et al.* 1972). It is assumed that there are two or more clinical forms of the disease that are contributed to by the same genetic and environmental factors, hence they can be ordered on the same continuum of liability where one form of disorder is common and less severe (the broad form) while the other is less common and more severe (the narrow form). Patients with either type of illness will have higher rates of the disorder in their relatives than is found in the population generally, but a greater proportion of relatives affected will occur among those with patients with the narrow form of the disorder. This type of model has been put forward to explain the familial coaggregation of multiple tics (the broad form) and Tourette syndrome (Pauls *et al.* 1981). More recently this has been applied to some twin study data and offered as an explanation for why co-occurring conduct disorder and ADHD appears to be more familial than ADHD alone (Thapar *et al.*, 2001).

Classic methods of study

As we have already discussed, genetic traits are necessarily familial, but familiarity does not necessarily indicate genetic influences. Traits and disorders may cluster in families, because of shared genes, shared environment or a combination of the two. Estimating the extent to which each of these contribute may not be straightforward but, fortunately, two 'experiments of nature' come to our assistance.

Twin studies

Twins are of two main types: monozygotic (MZ) or identical twins who have all of their genes in common; and dizygotic (DZ), non-identical or fraternal twins who, on average across all loci, share half of their genes. Similarities in members of twin pairs also result from the environments that they share. If we accept the *equal environment assumption* (EEA) that MZ and DZ twins share their environment to roughly the same extent, then any greater similarity in MZ than DZ twins should reflect genetic effects. It is therefore of importance to consider whether EEA usually holds or whether it is, on the contrary, frequently violated. In practice, when researchers have asked adult twins or the parents of younger twins direct questions about environmental sharing during childhood, MZ twins tend to report more sharing than DZ twins, with respect to having the same friends, being in the same class at school or dressing alike (Thapar & McGuffin 1994) and this is so even when studies are restricted to same sex DZ twins (McGuffin *et al.* 1996). A simple test of

whether this is problematic for EEA is to explore whether these types of environmental sharing influence similarity in the trait that is under investigation. For example, Thapar & McGuffin (1994) found that their measures of shared environmental effects had no significant relationship to twin similarity with respect to depressive symptoms in childhood. On the other hand, other studies have shown significant effects within MZ pairs for environmental features such as stressful life events and family negativity (Rutter *et al.* 1999b, 2000b). This violation of the EEA is to be expected whenever there are important environmental effects on a disorder and when individual differences in experiencing such environments are genetically influenced. That applies to both disruptive behaviour and the more common forms of unipolar depression but is much less likely to apply to autism, schizophrenia and bipolar disorder.

Another method of testing whether greater environmental sharing of MZ than DZ twins in childhood invalidates inferences from twin studies is to consider the pattern of similarity in relation to the twins' or their parents' own assumptions about zygosity as compared with a more objective methods of assessing zygosity. In a classic study of this type (Scarr & Carter-Saltzman 1979), a surprisingly high proportion (around 40%) of 400 adolescent pairs were mistaken about their true zygosity. On tests of cognitive ability, DZ twins who thought that they were identical were no more alike than DZ pairs who were correct about their zygosity. Similarly, MZ pairs who incorrectly believed themselves to be non-identical showed only slightly greater differences than MZ pairs who were not mistaken about their zygosity.

As we will discuss in more detail later, one of the reasons that the equal environment assumption is likely to be an oversimplification is that genes can have an influence on the behaviours that individuals carry out in shaping and selecting their environments. Therefore, it may be that variations in experience are systematically related to the trait being studied (Rutter *et al.* 1999b). More complicated methods of analysis, using multivariate methods, can be devised to take this into account (Slutske *et al.* 1997).

A more radical method of trying to overcome the possibility that MZ twins experience greater environmental sharing than DZ twins is to concentrate upon twins who have been separated early in life and then reared apart. Unfortunately, monozygotic twins reared apart are rare, their degree of separation is often incomplete and the method of ascertainment, e.g. by advertisement in the media, may introduce its own biases. The scarcity of reared apart twins makes this design of limited use in studying disorders, but the results have proved to be interesting in studies of continuous traits within the normal range, such as IQ and personality. The approach has been used most recently by Bouchard (1998) to study cognitive ability and various aspects of personality.

We have noted that twins and their parents may be mistaken about zygosity. Fortunately for researchers, objective and reliable methods are available and the best approach is to use a combination of several highly polymorphic DNA markers. This can

now be carried out relatively cheaply and efficiently. Nevertheless, in very large-scale studies involving hundreds or thousands of twins the expense may be prohibitive and therefore many researchers use questionnaire measures that have been 'calibrated' against the results of DNA genotyping. Typically, questionnaires can give agreement in the region of 90–95% with genotyping results and, in practice, experienced twin researchers can assign zygosity on appearance with sometimes even better accuracy (McGuffin *et al.* 1991). However, the use of a more objective method remains desirable in overcoming other potential sources of bias which could occur if the same researcher was assigning both diagnosis and zygosity.

Finally, attention to method of ascertainment is important in twin studies. This is particularly so in studies of disorders that includes treated cases. Simply asking for twins to be referred from hospital or clinics tends to result in a bias in the direction of 'conspicuous' pairs who are both MZ and concordant. This can be avoided by ascertaining via a hospital register which lists consecutively all new patients who are twins or by matching national or regional twin registers against registers of treated cases. Increasingly in childhood traits and disorders twin studies are being carried out on samples that are epidemiologically based. For example, in some parts of the UK it is possible to identify all of the twins in a particular area via community paediatric registers, while in the USA some states note twin births on their birth registers.

For continuous traits, twin similarity is expressed as a correlation (preferably the intraclass correlation) but for present/absent traits, concordance rates are reported. It is sometimes a source of confusion that these can be reported in more than one way. The most common way of reporting concordance rates are as *pairwise* and *probandwise*. Probandwise concordance is the number of affected cotwins divided by the total number of cotwins, whereas pairwise concordance is simply the number of pairs, both having the same diagnosis divided by the total number of pairs. These two concordance rates often turn out to be different if the method of ascertainment has been truly systematic. This is because ascertainment from a register ensures that every proband is included in a study series independently. Consequently, some twin pairs may appear twice where both are affected and both appear on the register as a proband. The aim here is not to inflate the MZ concordance rates spuriously; in fact, it is quite the reverse as twin series ascertained in a non-systematic way have inevitable bias, for the reasons mentioned earlier.

Adoption studies

Adoption studies provide the other mainstay of psychiatric genetics in an attempt to disentangle genes and environment. Adoption studies have been highly influential in convincing sceptics that there is a genetic contribution to adult psychiatric disorders, particularly schizophrenia (Gottesman 1991). There are three main designs.

1 Adoptee studies. The adopted-away offspring of affected parents are studied and compared with control adoptees.

2 Adoptee's family study. The index cases are adopted individuals who have developed the disorder under study. The rates of illness are then compared in their biological and adoptive relatives or with the rates in the relatives of control adoptees.

3 Cross-fostering study. The rates of illness in adoptees who have affected biological parents and were raised by unaffected adopting parents are compared with the rates in the offspring of normal parents brought up by affected adopting parents.

Despite the obvious appeal of adoption studies designs, a major drawback is that adoption is in many senses an abnormal event. The rates of psychopathology tend to be somewhat higher in adoptees than in the general population (Maughan & Pickles 1990). There is a tendency for adoptees to be born to unmarried teenage mothers who, in turn, are less likely than average to receive good obstetric care (Maughan & Pickles 1990; DeFries *et al.* 1994). A further complication is that the placement of adoptees is not random. On the one hand, there is a tendency with some adoption agencies to seek a good 'match' for physical social or ethnic characteristics between an adoptee and prospective parents and, on the other, adopting parents tend to be better educated and have more social advantage than average, as well as having unusually low rates of anti-social behaviour (Rutter *et al.* 1999b). The restriction in range of environmental conditions does create a problem for estimating the strength of genetic influences (Stoolmiller 1999).

Estimation of heritability and beyond

The contributors to complex traits (phenotypes resulting from multiple, genetic and environment effects) can be reduced to a simple basic formula:

$$\text{Phenotype} = \text{additive genes} + \text{shared environment} + \text{non-shared environment.}$$

Here we use the term *additive* genes because the simplest kind of model is one where scores on some continuous measure (such as height or IQ) result from simple addition of the phenotypic values contributed by genes at different loci. When considering present/absent or threshold traits, the genetic contribution to liability would be considered in the same way. There are obviously two sources of resemblance between relatives, additive genes and *shared environment* and one source of difference, *non-shared environment*. However, it should be noted that the non-shared environmental effect includes everything that is left over once the additive genetic and shared environmental components have been accounted for, and it therefore includes measurement error and random effects. Non-shared environment is therefore also sometimes referred to as *residual* environment. The proportion of variation in a phenotype explained by additive genetic affects is called the *heritability*, usually denoted as h^2 , and the proportion of variance contributed by common environment is usually given the symbol c^2 .

Estimates of h^2 and c^2 can be obtained for particular traits if we have measures on pairs of MZ and DZ twins or on the biological and non-biological relatives of adoptees. This is now

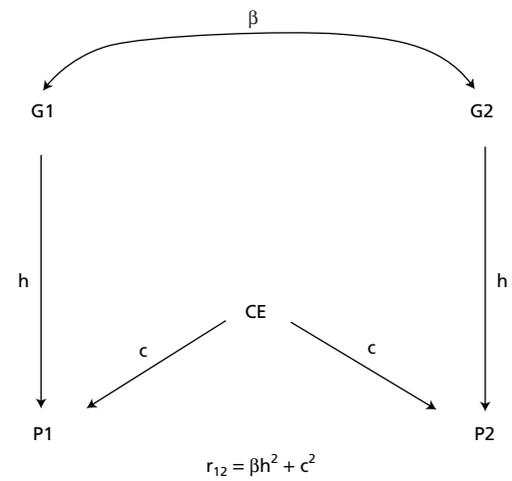

Fig. 12.1 A simple univariate path model: The expected value of the correlation, r_{12} between phenotypes P1 and P2 is the sum of the connecting paths via the common environment (CE) and the genotypes G1 and G2. The correlation β between genotypes is 1 for monozygotic twins and 0.5 for dizygotic twins.

most commonly performed using the structural equation modelling (Neale & Cardon 1992). Path analysis is used to derive the expected values for correlations (or covariances) between pairs of relative phenotypes for models such as the simple univariate one based on analysis of MZ and DZ data illustrated in Fig. 12.1.

A widespread application of genetic model fitting in childhood traits and disorder has been one of the major trends in recent research in the field. Although the details are complicated, the overall idea is straightforward. Essentially, the process involves a repetitive search for values of the model parameters that give the optimum fit. To carry this out the researcher provides the computer program with the relevant data and starting values for the parameters that are effectively his or her best guess what the 'correct' value should be. This information determines the initial value of a mathematical function supplied by the investigator, the form of which depends upon the model being tested. Typically, the mathematical function is either a χ -square or a log likelihood. The optimization routine on a computer program then calculates 'improved' estimates of the values that provide better fit (either an increase in the likelihood or a decrease in the χ -square). Iteration then ceases when either the maximum likelihood or the minimum χ -square is obtained yielding the 'best bet' estimates of the model parameters.

The standard approach is to start out with a full model containing, e.g. additive genetic (A), shared environment (C) and non-shared environmental (E) components and then attempt to fit a reduced model, such as an AE or a CE model, to see whether a more parsimonious explanation of the data can be achieved without worsening the fit. An illustration of model fitting on some data from child and adolescent twins examining social cognitive ability as measured by questionnaire is given in Table 12.1. Despite its obvious advantages, it should be noted that the model fitting approach will sometimes involve the dropping of

Table 12.1 Results of model fitting on social cognition examining differences across sexes in all twins. (Adapted from Scourfield *et al.* 1999.)

Model	Proportion of variance explained					$\chi^2_{(df)}$	P	AIC
	Male additive genetic variance	Male unique environmental variance	Female additive genetic variance	Female unique environmental variance	Female non-additive genetic variance			
I	0.7440 (0.67, 0.80)	0.256 (0.20, 0.33)	0.7264 (0.44, 0.79)	0.2736 (0.21, 0.35)	0.0000 (0.00, 0.33)	6.912 ₍₁₀₎	0.7	-13.088
II	0.7440 (0.67, 0.80)	0.256 (0.20, 0.33)	0.7264 (0.44, 0.79)	0.2736 (0.21, 0.35)	—	6.912 ₍₁₁₎	0.8	-15.088
III	0.7350 (0.68, 0.78)	0.2650 (0.22, 0.32)	0.7350 (0.68, 0.78)	0.2650 (0.22, 0.32)	—	7.089 ₍₁₃₎	0.9	-18.911

(df), degrees of freedom.

effects that fall short of statistical significance but which, in reality, are valid and important (Rutter *et al.* 1999b).

Uses and abuses of 'heritability'

We need to stress that heritability is no more than an estimate of the proportion of population variance explained by additive genetic affects, and therefore it has no meaning at an individual level. Moreover, an estimate of heritability is only applicable to the population from which the estimate is derived. Other populations may show greater overall variance or different proportions of the variance that can be explained by genetic and environmental effects. This means that heritability may differ for a trait, not just between different populations, but that it may also change over historical time. For example, if height is influenced by both genes and an environmental factor such as nutrition, heritability is necessarily less in the situation where there is large variability in access to adequate nutrition than where all growing children receive an adequate diet.

It must also be pointed out that finding that a disorder or trait is heritable does not mean that it cannot be altered by non-physical methods. Thus, there is no incompatibility between twin study evidence that depressive disorder is substantially influenced by genes and the clinical trial evidence that depression responds well to cognitive behavioural therapy.

Unfortunately, debates about heritability often centre upon the issue of what is the 'correct' estimate without taking these caveats into account. This has been particularly true of contentious areas, such as analyses of the proportion of variance in IQ that is explained by genes (McGue 1997). Such debates are inevitably of the 'more heat than light' variety. Although it is of interest that there is a substantial genetic contribution to a trait such as cognitive ability, or a disorder such as depression, it matters less whether the heritability in the samples studied was actually, say, 0.4 rather than 0.6.

Nevertheless, it may be of some value to differentiate between disorders with very high heritability (say, 70% or greater) as estimated from a range of different samples, and those with only moderate heritability (say, 30–60%). The first group includes

autism (Rutter 2000a), schizophrenia (McGuffin *et al.* 1994), bipolar affective disorder (Craddock & Jones 1999) and ADHD. Although these are multifactorial disorders subject to environmental as well as genetic influences, the high heritability (together with other biological findings; see, e.g. Hollis, Chapter 37) suggests that identification of susceptibility genes is likely to provide leads on causal neural mechanisms (see below). The second group includes the more common varieties of unipolar depression (Sullivan *et al.* 2000), oppositional/defiant and conduct disorders that do not include hyperactivity (Rutter *et al.* 1998), and probably anxiety disorders (see Klein & Pine, Chapter 30). These too are likely to involve some form of neural substrate but the lower heritability suggests that it is more likely to comprise indirect dimensional risk factors (such as temperament) and the operation of nature–nurture interplay. Of course, there is no sharp dividing line between these two groups, and the implications are probable rather than definite. It should be added that there are other child psychiatric disorders for which the heritability is much less certain, either because of inconsistencies in findings, concerns over ascertainment, the need to consider multiphase causal pathways, and/or doubts over the boundaries of the phenotype. Eating disorders, tics, drug dependency and obsessional disorders probably all fall in this uncertain category.

Changes over time

Not only may heritability change over historical time, but, for many traits, it varies over a lifetime. One of the first studies to indicate changes during early development was the Louisville twin project (Wilson 1978). A large variety of measures was carried out on twin and other siblings at frequent intervals from the ages of 3 months to 6 years. Before the age of 18 months, the overall MZ and DZ correlations on measures of cognitive ability showed only small differences, although MZ pairs showed a striking similarity in their profile of mental development over time. By contrast, DZ pairs became less similar during their preschool years so that by the age of 6 the intraclass MZ correlation had stabilized at 0.85 and the DZ correlation at 0.63. More

recent work on twins of different age groups (McGue *et al.* 1993) showed that MZ–DZ differences in twin correlations for measures of IQ increase a little further in late adolescence and early adult life, and even into old age (McClearn *et al.* 1997). This suggests that genetic influences on the trait increase as we grow older. This may seem surprising from a common sense viewpoint, because as we grow older we accumulate more experiences and tend to be exposed to an increasing variety of environments. The explanation, almost certainly, is that two of the ways in which genetic influences operate are through effects on susceptibility to environmental risks and on the likelihood of experiencing such risks (through gene–environment interaction and correlations, respectively; see below). Although in reality these involve genes and environment working together, they appear as a purely genetic effect in most traditional forms of analysis (Rutter *et al.* 1999b).

Some psychopathological phenomena also show changes in heritability during development. The familial aggregation of depressive disorder in adults has received considerable attention and there is reasonably consistent evidence that early onset of unipolar depression is associated with high degree of familiarity, a finding which is striking in some (Weissman *et al.* 1986), but not all, studies (McGuffin *et al.* 1987b). It might therefore be predicted that very early onset of depressive disorders or symptoms in childhood would be associated with even greater familial effects. As it turns out there have now been four twin studies showing that genetic influence on depression is stronger in adolescents than in younger children (Thapar & McGuffin 1994; Murray & Sines 1996; Eley & Stevenson 1999; Silberg *et al.* 1999). There has been some support from a family study (Harrington *et al.* 1997) which found that family loading did not vary substantially according to age of onset of depression in childhood and adolescents, but that early onset did seem to be associated with a history of antisocial problems in relatives in addition to depression alone.

Gene–environment correlation

Thus far we have considered genes and environment as coacting in an additive fashion but have indicated that this may not always be the case. In fact, it seems likely that there will be situations in which genes and environment are positively correlated (or show covariance). There are at least three different possible mechanisms by which this can arise (Plomin *et al.* 2000).

Passive gene environment correlation results from parents not just passing on genes to their children, but also rearing them and therefore helping create their early environment. Parents may pass on susceptibility genes for a disorder such as depression, but also influence the child's environment by their own behaviour. For example, studies of families where one parent is mentally ill found that parental psychopathology tends to be associated with increased family discord and conflict (Quinton & Rutter 1988). Interestingly, this may result in differences and outcome in the children as there is often a tendency for one child to bear the brunt of the family's upset (Rutter *et al.* 1997b),

which might actually result in negative gene environment correlations. There is comparatively little work published to date attempting to detect gene–environment correlation using model fitting approaches, but there is a suggestion that passive gene–environment correlation may occur with respect to the occurrence of depression and provision of adverse parenting (Kendler *et al.* 1997). This is potentially important because if gene–environment correlation is simply ignored in model fitting but does actually exist, the result is an overestimate of the genetic contribution to variation in liability.

Active gene–environment correlation describes situations where individuals of a particular genotype will tend to seek out a particular sort of environment. For example, it could be that individuals with a higher innate ability for intellectual and scholastic tasks will tend to find themselves in cognitively more stimulating environments than those who are innately less able. Over the course of a lifetime, this will tend to increase so that a gene–environment correlation is induced. This could explain, at least in part, the apparent increase in heritability of cognitive ability with increasing age.

Gene–environment correlation can be explored using adoption designs. Psychopathology in the biological parent is used as an index of the genetic risks and rearing environment of the adopting parents as indexing the environmental risks. In a study of antisocial behaviour in adopted-away children who were at high genetic risk, O'Connor *et al.* (1998) found that the children experienced increased negative parenting from their adoptive mothers which in turn derived from the children's own disruptive behaviour. This finding represents a third source of correlation between genes and environment sometimes called *evocative* because the individual genetically influenced phenotype plays a part in evoking (or perhaps in this case provoking) an environmental response.

Some of the difficulties posed by gene–environment correlations and some possible solutions to unravelling them have been explored in recent twin studies. Three different studies on children (Kendler & Karkowski-Shuman 1997; Thapar *et al.* 1998; Silberg *et al.* 1999) showed an overlap between the liability to depression and to report negative life events. These suggest that there may be ways in which some individuals behave that predispose them to encounter negative experiences. However, it is difficult to distinguish between the phenomena of actually encountering unpleasant events and merely showing a tendency to remember and report negative experiences. Furthermore, family data on adults, although they show a tendency for family loading for depression and for unpleasant events to cluster together (McGuffin *et al.* 1988), it may be partly or even totally explained by the same events impinging upon more than one family member.

Gene–gene interactions

The other category of non-additive effects is termed *interactions*. Gene–gene interactions occur at single loci where there is dominance. Again, we can consider a single locus with two

alleles a and A contributing to some phenotype that can be measured on a continuous scale. The effects would be additive if the value on the continuous measure of the heterozygote Aa were mid-way between that of the homozygotes aa and AA . Deviations from such additive effects are termed *dominance deviations*. The presence of dominance variance in traits resulting from multiple genes presents complications in estimating heritability. This is because the effect of dominance variation in contributing to similarities between relatives is less straightforward than it is for additive variance. For example, covariance between MZ twins, because they share all of their genes, is the sum of the additive and the dominance variance. On the other hand, for DZ twins or full siblings, the genetic covariance is the sum of half the additive variance plus one-quarter of the dominance variance. The reason for half of the additive variance contributing to the covariation is straightforward because, averaged across all loci, DZ twins or siblings share half of their genes. Why it is a quarter of dominance variance is less obvious and proof of this requires some algebra (Falconer & Mackay 1996) (but a quick explanation is that the probability of a pair of siblings sharing two alleles identical by descent at a given locus is one-quarter: 0.5×0.5). Dominance variation should be suspected if the MZ correlation for a trait is more than double that of the DZ correlation. Sibling correlations will also be higher than a parent offspring correlations in the presence of dominance (again a proper proof requires algebra, but a quick explanation is that a parent offspring pair can never have two alleles at a given locus identical by descent and therefore *dominance variation* does not contribute to parent offspring covariation).

If the aim is simply to estimate how much of a trait is contributed by any type of genetic effect, these subtleties are sometimes ignored and researchers content themselves with estimating *broad heritability*, also sometimes referred to as a degree of genetic determination (Falconer & Mackay 1996).

Gene–gene interactions *between* loci, *epistasis*, can also occur. This is when two or more loci have multiplicative effects. It has been suggested for example that in schizophrenia, the large difference in concordances between MZ twins (over 40%), DZ and other categories of first-degree relatives (10–15%) and a rapid fall-off in pairs of second-degree or more distant relatives (around 3–4%) suggest a small number of loci acting together in a multiplicative fashion (Risch 1990). A similar and indeed even more dramatic difference in relative concordance rates is found in childhood autism moving from MZ twins to siblings to more distant relatives; again statistical model fitting exercises suggest that epistasis may be present (Pickles *et al.* 1995). One of the great challenges for current molecular genetic studies attempting to locate and identify the genes involved in complex disorders is in detecting susceptibility loci where there are interactions rather than merely additive coactions.

Gene–environment interactions

Although the term *gene environment interaction* is sometimes used in a rather loose way to mean any form of genetic–

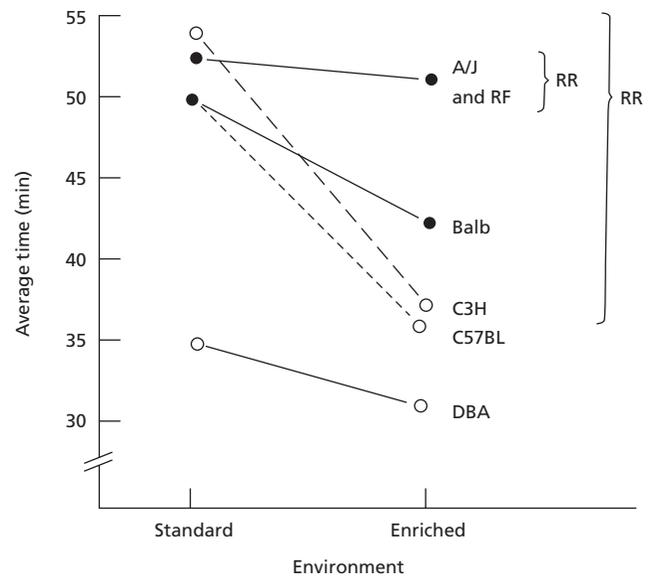

Fig. 12.2 Average time required to reach food for six inbred mouse strains reared in two different environments. RR = reaction range. Data from Henderson (1970).

environmental interplay, the strict meaning of the term interaction denotes non-additive effects (Rutter & Silberg, *in press*). The biological reality of gene–environment interaction has been amply demonstrated in laboratory animals, where it is possible to breed genetic homogenous strains and experimentally rear them in differing environments. The results from one such classic experiment (Henderson 1970) are summarized in Fig. 12.2. Mice reared in an enriched environment do better than those in a standard environment on a timed task involving food finding. However, some strains (A/J and RF in the figure) showed only modest improvement whereas other strains, such as C3H, show a marked improvement under a purely additive model. All would be expected to show a parallel improvement in the performance of their tasks, whereas in fact this is not the case and even the rank order of the phenotypes changes from one environment to the next. This experiment also demonstrates another aspect of a complex trait which is that genes do not determine or fix the phenotypes but rather prescribe a *reaction range* (Gottesman 1963) so that what is actually observed at a point in time is a dynamic interplay between the relevant genes and the relevant environmental stimuli.

Because such environmental manipulations are not possible in humans, gene–environment interactions have been more difficult to demonstrate, but natural experiments, such as adoption studies, provide evidence that they exist. For example, Cadoret *et al.* (1995) studied adoptees with and without a biological predisposition to antisocial behaviour (with and without a biological antisocial parent). They showed that adverse circumstances associated with rearing, plotted on a linear scale, had a direct relationship with adult antisocial behaviour only in those adoptees with a biological predisposition but had negligible effect on those without an antisocial biological parent.

Assortative mating

Another complication that needs to be considered is that one of the basic assumptions of a simple model is the existence of a 'random mating population'. In practice there is evidence that people select their mates in a non-random fashion so that there is a tendency for like to pair with like. This is referred to as assortative mating or homogamy. Positive correlations between spouses tend to be particularly high (at 0.3 or more) for IQ and for antisocial behaviour, but there is also a tendency for couple resemblance for some personality traits and disorders, such as affective disorder, schizophrenia and alcoholism, to be greater than would be expected by chance (Plomin *et al.* 2000). There are broadly two types of mechanism to account for this. The first is social homogamy where pairing off of couples tends to occur because of opportunity, as, for example, because both are in the same class at school or college, or work in the same place of employment. However, opportunity will also be influenced by styles of social life (Pawlbly *et al.* 1997a,b) and by their 'currency' in the marriage market (Engfer *et al.* 1994). Thus, the strong tendency for antisocial individuals to mate with others showing the same behaviour probably reflects both their peer group and who is willing to live with them. The second is phenotypic homogamy whereby men and women have a direct preference for mates who are similar to themselves. Taking IQ as an example, it is plausible that both types of mechanisms operate.

Over the course of time, assortative mating for a heritable trait has the tendency to increase the genetic contribution (Falconer & Mackay 1996). However, somewhat paradoxically, assortative mating causes an underestimate of heritability in twin studies. This is because it increases the genetic similarity of DZ but not of MZ pairs.

Locating and detecting genes

So far, we have discussed genetic effects in a quantitative and somewhat abstract way. However, human genetics has changed in a most dramatic fashion over the past 20 years with the introduction of molecular genetic approaches that enable specific genes involved in disease to be located and identified. Having identified genes, we can study their structure, sequence, and investigate the variations in the proteins that they encode for that are involved in the causation of pathology. This whole process, called *positional cloning* (Collins 1992), has had a revolutionary effect in improving understanding of the biological underpinnings of single gene disorders and, more recently, complex multigene disorders. The vital first step in bringing about this modern era of *positional cloning* was the introduction of improved marker maps of the human genome (the 23 pairs of chromosomes) based upon new methods for reliable genotyping of DNA polymorphisms.

Before the introduction of molecular genetic methods, attempts to map genes had to rely on what are now termed classical genetic markers. A genetic marker, by definition, is a

characteristic that has simple Mendelian transmission and two or more common alleles. Classical markers include ABO, Rh and other blood types, HLA antigens, various protein polymorphisms found in the blood and various red cell enzymes. By the early 1980s a few dozen such markers were known and only some had had their chromosome locations assigned, so that carrying out linkage studies aiming to detect and identify disease genes was definitely a pursuit for optimists only. Even with very good collaboration among several laboratories, it would be difficult to study more than about 30 markers in a single disease (McGuffin *et al.* 1983), whereas about 10 times that number of markers is required to carry out a systematic search throughout the genome using a linkage study design (see below).

The first type of marker to provide a solution was restriction fragment length polymorphisms (RFLPs) (Botstein *et al.* 1980). Markers of this type are detected by first digesting DNA using bacterial enzymes of a class called endonucleases. These are also known as restriction enzymes because each enzyme in this class has a site of cleavage of DNA molecules that is restricted to a certain sequence of DNA. If these sequences are changed by mutation (e.g. by the deletion or insertion of a single nucleotide where restriction site is lost) such changes bring about variations in the length of DNA fragments which result after DNA is digested using a particular restriction enzyme. Fragments of different size can then be separated by electrophoresis, probed with a radio-labelled short sequence of DNA (an oligonucleotide) that has a complementary based sequence to the target RFLP and then blotted on to filter paper before exposure on to X-ray film. This process, known as Southern blotting (Southern 1975), had a revolutionary effect and led to the first nearly complete marker map being published in 1987 (Donis-Keller *et al.* 1987).

Although RFLPs remain important mapping tools in certain circumstances, they have now largely been superseded for systematic mapping studies by a category of markers called microsatellites or short sequence repeat polymorphisms (SSRPs). SSRPs consist of repeated sequences of di-, tri- or tetra-nucleotides, with the most common being dinucleotide repeats of cytosine-adenosine (CA). Apart from the fact that these are abundant throughout the genome and therefore allow the possibility of very dense marker maps consisting of thousands of markers, CA repeats or other SSRPs can be genotyped using rapid semiautomated high throughput methods. These depend first on amplifying the DNA using the polymerase chain reaction (PCR). Here, oligonucleotides are constructed, called 'primers', that recognize opposite ends of each of the two strands of double stranded DNA. DNA is 'melted' into its two single strands by heating it in a machine called a thermocycler. The primers then attach to the single strands and, in the presence of a thermostable enzyme, *Taq* polymerase initiate the reaction where two new strands of complementary DNA are formed. Cooling then takes place and the strands of DNA reanneal, after which the whole reaction is repeated multiple times. During PCR two, then four, then eight (and so on) copies are produced. By incorporating a fluorescent label in the primers, the resultant amplified fragments of DNA can be detected and again, are separated

on a gel according to length, where length is dictated by the number of dinucleotide (or tri- or tetra-nucleotide) repeats. Microsatellite markers tend to be highly polymorphic with many alleles and are therefore particularly useful in mapping studies.

Currently, huge efforts are being invested in a 'third generation' of DNA markers, single nucleotide polymorphisms (SNPs) and a large-scale collaboration is taking place between industry and academic centres in an attempt to produce an extremely fine-scale map of the human genome based upon about 100 000 such markers. SNPs occur as a result of a single base change on average about every 1000 base pairs throughout the genome. They can be detected efficiently within known genes using methods such as denaturing high-performance liquid chromatography (DHPLC; O'Donovan *et al.* 1998) and a variety of other methods including direct sequencing. Methods are currently being developed and refined for very rapidly genotyping thousands of SNPs. These use oligonucleotides placed on to microarrays ('SNPs on chips') (Southern 1975; Asherson *et al.* 1998).

Linkage

The starting point for positional cloning is the discovery of where genes are within the genome, going on to take advantage of knowledge about their position to study the genes themselves and the ways in which their allelic variation may affect protein structure or expression. Positional information is gained by two types of related, but somewhat different approaches: linkage and association. Linkage is the phenomenon whereby pairs of loci in close proximity on the same chromosome fail to follow Mendel's law of independent assortment. For example, if we consider two bi-allelic loci with alleles *A*, *a* and *B*, *b*, a double heterozygote parent of the type *Aa Bb* whose partner is homozygous at both loci, *aa bb* will, in the case of independent assortment have offspring of the types *Aa Bb*, *aa Bb*, *Aa bb*, *aa bb*, occurring with equal probability. This is because, if the loci are on different chromosomes or are far apart on the same chromosome, during meiosis in the germ line cell of the double heterozygote parent, the alleles of the two loci will remain together half the time and for the other half will cross-over (or recombine). However, if the two loci are close together on the same chromosome, a different pattern is seen. This depends on the *linkage phase*, that is whether *A* is on the same chromosome as *B* rather than *b*. But let us suppose that *A* and *B* are on the same chromosome (*a* and *b* on the other member of the homologous or paired chromosome). Offspring of the type *Aa, Bb* and *bb, bb* (non-recombinants) will outnumber offspring of the types *aa, Bb* (recombinants).

The number of non-recombinant offspring divided by the total number of offspring is called the recombination fraction and has a maximum value of 0.5 because in independent assortment, the average numbers of recombinant and non-recombinant offspring are equal. Over small distances, the size of the recombination fraction is roughly proportional to the physical distance between the two loci. For example, recombi-

nation that occurs 1 time in 100, a unit of recombination which defines a linkage map distance of 1 centimorgan (cM) corresponds approximately to a physical distance of one million bases (1 Megabase).

It is therefore the aim in linkage studies to attempt both to detect recombination fractions of less than 0.5 and to estimate their size. In experimental plants and animals, this is relatively straightforward because mating can be performed experimentally. Unfortunately, humans pose greater problems and, inevitably, the statistical methods become more complicated. The standard approach for detecting linkage and estimating recombination for Mendelian traits in humans is lod score analysis (Morton 1955). Logarithm of the odds (lod) scores use odds ratios to compare the likelihood of linkage (a recombination fraction <0.5) with the likelihood of no linkage (a recombination fraction = 0.5). A curve can be plotted for values of the recombination fraction between 0 and 0.5 and its peak can be taken as the maximum likelihood (or best bet) estimator of the recombination fraction. By convention, a lod score of 3 or greater is considered as proof of linkage while odds of -2 or less is accepted as excluding linkage. A lod of 3 corresponds to odds in favour of linkage of 1000 : 1, but it can also be shown to be the equivalent of a χ -square of 13.8 with one degree of freedom giving a nominal one tailed *P*-value of 1×10^{-4} . This may sound excessively conservative but the original reasoning of Morton (1955) was that the prior probability of two loci being found in linkage was low and, when this is taken into account, a lod score of 3 corresponds to a reliability of 95% and hence is equivalent to the conventional cut-off level for statistical significance of 0.05.

The lod score method can be adapted to non-Mendelian traits by invoking the general SML model that we discussed earlier in the chapter. The main difficulty about doing this is that the parameters defining the model for a given trait need to be specified correctly. Where these are mis-specified, at best the recombination fraction will be estimated incorrectly and at worst linkage will fail to be detected when it is actually present (Clerget-Darpoux 1991). A common method of attempting to overcome this problem of false negatives in linkage analysis of complex traits is to try out several models, but this then introduces the problem of multiple testing and increases the risk of false positives. Nevertheless, providing that this problem is taken into account, maximizing a lod score over multiple models has been shown to be a useful approach (Abreu *et al.* 1999).

Despite the difficulties, applying lod score approaches to complex traits has resulted in considerable success in some complex disorders, e.g. Alzheimer disease (Sandbrink *et al.* 1996), but has been confusing with no definite loci identified so far in other disorders, such as schizophrenia (Riley & McGuffin 2000). The reason for this varied picture almost certainly depends upon whether the simplifying assumptions that need to be made about a complex trait are realistic. These assumptions are first that a major gene is involved in the transmission of at least some forms of the disorder and, secondly, that at least within families containing two or more affected individuals homogeneity can be assumed. That is, even if the disorder as a whole is genetically

heterogeneous, affected relatives can be assumed to be carrying the same major gene. Thirdly, there is the assumption that, even if the mode of transmission is not known precisely, it can be specified approximately. As it turns out, Alzheimer disease exists in some comparatively rare early onset forms where the pattern of transmission complies fairly closely to autosomal dominance. In other adult psychiatric disorders, such as schizophrenia and bipolar disorder, although a large number of families containing multiple affected individuals have now been studied and although some linkage findings replicate across more than one centre (including loci on chromosomes 6p, 8q, 13q and 22q), there are no apparent major gene effects. In other words, no locus so far implicated in schizophrenia appears to be necessary or sufficient to cause the disorder, so that it seems likely that major gene forms are rare or non-existent. Therefore, although highly heritable in the vast majority of cases, schizophrenia is oligogenic (resulting from the effects of several genes) or polygenic (resulting from many genes). It has been suggested that this will be the rule rather than the exception for the majority of complex traits and disorders (Plomin *et al.* 1994). There has therefore recently been a tendency in complex diseases to focus on nuclear families containing affected sibling pairs rather than on extended multiplex pedigrees.

There are several attractions of the affected sibling pair approach. Nuclear families containing just one pair of affected individuals are likely to be more common than extended multiplex families and therefore arguably more representative, as well as easier to collect. In addition, using affected sibling pairs requires no assumptions about the mode of transmission of the disorder. This is because for any given marker locus, the expectation of sharing zero, one or two alleles is one-quarter, one-half and one-quarter, respectively. Significant departure from expectation in the direction of increased allele sharing in affected sibling pairs indicates that the marker is linked with a susceptibility gene contributing to the disease.

Systematic genome searches using closely spaced microsatellite markers have been useful in identifying loci conferring susceptibility to physical diseases, such as insulin-dependent diabetes (Cordell & Todd 1995), and have now been employed by several groups in childhood autism (see review by Lamb *et al.* 2000; also Lord & Bailey, Chapter 38) with fairly consistent evidence of linkage with a susceptibility locus on chromosome 7 and suggestive evidence elsewhere, particularly on chromosomes 13 and 15. One of the recurrent problems in such studies has been how to decide if a replication really does confirm a previous positive finding if the locus is not in precisely the same spot on the chromosome. In that connection, it is important to appreciate that there is substantial chance variation in the location estimate (Roberts *et al.* 1999), but also that the length of a peak may help in deciding whether it is a true or false finding (Terwilliger *et al.* 1997).

Sibling pair linkage approaches can also be applied to quantitative traits (Haseman & Elston 1972). Here the idea is that the degree of similarity between siblings for phenotypic scores depends upon the degree of allele sharing at a quantitative

trait locus (QTL). This approach has been elaborated (Fulker & Cardon 1994) and used to locate a gene contributing to a reading disability on the short arm of chromosome 6 (Cardon *et al.* 1994). This has subsequently been supported by other studies (Grigorenko *et al.* 1997; Fisher *et al.* 1999; Gayan *et al.* 1999).

Alternative approaches for mapping QTLs include variance components analysis in pedigrees, taking into account other types of relative pairs in addition to siblings (Amos 1994). However, such methods depend on the QTLs having relatively large effects, that is being able to explain at least 10% of the total variance. For QTLs where the effect size is smaller than this, the sample needed to detect linkage may be enormous, running into several thousand sibling pairs (Fulker & Cardon 1994). Similarly, for dichotomous phenotypes, such as the presence or absence of a disease, affected sibling pair approaches are only really efficient at detecting moderately large effects (a locus contributing a relative risk of 3 or more). Sample size requirements become very large for loci contributing a relative risk of 2 or less (Risch & Merikangas 1996).

Allelic association

Because of the problems of detecting small effects using affected sibling pairs or QTL linkage approaches, there has been increasing interest in using allelic association to detect genes involved in complex traits. The standard approach to allelic association simply compares allele frequencies in a sample of cases affected by a disorder and a sample of ethnically matched controls. This case-control design can be easily extended to quantitative traits by selecting 'cases' as having an extreme score on a quantitative measure, comparing them with controls who have either average score or, preferably in terms of maximizing power, low scores. The attraction of case-control studies, in addition to the simplicity of design, is that they have long been known to be capable of detecting genes of small effect contributing as little as 1% variance (Edwards 1965; McGuffin & Buckland 1991). Allelic association arises for three main reasons (Edwards 1991).

- 1** The marker locus itself may have some causative role in the disease or trait. This is sometimes referred to as pleiotropy (a gene having two or more apparently different effects).
- 2** The marker itself may not have a direct role, yet be very closely linked to a gene that does, so that the association is undisturbed over many generations of recombination. This is known as linkage disequilibrium. Except in special circumstances, such as recently founded populations, linkage disequilibrium will only occur between loci that are very close together, the distance apart being around 1 cm or less.
- 3** Population stratification arises when there has been a recent admixture of populations that have different distributions of a particular trait, as well as different frequencies of polymorphisms. Let us suppose, for example, that there is a wave of immigration of a particular ethnic group who on average are markedly taller than the indigenous population. It is likely

with a highly polymorphic marker, such as a DNA microsatellite, that the populations also show differences in marker allelic frequency. Therefore, an association study, which simply compares allelic frequencies in samples drawn from the tallest vs. the shortest sections of the population without taking ethnic origin into account, might find an association. Such an association would be unlikely to have anything to do with the biological basis of stature and will be more likely to reflect the frequency of alleles in tall people in the immigrant population.

In an attempt to overcome spurious associations arising because of population stratification, family-based association studies using ‘internal controls’ have been developed. One such approach is to apply the transmission disequilibrium test (TDT; Spielman *et al.* 1993) which uses trios of affected individuals and both of their parents. At least one of the parents has to be heterozygous at the marker locus for the test to be applied. The TDT has been elaborated in various ways to include multi allelic markers (Sham 1998) and continuous traits (Page & Amos 1999). However, it has been pointed out that provided proper matching of cases and controls is carried out, the classic case–control design is both more efficient (Morton & Collins 1998) and more powerful (Page & Amos 1999) than the TDT or similar tests.

Because allelic associations of the biologically informative kind only arise when the polymorphism is actually in a susceptibility locus or QTL, or very close to it, allelic association studies have an additional disadvantage compared with linkage studies. This is that thousands rather than hundreds of markers would be required to perform a whole genome scan attempting to find disease susceptibility loci or the QTLs underpinning a continuous trait. To date, no whole genome scan has been undertaken using allelic association/disequilibrium approaches but, as we have discussed earlier, non-gel-based methods of performing very high-throughput genotyping using microarrays are now being developed to facilitate such studies.

In the meantime, an alternative approach has been put forward based on DNA pooling (Daniels *et al.* 1998). This uses microsatellite markers and instead of initially genotyping all subjects individually, the DNA from cases is pooled and the DNA from controls is also pooled and the results compared. It relies on the assumption that all cases can be combined on the basis of homogeneity (which may be a problem in some circumstances; Rutter 2000a). Any differences from the two groups that emerge at this initial screen stage can then be checked using individual genotyping. So far, the approach has been used in searching whole chromosomes for genes that may be involved in cognitive ability (Fisher *et al.* 1999; Hill *et al.* 1999). Such rapid screening methods would also be useful in following up positive findings on regions of interest identified by linkage studies. Indeed, it is becoming increasingly obvious that linkage and association are complementary strategies that need to be employed in studying complex diseases and traits rather than ‘either or’ alternatives.

The reason for this is that association studies are ‘short-sighted’, presenting difficulties in searching large stretches of

Table 12.2 Comparing some of the main features of linkage and association studies.

Linkage	Association
Cosegregation of markers and disorder in families	Comparison of allele frequencies in case and control populations or in families using ‘internal controls’
Capable of detecting only comparatively large gene effects (e.g. odds ratio of >2 or variance explained of >10%)	Capable of detecting small effects (e.g. odds ratios of <2 or variance explained of as little as 1%)
Detection possible over fairly large distance (e.g. 10–15 cm)	Detection possible only over small distances (<1 cm)

genome but, on the other hand are more capable than linkage of detecting small effects and of locating the genes precisely (Morton & Collins 1998) while linkage is ‘far-sighted’ but can only detect large effects. For example, Morris *et al.* (2000) followed up the findings which originally came from linkage analysis in multigenerational families of a gene contributing to reading disability located on chromosome 15 (Smith *et al.* 1983; Grigorenko *et al.* 1997). Closely spaced microsatellite markers were studied in a two-stage family-based linkage disequilibrium mapping design, identifying a small region containing a number of potential candidate genes.

Some of the more important features of linkage and association are compared and contrasted in Table 12.2.

Candidate genes

The most direct approach to detecting allelic association is to focus on polymorphisms in or very close to genes that encode for proteins that are thought to be involved in the biochemical bases of the trait. So far, in psychiatry, as with most common diseases, potential candidate genes have been identified by indirect roots, e.g. by knowledge of the mode of action of a drug which has shown to be beneficial in treating the disorder. However, it is likely in the future that with the sequencing of the entire human genome, now close to completion, and the subsequent inevitable identification of all genes, that candidates will be identified by a combination of positional methods and computer searching of databases. For example, the region on chromosome 15 implicated by the linkage disequilibrium mapping study of Morris *et al.* (2000) of reading disability contains 20 known genes in the publicly accessible databases of which three are known to be involved in the regulation of neurotransmission and one is a member of the same gene family as a dyslexia candidate gene in the region identified by other groups on chromosomes 6p.

Some interesting results in child psychiatry have recently been produced using a pharmacologically driven search for candidates. It is known that methylphenidate is beneficial in controlling symptoms of ADHD and this works at least in part by

arguing dopaminergic transmission. Therefore, candidate gene association studies in ADHD have mainly concentrated on candidates that encode for proteins involved in dopamine pathways. There is now fairly consistent evidence of an association with a common variant in the dopamine *DRD4* receptor gene and somewhat less consistent, but nevertheless suggestive, evidence of an association with a polymorphism in the dopamine transporter (*DAT1*) gene (Thapar *et al.* 1999).

Impact of genetics on child psychiatry

Research developments

In the early days of psychiatric genetics, it was important to use twin and adoptee studies to quantify the strength of genetic influences on the underlying liability to each type of psychiatric disorder. That was because, at the time, there was a considerable scepticism about the suggestion that genetic factors might play *any* significant part. That day has passed and it is now abundantly clear that genetic factors play a part in most, or perhaps all, forms of psychopathology, and a good deal is known on those for which genetic influences are strongest. There was also a time when there was an equal degree of scepticism over the suggestion that genetic factors could play a part in influencing individual differences in behaviours giving rise to environmental risk exposure. Again, it is now clear that genetic factors play a part in relation to individual differences in all human behaviour, and not just liability to disorder. Thus, genetic factors influence the likelihood that someone will experience divorce, stressful life events or maladaptive parenting (Plomin 1994; Jockin *et al.* 1996). The findings have important implications for the research designs that must be used to test for environmentally mediated risks (Rutter *et al.*, 2001b). The case has now been made and should be accepted. Although it is true that there are still traits for which there are few data on heritability, there is limited value in carrying out further studies to obtain that information alone. More interesting and potentially important topics are:

- 1 nature–nurture interplay;
 - 2 continuities between normality and disorder;
 - 3 phenotypic definition;
 - 4 comorbidity; and
 - 5 continuities/discontinuities over the course of development.
- Gene–environment interactions in both directions may be important. For example, genetic factors may moderate sensitivity to environmental stressors—as suggested by findings with respect to both life events with relation to depression (Silberg *et al.*, 2001) and adverse parenting in relation to antisocial behaviour (Crowe 1974; Cadoret *et al.* 1995). Alternatively, if genetic and environmental factors operate through independent routes, it may be that genetic influences are least when environmental conditions are worst, as suggested by a finding from one study (still to be replicated) regarding the effects of socioeducational disadvantage on intelligence (Rowe *et al.* 1999). As dis-

cussed earlier, dimensional traits may provide good indicators of the liability to a disorder, but sometimes the role of genetic factors at the extreme end of a distribution may differ from those affecting variation within the normal range. This appeared to be the case in one study of language levels at age 2 years (Dale *et al.* 1998), although again the finding has still to be replicated.

One of the important findings with respect to many serious psychiatric disorders has been that the genetic liability extends well beyond the traditional diagnostic category involving major handicap. For example, this has been evident with both autism (see Lord & Bailey, Chapter 38) and Tourette syndrome (see Leckman & Cohen, Chapter 36). Quantitative genetic studies can be very helpful in defining the boundaries of these extended phenotypes. Comorbidity, the co-occurrence of supposedly separate psychiatric disorders (Caron & Rutter 1991; Rutter 1997; Angold *et al.* 1999), is widespread in psychiatry. Cross-twin, cross-trait analyses of twin data, especially when combined with longitudinal data, can be very helpful in sorting out the possible meaning of such patterns. For example, findings both with adults (Kendler 1996) and children (Thapar & McGuffin 1997) suggest that, to a considerable extent, the liability to both anxiety and depressive symptoms or disorders may derive from the same genes. It also seems that the overlap between ADHD and conduct disturbance to a considerable extent reflects shared genetic liability (Nadder *et al.* 2001). One of the oddities with respect to several areas of psychopathology is that, as mentioned earlier in this chapter, even disorders showing high continuities over time (such as depression or antisocial behaviour) may show marked age-related changes in heritability (and see also Harrington, Chapter 29; Earls & Mezzacappa, Chapter 26). Quantitative genetic analyses of longitudinal data can be very helpful in sorting out how this happens. They can also be informative with respect to the different phases in the development of drug dependence. For example, the influences on first taking drugs, moving on to using them regularly and heavily, and then becoming dependent, may not be identical (Vanyukov & Tarter, 2000).

Molecular genetics research is still at an early stage in psychiatric disorders but this is also true for much of the rest of internal medicine, in that it is proving difficult to identify susceptibility genes for multifactorial disorders. That is partly because it is generally the case that each susceptibility gene has only a tiny effect (although the accumulation of effects of several genes can be quite great), because genetic effects may be most evident in environmental high-risk groups if genetic effects operate through susceptibility to environmental stressors, and because gene–gene interactions may be important. The problems are immense but they are ultimately tractable. The solutions lie in several different developments.

- 1 Technological advances, such as the availability of SNPs and the use of DNA pooling.
- 2 Better use of clinical, quantitative genetic, and biological data to define phenotypes.
- 3 Pooling of data from several different studies using the same standardized methods will enable much larger samples to

be investigated. However, in doing this it will be important to appreciate that often there will be differences among populations in the specific allelic variations, or even the genes, that predispose to disorder, and that there may also be ethnic variations in the strength of effect of susceptibility genes (Rutter, 2001).

4 Rather than survey the total population, greater leverage on the identification of susceptibility genes may be afforded by a focus on high-risk groups. This will be particularly important when the genetic influences operate through effects on environmental susceptibility.

5 An iterative interaction among genetic research, psychosocial research and biological research will be helpful. Too often, each of these has operated in isolation. Each should provide leads for what needs to be done in one of the others and, as genetics is informative on both environmental risk factors and biological risk mechanisms, it will be equally important for molecular genetics research to take on the lessons that come from research in these other two fields.

Mode of operation of genetic risk factors

Non-geneticists sometimes assume that identification of important genetic influences on mental disorder automatically equates with genetic determinism. Nothing could be further from the truth. One of the important findings from genetic research is the multiplicity of ways in which genetic factors may operate (Rutter, 2001). For example, even with wholly genetic Mendelian disorders (which are likely to account for a trivial proportion of child psychiatric disorders) the effects may be on neural functioning that almost inevitably results in a particular psychiatric disorder (Huntington disease would be an example of this kind); alternatively, when the genes operate through susceptibility to some aspect of the environment, whether or not functional impairment results may be entirely dependent on the environmental factor (phenylketonuria is the obvious example here); or the neural effects may be direct and wholly genetic but yet clinical outcome immensely varied for reasons that are as yet ill-understood (tuberous sclerosis is an example of this kind).

With multifactorial disorders, the modes of operation of genetic influence are even more varied. Genetic risk factor could operate through the creation of a relatively direct risk for the disorder even though the effects are probabilistic and require additional environmental risk factors. It is not known if this is the case with any psychiatric disorder but it could turn out to be so for schizophrenia or autism. A second possibility is that the genes may have relatively direct effects (through their influence on proteins) on part functions that, when combined with other functions, serve to make up the disorder. That could turn out to be the case with elements of dyslexia (see Snowling, Chapter 40). Thirdly, genes may influence temperamental (or other) dimensions that, in themselves, do not constitute the disorder, but which serve indirectly to increase the risk of disorder when combined with other risk factors. That is thought to be the case with respect to the role of neuroticism and the increased risk of affective and anxiety disorders (Kendler 1996) and it could be the

case with respect to sensation-seeking or novelty-seeking and the risk for ADHD (see Schachar & Tannock, Chapter 25). The implication here, however, is that personality feature involves no direct risk for disorder even though, in some circumstances, it may predispose to it. Thus, novelty-seeking could foster behaviours as varied as creative science, risky sports such as rock climbing, or antisocial behaviour.

A fourth alternative is that the genes may act through their role in increasing (or decreasing) environmental risk exposure — this coming about through passive, active or evocative gene–environment correlations (Rutter *et al.* 1997a). The genes, of course, do not cause the environmental risks directly; rather, they do so through their effects on behaviour. People's behaviour does much to shape and select environments that they experience.

Fifthly, genes may exert their effects through influences on susceptibility to environmental risks; that is gene–environment interactions. Molecular genetic studies in internal medicine have begun to document specific genetic risks in relation to features as varied as infections, allergies, immune responses, head injury and cigarette smoking (see Rutter 2000b). The findings from quantitative genetics in the field of psychopathology indicate that it is highly likely that the same will be found there.

It is clear that evidence of high heritability, or even of specific susceptibility genes, of itself provides no information on the nature of risk processes. Genetic findings provide a hugely helpful lead but they constitute the beginning, and not the end, of research into causal mechanisms. An important future goal is sorting out how nature–nurture interplay predisposes to, or protects from, psychopathology.

Another important misconception is that genes can be subdivided into those that are inherently 'bad' and those that are inherently 'good'. To begin with, the same genetically influenced behavioural trait may have both risk and protective functions. For example, an anxious emotionally hyper-responsive temperament constitutes a risk for anxiety disorders but a protection against antisocial behaviour. Many genes have effects on several different functions and these may involve both adaptive and maladaptive consequences. Sometimes the concept of 'good' and 'bad' genes is extrapolated to the potential to identify genetically high-risk and low-risk individuals, with the assumption that genetic profiling of fetuses should enable parents to choose which pregnancies to proceed with. The possibility raises important ethical issues (Rutter 1999) but it would not in any case be practical. Diseases derive from the action of multiple genes and the strong likelihood is that everyone carries important susceptibility genes for some undesirable outcome. It would be necessary to balance an increased risk for one disorder against a reduced risk for another one. In any case, whether or not a particular genetic susceptibility would actually lead to disease would depend in part on environmental risks. The risks are both probabilistic and contingent on circumstances. It should be added that the genetic risks are also not universal across individuals and across populations. Thus, the strength of the risk for Alzheimer disease associated with *APOE-4* varies across ethnic

groups (Farrer *et al.* 1997). It is also the case that some simple single gene disorders, such as phenylketonuria, result from several different mutations in the same gene whereas others, such as spino-cerebellar ataxia, result from mutations in several distinct genes. The practical consequence is that, even in these relatively straightforward examples, it is easier to be sure that a person has a susceptibility gene than that he or she has not.

Potential for clinical practice from gene identification

Understanding the neurobiology of mental disorder

At least with respect to highly heritable neurodevelopmental disorders such as autism, schizophrenia and ADHD, the greatest benefit that is likely to come from molecular genetic research is the leads that will be provided for biological studies that could delineate the causal neural processes that constitute the biological underpinning of the conditions (Rutter & Plomin 1997; Rutter 2000a, 2001). Up to now, the findings from biological research have been frustratingly inconclusive on the specifics and have not been much help in delineation of diagnosis-specific pathophysiology or even non-specific brain processes that truly mediate psychopathological risk, albeit risk that spans several diagnoses (see Hollis, Chapter 37; Lord & Bailey, Chapter 38; Schachar & Tannock, Chapter 25). The identification of susceptibility genes will not, on its own, provide an answer but the determination of what the genes ‘do’ is likely to do much to provide the leads that are greatly needed to redirect biological studies. It has to be appreciated that determination of gene effects is far from straightforward and the research enterprise is likely to take quite a long time and will certainly involve areas of science that go beyond molecular genetics. Experimental gene ‘knockout’ and ‘insertion’ studies in species such as the mouse (genetically remarkably similar to humans) is going to be an essential first step (Wicker *et al.* 1995; Sibia & Wagner 1996; Flint 1999). The need is to have a model that reflects the genetic alterations and which gives rise to a behavioural picture that recreates essential components of the human condition. That has not proved at all easy to do in the field of internal medicine and it will be even more difficult with mental disorders. This needs to be followed by research into the structure and interplay among proteins, proteomics (Pandey & Mann 2000). That requires entry into the burgeoning field of protein chemistry and so-called functional genomics. However, even that will not be the end because there is a need then to determine how these effects on proteins lead on to the clinical picture. That is likely to involve study of the interplay between genes and the environment, bringing in the field of molecular genetic epidemiology. This will need to lead on to a model, or series of possible models, of what might be the basic pathophysiology and the process by which it leads to the disorder (Rutter 2000a).

Although it is necessary to appreciate the long haul ahead, it is equally important to appreciate that molecular genetic findings may well constitute the key that will open the door to biological studies that will at last provide an understanding of the biological

processes underlying mental disorder, and of the ways in which they relate to environmental risk factors. That understanding is certainly going to have implications for both prevention and intervention and it is a safe prediction that it will alter clinical practice, even though it is not possible to predict quite what changes will occur.

Pharmacogenetics

The same research process should also be helpful in providing leads for the development of more effective pharmacological interventions. Some effective drug treatments are already available in child psychiatry (see Heyman & Santosh, Chapter 59; and other chapters on specific disorders) but there are conditions, such as autism, where one might expect to find benefits from drug treatment but where, so far, these have proved quite minor (see Lord & Bailey, Chapter 38). Even when effective drugs are available, it is evident, as it is throughout psychiatry and internal medicine more generally, that there is marked individual variability in people’s response to drugs. We know a good deal about which groups of drugs tend to benefit which groups of patients but we know much less about what differentiates those within those groups who do and do not respond. Molecular genetic findings could help greatly in that connection—the growing field of pharmacogenetics (Evans & Relling 1999).

Nature–nurture interplay

Throughout this chapter we have emphasized the fact that child psychiatric disorders are multifactorial in origin. This means not only the involvement of both genetic and environmental risk factors, but also that the causal processes often derive from an interplay between the two, stemming from gene–environment coactions, correlations and interactions. Although the importance of this interplay has been evident from quantitative genetic studies, as well as implied from epidemiological findings (Rutter & Silberg, *in press*), the study of such interplay has been constrained by both limitations on identifying factors where the risks are truly environmentally mediated and that genetic risks could not be assessed at the individual level. The former difficulty has been diminished by the development of research strategies that can test environmental risk hypotheses (Rutter *et al.*, 2001b) and the findings have been successful in identifying environmentally mediated risk processes, albeit at a more general level than one would wish (Rutter, 2000b).

The identification of individual susceptibility genes will allow the identification of genetic risks in the individual and that should greatly facilitate both the identification of environmental risks, and the interplay between the two (Plomin & Rutter 1998). The major practical problem that lies ahead is that there will usually be many susceptibility genes and partialling out specific genetic effects will depend on identification of all, or at least most, of the relevant genes and not just a few of them. That constitutes quite a challenge and will not be achieved easily.

Nevertheless, ultimately there is no doubt that much of the potential of molecular genetics will lie in its value for studying nature–nurture interplay. It should also help in determining whether the causal neural processes that underlie environmentally mediated risks are the same as those that underlie genetic risks. For example, in so far as institutional rearing predisposes to inattention/overactivity (Rutter *et al.*, in press) or quasi-autistic patterns (Rutter *et al.* 1999a), does it do so by affecting the same neural processes as ‘ordinary ADHD’ and ‘ordinary autism’ or is the pathophysiology quite different?

In considering environmental influences it will be essential to go beyond psychosocial factors to include physical risks, such as those deriving from maternal alcohol consumption, obstetric–perinatal complications, and minor developmental aberrations (Rutter 2000a,b).

Psychiatric diagnosis

Because psychiatric diagnosis has lacked an external validating criterion, such as some physiological test, it has proved very difficult to establish what the true boundaries, criteria and demarcations should be. The identification of susceptibility genes will be of some use in that connection (Farmer & Owen 1996; Rutter & Plomin 1997). Thus, for example, it will enable determination of which social and communicative abnormalities are part of the same genetic liability as autism and which are caused by something quite different. The same applies to schizotypy and schizophrenia (see Hollis, Chapter 37) and obsessive-compulsive phenomena and Tourette syndrome (see Leckman & Cohen, Chapter 36). Those constitute major advantages but this approach to diagnosis works best when there is a major gene that *directly* causes the disease and that applies to only a tiny proportion of psychiatric disorders. Moreover, it is necessary to appreciate that most medical diagnoses are *not* based on a primary cause; rather, they are based on a unifying pathophysiology (see Taylor & Rutter, Chapter 1). The consequence is that the real progress in psychiatric diagnosis will come from the understanding of the underlying neurobiological processes, rather than from identification of the susceptibility genes as such (Owen *et al.* 2000).

Genetic screening

Some people have expressed high expectations of what could be achievable in the future through genetic screening. The ‘Star Wars’ scenario is that once we have identified all the relevant susceptibility genes (that is certainly going to take a long while) each person could be given their genetic profile that would specify whether or not they will develop one or another of a range of disorders. However, it will not actually work like that, because disease liability is not influenced by just one gene but rather by several genes. In theory, genetic research could provide that information but whether or not it will do so remains uncertain. More crucially, however, even when the full picture of genetic liability is available, the prediction of disease outcome

will still depend on whether or not the individual encounters particular environmental hazards. The ways in which multifactorial disorders function will not lend them easily to a deterministic approach. On the other hand, through provision of an understanding on the mechanisms underlying nature–nurture interplay, genetic research should provide invaluable leads on which environmental manipulations could *lower* the risk of a disease outcome which does constitute a really important potential.

Genetic counselling

Much the same considerations apply to genetic counselling (Scourfield *et al.* 1999; see also Simonoff, Chapter 66). Molecular genetic findings will be helpful because predictions of genetic liability can be made on an individual basis, and not just on the basis of population averages. Unfortunately, the situation with respect to multifactorial disorders is much complicated by the fact that the risks are probabilistic and not deterministic, and are contingent on future life circumstances. Genetic advances will help the field of genetic counselling but the range of skills involved in this important speciality is going to be rather broader than is the case today. Genetic counsellors will have to have a good understanding of clinical diagnosis and of environmental risk processes.

Ethical issues

We need to end this chapter with a recognition that there will be crucial ethical issues arising as a result of genetic advances in the future. Although these are many and various, they should be manageable if properly dealt with (Farmer & McGuffin 1998; Rutter 1999). Nevertheless, history tells us that scientific findings have often been misused in ways that misrepresent the science and ignore ethical issues. Society as a whole will need to ensure that this does not happen and researchers have a special responsibility in that connection. Several concerns need highlighting.

First, concern has been expressed that an excessive focus on the priorities of molecular genetic research could result in a seriously damaging neglect of research into environmental risk mechanisms. As we have pointed out, although that is a risk that requires attention, genetic findings are clear-cut in pointing to the need for research into both environmental and genetic risk factors, and most especially on their interplay. A related concern is that genetic research will encourage a misleading genetic determinism that will impair policy initiatives and practical innovations to deal with serious environmental hazards (Rose 1995). Again, that is a risk but, once more, it arises out of a *misunderstanding* of the messages of genetic research. This is sometimes linked with a concern that genetic advances will lead to a ‘medicalization’ of social problems, with a consequent excessive use of drug treatments, to the neglect of interventions focusing on psychosocial risk factors. In that connection, one of the key messages of genetic research is that genetic factors are *not*

just concerned with disease. They concern the whole of human behaviour and carry no implications one way or the other with respect to medicalization. On the other hand, although nothing to do with genetics, it has to be said that the risk of excessive use of drug treatments given by community practitioners who lack expertise in their use is real, because such treatments can be viewed as cheap, undemanding and saving of time (Zito *et al.* 2000). Another often expressed concern is that genetic findings may increase psychiatric stigma. Although anything could happen, we see that as a curious expectation because the existing stigma arises in considerable part because of an attitude that mental disorders arise because people are acting irresponsibly, not coping when they should, and not trying hard enough, and it seems to us likely, at least if biological findings are responsibly handled, that evidence of contributory biological propensities could well reduce stigma, rather than increase it (Farmer & McGuffin 1998).

A rather greater concern is that genetic information could be used to disadvantage individuals with respect to health or life assurance, or employment (Royal Society 1997). It has to be said that that is a definite risk and it is appropriate, and necessary, that governments throughout the industrialized world are considering what legislation is needed to avoid the misuse of genetic data in this way. However, the probabilistic contingent nature of genetic risks in relation to multifactorial disorders means that the main problem comes from a misuse and misunderstanding of genetics, rather than from genetic findings as such.

Conclusions

The section of this chapter that has sought to look into the future is substantially longer than that in most other chapters. That is because the field of genetics is one of the fastest moving fields of research and because many of these advances are so recent that practitioners will have undergone their main training at a time when much of this was not even on the horizon. As a consequence, there is the twin danger of people underestimating how useful genetic findings are going to be and also overestimating the attendant risks. We have tried to convey something of the excitement and high potential of genetics while at the same time being realistic about how much remains to be done (see Rutter, in press). Of all the chapters in this volume, this is the one most likely to require major revision by the time the next edition appears.

Molecular Genetic and Chromosomal Anomalies: Cognitive and Behavioural Consequences

David H. Skuse and Jonna Kuntsi

Introduction

Behavioural phenotypes are the psychological equivalent of the somatic or physiological manifestations of a syndrome that has a genetic aetiology. There is no consensus about how they should be defined. Flint (1996) suggested they constitute 'behaviour(s), including cognitive processes and social interaction style, that [are] consistently associated with, and specific to, a syndrome which has a chromosomal or a genetic aetiology'. He added 'where there is little doubt that the phenotype is a consequence of the underlying anomaly', but others feel that additional definition is too restrictive (Hodapp 1997; Finegan 1998). Dykens & Cassidy (1995) suggested behavioural phenotypes should be characterized as 'the heightened probability [that] people with a given syndrome will exhibit certain behavioural sequelae relative to those without the syndrome' (see also Volkmar & Dykens, Chapter 41). Hodapp (1997) emphasized the point that genetic disorders should not be considered to have uniform effects, either on behaviour or on somatic aspects of the phenotype. There is great variability in the expression of even the most 'characteristic' features of a syndrome. The remaining genotype of the affected individual will modify the behavioural expression of the anomaly, as will developmental trends, and the impact of the environment in which the child is raised. Thus, it is unusual for a genetic disorder to be associated with a pattern of behaviour that is specific to that condition, especially in the context of mental retardation. However, it is not unusual for two or more genetic disorders to lead to outcomes that are not shared by others with equivalent learning difficulties (Hodapp 1997).

Opinions are divided between those who regard the study of behavioural phenotypes as being generally worthwhile, and those who have their doubts. A few moments reflection indicates that there are many problems with the concept. First, is the term to be restricted only to disorders in which a genetic anomaly has been identified? Many conditions appear to have a genetic origin, as well as characteristic behavioural features, but the nature of the genetic deficit is not known. Should the clinical manifestations of such conditions be classified as behavioural phenotypes? Secondly, is it likely that any specific cognitive or behavioural features will be consistently found associated with a genetic anomaly, unless they are part of the syndrome's definition? The genetic background of the individual will inevitably modify phenotypic expression; if there is no specificity in the

narrow sense, the behavioural phenotype may be so vague as to be virtually meaningless. Thirdly, because behaviour is modified by experience, any phenotype is likely to vary in intensity for that reason alone, independent of genotype. How then should we differentiate between the direct effects of the genetic anomaly and the indirect influence of the circumstances of upbringing? Finally, how is it possible in studies of humans, as opposed to model systems (Skuse 2000a), to clarify the mechanisms that link genetic anomalies to behaviour, and to show they are causally related to cognitive or behavioural manifestations?

The term 'behavioural phenotype' is used here for a typical style of behaviour that occurs in association with conditions in which a genetic anomaly has been demonstrated in a substantial proportion of cases. To include features of a disorder in which a genetic anomaly is only suspected, but where it has not been demonstrated, is liable to cause confusion. The danger is a widening of the concept to include the cognitive and behavioural features of all conditions that are highly heritable (such as autism or attention deficit hyperactivity disorder; ADHD) irrespective of whether any aetiological chromosomal or genetic anomaly is known. The term will therefore be restricted to conditions in which a genetic deletion/mutation or at least a chromosomal anomaly has been identified. Of course, conditions that have not met this criterion to date could meet it in the future, if a genetic cause for the syndrome is identified. A case in point is Rett syndrome, for which no genetic aetiology was known until the discovery that a mutation in the gene *MECP2* can lead to the onset of the condition in a minority of cases (Amir *et al.* 1999). Behavioural phenotypes may occur as a consequence of sporadic events, such as a mutation, or of a chromosomal rearrangement that has not been inherited, as well as those that are heritable.

Why study behavioural phenotypes?

The concept of behavioural phenotypes has clinical value. For many parents it is perplexing to be faced with a child who has a genetic disorder with easily identifiable somatic manifestations, such as short stature and facial dysmorphology, who also displays disturbed behaviour that is inexplicably starkly different from that of their siblings. To be able to reassure parents that features such as the hyperphagia of Prader-Willi syndrome

(Cassidy 1992) or the self-injury associated with Lesch–Nyhan syndrome (Nyhan 1997), are characteristic of the disorder may be helpful in alleviating unwarranted guilt. Parents need to be reassured that behavioural manifestations of the condition are not their fault, nor are they a result of wilfulness on the part of the child; yet often they are manageable.

Another reason for interest in behavioural phenotypes is the hope that by understanding how they arise from a genetic anomaly, they can facilitate location of genes that influence specific behavioural patterns. Much genetic research to date has been ‘top-down’ in its approach to quantitative genetic analysis of complex traits (see McGuffin & Rutter, Chapter 12). We commonly use linkage or association strategies to track down naturally occurring alleles of candidate genes in a ‘wild-type’ population. Alleles are stable alternative forms of the same gene that differ in their identified DNA sequence at a particular location. Different forms of the same gene (so-called polymorphisms) may have functionally different effects upon the phenotype. On the other hand, if those alleles are naturally occurring variations and thus widely distributed in the population at large they are likely to have only a minor influence upon the phenotype of the individual. This is so, simply because alleles with a more dramatic effect could reduce fitness and so would be selected against during evolution.

There is the prospect of genes that influence the development of brain systems that regulate the cognitive skills and behaviour. Importantly, such genes are unlikely to account for individual differences in the normal distribution of traits such as intelligence, personality or talents. The genes that are disrupted or lost in conditions that have a behavioural or cognitive phenotype may, however, be important in predisposing toward specific learning difficulties or psychiatric illness, in a (probably very small) proportion of individuals with those disorders. Identifying such genes may be rather easier than locating susceptibility loci from linkage or association studies. Identification of a behavioural phenotype implies that disruption to a particular gene, or a set of genes at a particular locus, consistently leads to specific cognitive or behavioural consequences. Having shown this, it is a fair assumption that the genetic locus in question regulates the development of a cognitive or behavioural system. The next stage of an investigation would be to show that targeted disruption of the locus in an animal model may also lead to cognitive or behavioural deficits. If so, the role of that locus in brain development and function becomes open to direct study (Skuse 2000a).

The investigation of behavioural phenotypes provides an indirect route to understanding the development of neuro-behavioural systems that are dysfunctional in a range of neuro-developmental disorders and specific learning difficulties, both in childhood and adulthood. There is an important related point: occasionally, a particular genetic mutation, or deletion, is associated with a behavioural phenotype that looks like a known disease, such as autism or schizophrenia. The finding should not be taken to imply the genetic locus has any direct part to play in the predisposition of individuals from the general

population to develop that disorder. Major psychiatric disorders are likely to have a multigenic aetiology. Predispositions are not caused by mutations in single genes. If they were, the individuals carrying those mutations would probably have such reduced fertility that they would be eliminated in the course of evolution.

Rather, the discovery that a behavioural phenotype resembles a known disorder provides a key with which it may be possible to unlock the secrets of the development of a particular cognitive or behavioural brain system which, if disrupted, may lead to a conventionally identifiable disorder. (Of course, we should not assume all instances of the disorder are necessarily going to be associated with dysfunction of that system.) Cases of the disorder that are identified from the general population are likely to have a multigenic or polygenic aetiology. Particular configurations of functional gene variants will usually be required to cause its full manifestations. These will act epistatically (synergistically) to increase the risk of a disease phenotype becoming manifest. Environmental risk factors may also play a part in tipping the balance toward disease. However, we may gain valuable information about how the systems that maintain—for example, normal social cognition—have evolved by studying the impact of a known genetic mutation on brain development and function.

Genetic mechanisms leading to behavioural phenotypes

We normally have 46 chromosomes in every cell of our body, with the exception of germ cells in the testis and ovary. Each chromosome has both a long and a short arm (in some cases the short arm is much abbreviated). These arms are joined by a region known as the centromere, which is essential for normal cell division to take place and which does not contain expressed genetic material. At the end of each is a cap of repetitive DNA sequences known as the telomere. Autosomes are numbered from 1 to 22, approximately in descending order of their size. There are two sex chromosomes. The X chromosome is moderately large, and possesses about 1000 genes. It lies between autosomes 7 and 8 in magnitude. The Y chromosome consists of relatively little genetic material, and has only 30–40 expressed genes (D.C. Page, personal communication). Our genotype comprises the set of 30 000–40 000 protein-coding genes that are expressed at some time or another from our genome. Not all are switched on all the time, and different tissues will express different combinations of genes. How the regulation of switching on and off during development is achieved is still a matter of speculation. Each gene is defined by characteristic sequences of DNA. In general, at any one genetic locus there will be a pair of genes, one of which was inherited from our mother and the other from our father. Most, but not all genes, are concerned with the production of proteins; others have regulatory functions. The outward manifestation of our genetic constitution comprises our phenotype.

Our chromosomal constitution can be visualized under a microscope, after appropriate preparation. Chromosomes can be seen in dividing cells, and blood cells are the usual source for cytogenetic investigations after they have been induced to divide by chemical treatment. T lymphocytes are stained and otherwise manipulated to make their nuclear material visible. The complement of chromosomes visualized in this way is known as our karyotype. Banding patterns, effectively dark and light stripes of differing widths, can be recognized by cytogeneticists and provide useful information about gross structure.

Mutations and polymorphisms

A germ-line mutation that occurs in the DNA of cells that produce gametes (sperm or eggs) is inherited by the cells of subsequent generations. Any change in a DNA sequence is a mutation. Most such changes are neutral, with no effect on the phenotype. This is because most of the human genome consists of material that is not transcribed by the machinery that reads the genetic code. Not all genes that are transcribed are subsequently translated into a protein product, and even within the coding regions a base change may only lead to the substitution of one synonymous codon for another. There is redundancy within the system and many synonyms in the genetic code, so the protein product may ultimately not be affected at all by nucleotide substitutions. These neutral mutations will, nevertheless, lead to DNA polymorphisms, which are alternative forms of DNA sequence within a population. Such polymorphisms (which may or may not affect the function of the gene, such as the speed of its translation) are important for tracking down genes in families or populations, but they are individually unlikely to have other than a subtle effect on the phenotype.

Mutations have sometimes been thought to imply alterations in gene product that are detectable by some phenotype change. Inevitably, the evidence for such change will depend on the sensitivity of the measures used to detect it. It should not be taken to imply disease as such. In complex disorders, the phenotype will be influenced by the interaction of a range of polymorphisms (each of which may be regarded as a 'mutation') on different chromosomes. Each of these may be insufficient to produce a disease phenotype in its own right, but generally they act in combination (either additively or synergistically) to increase susceptibility to disease. In other words, the genotype at any given locus may affect the probability of disease but yet not fully determine the outcome. Environmental factors also have a crucial part to play.

Mendelian inheritance

The term Mendelian inheritance is used to describe conditions directly caused by inherited single mutant genes. Homozygotes have two copies of the mutant allele, but heterozygotes only one. Recessive conditions are seen only in the homozygote. If the mutation in just one allele is associated with a phenotype, the condition is said to be dominant. In most syndromes that

result from simple Mendelian mechanisms, phenotypic manifestations are variable. Genes often have multiple different (pleiotropic) effects. For example, children with untreated phenylketonuria have distinctive skin and hair colour as well as mental retardation (Simonoff *et al.* 1996), but this is a single-gene disorder. The 'classic' presentation of genetic syndromes may be rather more variable in the general population than is ascertained by the study of cases from a specialist referral centre. Diagnostic criteria for syndromes that are inherited in a simple Mendelian fashion are usually uncontentious. It is a straightforward matter to establish which clinical features are caused directly by the genetic disorder (such as mental retardation) and which are indirect (such as temper tantrums precipitated by frustration).

Chromosomal anomalies

Some behavioural phenotypes are not associated with abnormalities in a particular gene, but with numerical or structural abnormalities in a chromosome. These relatively gross genetic anomalies affect the expression of several or even many genes. Numerical abnormalities are associated with either the loss of one of a pair of chromosomes completely, or with the aberrant formation of more than one copy of a chromosome (as in trisomy 21, or 47,XXY). Structural anomalies are more subtle, and usually involve microdeletions of a few thousand nucleotide bases or, more rarely, the loss of a substantial part of a chromosome (such as the short arm of an X chromosome). Structural anomalies may sometimes be associated with the doubling or tripling of segments of a chromosome; lengthening it. They can also result from the aberrant translocation of a part of one chromosome onto another.

Such anomalies may occur during the formation of the sperm or egg; they may occur during formation of the zygote, when the egg and sperm fuse; or they can occur after cell division begins in early embryonic development. In the first situation, the abnormality is going to be represented in every somatic cell. If the structural problem occurred later, in just a proportion of developing cells, the individual will be a mosaic for the abnormality, with some cells showing it, and colleagues not. The distribution of the affected cells will be clonal (rather than random), reflecting the original population of normal or abnormal cells from which they were derived. If the affected cells are not capable of functioning to a certain minimal degree of efficiency, they could be selected against as the tissue develops over time, and would not then be represented. Somatic mosaicism for genetic anomalies may explain, to some degree, the phenotypic variability associated with a chromosomal anomaly such as Turner syndrome. For example, in about 5% of individuals with that phenotype there is both an abnormal set of cells with just 45 chromosomes (they lack a second X chromosome), and also an entirely normal set with a 46,XX constitution just like other females (Jacobs *et al.* 1997). The degree of phenotypic severity varies with the proportion of normal cells to abnormal cells.

Structural chromosomal anomalies

Structural abnormalities include deletions of part of the long or short arms, which may be terminal or within the arm (interstitial). Gene dosage is usually a delicate affair, and if it is interfered with in a major way (e.g. by monosomy or triploidy) a phenotype results.

Spontaneous breaks in chromosomal material can occur during the formation of the germ cells, or during recombination which occurs normally only during meiosis. The germ cells contain just 23 chromosomes, and if any of these are broken they can be repaired. However, sometimes if two breaks have occurred the joins may mismatch, resulting in a ‘translocation’ of material from one chromosome to another. If such breaks have damaged genetic material, phenotypes may result even though there is no net loss of genetic material. If there is a net gain or loss of genetic material, chromosomal structural abnormalities are known as ‘unbalanced’. Other forms of break include loss of material from within the q or p arm (interstitial), or from the end of the arm (terminal). Material may be turned around within the arm (paracentric inversion), or between arms (pericentric). Rarely, there is a normal complement of chromosomes but one pair derives from maternal or paternal origin. Obviously, cells that contained all three copies will have been lost. Rather more frequently, a small area of one chromosome within the long or the short arm derives from maternal or paternal origins on both copies. This may not cause any problems provided the region does not contain an imprinted locus, containing a gene that is expressed systematically from either a maternal or a paternal allele.

Numerical chromosomal anomalies

Numerical chromosomal abnormalities include too few and too many chromosomes. Complete duplication or erasure of a chromosome is only possible with the sex chromosomes, and chromosome 21. So, for instance, there are duplications of the sex chromosomes (e.g. XXX, XYY, XXY), and there is monosomy (45,X, but never 45,Y).

Imprinted genes

A few genes are systematically different in their activity, depending on whether they have been inherited from the mother or from the father—genomic imprinting (Tilghman 1999). There is consequently monoallelic expression; that is to say, the gene is expressed from only one of the pair of alleles, but it is important to note this may only be detected in certain tissues, or at certain periods of development. There is no alteration in the underlying DNA sequence. The existence of imprinted genes in a region may be revealed when the only active copy is mutated or lost because of a structural abnormality of the chromosome containing it. Alternatively, that chromosome, or region of a chromosome, may show uniparental disomy, both copies of the gene in question (and part of the surrounding genome) having been inherited

from just one parent. In general, the clinical phenotypes that result from abnormalities involving imprinted loci tend to be severe.

It is important to bear in mind that the phenotypic manifestations of our genotype will depend in part on epigenetic phenomena, such as genomic imprinting, and in part on the interaction over time of our genotype with the environment. Epigenetic mechanisms are factors that can be transmitted to progeny cells following cell division, but which are not directly attributable to the DNA sequence of the genome (Strachan & Read 1999). They tend to be influences that alter the expression of genes, and by definition do not alter the underlying nucleotide sequence itself. Imprinting is a good example of an epigenetic mechanism (Petronis *et al.* 2000).

Trinucleotide expansion repeats and anticipation

Dominant conditions sometimes result in phenotypes that become more severe in successive generations—the phenomenon of anticipation (McInnis 1996). This is exemplified by the fragile X syndrome (Turner *et al.* 1997) and by Huntington disease (Huntington’s Disease Collaborative Research Group 1993). Trinucleotide repeat expansions have been proposed as its biological basis (Margolis *et al.* 1999). Trinucleotide repeats are triplets of nucleotides, usually cytosine, guanine and arginine. These are designated CGG, CAG, and so on. The repeats may occur within genes, or they may be found in regions of DNA that lie between genes. If they lie actually within genes they may be in transcribed sequences (exons), or within DNA sequences that are excised by the RNA-making machinery (introns). Expansions occur in the course of DNA replication (Margolis *et al.* 1999) and the repeats grow in length as they are passed from one generation to the next.

For reasons that we do not understand, there are proportionately more neurological than other diseases caused by expansion of CTG, CGG, CAG or GAA repeats (Weatherall 1999). The conditions caused by the expansion are associated with considerable phenotypic heterogeneity because of variability in the length of the repeat sequences, and in the degree to which they disrupt transcription and function of the genes with which they are associated. Conditions associated with this phenomenon include fragile X syndrome (CGG repeats), Huntington chorea and other conditions associated with CAG repeat expansions such as dentatorubral pallidolusian atrophy, and myotonic dystrophy (CTG repeats).

Genetically complex disorders

Many psychiatric problems in childhood or adulthood, and specific learning difficulties such as dyslexia, are likely to be genetically complex (see McGuffin & Rutter, Chapter 12). While a substantial heritability can be demonstrated by twin studies (Rutter *et al.* 1999) their genetic predisposition reflects the contribution of many different genes. One of the greatest challenges facing psychiatric genetics is to understand how

such multigenic diseases result in behavioural or cognitive phenotypes.

Complex disorders, especially in psychiatry, have a number of characteristics in common. First, people with the phenotype may not have inherited any susceptibility alleles but manifest the disorder because of non-genetic causes (*phenocopies*). Secondly, the probability that someone who is carrying a susceptibility allele or alleles will actually develop the disorder will vary according to influences such as age, sex, environment and other genes. For example, boys are substantially more susceptible to autism or Tourette syndrome, but the former usually has its onset before 2 years of age, whereas the latter usually first manifests in middle childhood. We do not know why this is so. Schizophrenia, on the other hand, has its onset in later adolescence or adulthood. In all three diseases it is indisputable that some form of genetic susceptibility is inherited, but the relative roles of genes and environment in influencing phenotypic expression are unclear.

The greatest progress in understanding how a complex genetic predisposition results in a disease has been with type 1 diabetes. It serves as a paradigm for psychiatric geneticists, although it is a disease that is characterized by an unambiguous phenotype that is easily recognized. Unfortunately, the same cannot be said for most psychiatric disorders. A decade ago, Todd first showed that the development of this autoimmune condition was largely caused by an interaction between the environment and alleles at many different loci (Todd 1991; Mein *et al.* 1998). More recently Todd (1999) has demonstrated that susceptibility to the disorder is almost incredibly widespread in the general population, with up to 30% of us possessing susceptibility alleles. It is unlikely that predisposition to psychiatric disorders will be any less prevalent.

Genetic or locus heterogeneity

Many conventionally specified disorders that are highly heritable (ADHD is an example) could theoretically be caused by mutations in any one of a variety of genes, all of which result in apparently identical phenotypes. *Genetic heterogeneity* could come about because a range of specific genes is required for a common biochemical pathway or cellular structure. When trying to identify cases of psychiatric disorder to study genetically we would like them all to have the same genetic predisposition! Unfortunately, in practice, we have no way of knowing this, both because of genetic heterogeneity and also *allelic heterogeneity*. In the latter condition, different mutations (or polymorphisms) at the *same* locus produce the same, or a very similar, phenotype. Such allelic heterogeneity occurs archetypically in the inherited disorders of haemoglobin. Weatherall (1999) commented that the study of the genetic predisposition to autoimmune disease such as insulin-dependent diabetes type 1 is helping us understand complex mechanisms. However, when it comes to psychiatric disease ‘we are dealing with a level of complexity that is infinitely greater than that which underlies the phenotypic diversity of the monogenic diseases. So, it may be a

very long time before we are in a position to use this information in clinical practice.’

Quantitative trait loci

Most commentators do not use the term ‘behavioural phenotype’ to indicate the consequences of variation in so-called quantitative trait loci (QTL). These are non-Mendelian characteristics, which reflect variation at a number of loci, and such variation may be very common in the general population. QTL can be thought of as influencing the quantity of a phenotype, and are likely to be important in the determination of complex traits such as intelligence. The haplotype at a locus may be influential in determining a QTL, rather than the variation of one or other allele. A haplotype is a set of alleles that are on the same small segment of the chromosome, and which tend to be transmitted down the generations as a block because they are so very close together. Very little is known about how QTL actually contribute to variation in psychological abilities or disabilities, although there has been some interesting work tracking down loci that apparently contribute to genetic susceptibility to dyslexia (Grigorenko *et al.* 1997; Fisher *et al.* 1999; Gayan *et al.* 1999).

Epistasis

Most contemporary data analysis and statistical modelling strategies for genome scanning investigations assess the significance of only the main effects of potential trait loci, meaning the average effect of a gene above those of all other genes with which it may or may not interact. Consequently, the influence of key genes on neurodevelopment may be missed, because their effect could only be detected within a framework that accommodates epistasis (Frankel & Schork 1996). *Epistasis* is relevant to gene mapping efforts for complex traits and is said to occur when the combined effect of two or more genes on a phenotype could not have been predicted as the sum of their separate effects. To date, there has been relatively little discussion of epistasis in the child psychiatric genetic literature, although its potential importance was pointed out by Rutter (Rutter 1994a). It seems likely that all the common child psychiatric disorders with reasonably high heritability, such as ADHD and autistic spectrum disorder, are caused by the additive or interactive effects of alleles at a small number of genes rather than to a single mutation at a major gene locus.

Using behavioural phenotypes to identify genes that influence cognition and behaviour

Biologically meaningful phenotypic markers

Genetic modelling might be facilitated if a discriminating biological trait was closely correlated with the liability to develop

the disease. For example, schizophrenia researchers have become interested in defects in smooth pursuit eye movements, which may be found in the first-degree relatives of those with the disorder (Lencer *et al.* 1999). There may be a genetic link between eye-tracking problems or inhibition of the P50 auditory evoked response to repeated auditory stimuli and liability to develop schizophrenia (Adler *et al.* 1999). Although this notion has been explored in connection with adult psychiatry, it has not been used in child psychiatric genetic research to date. What we are seeing here, it seems, are the phenotypic effects of one aspect of the polygenic predisposition to a major mental illness. Whether there is any such specificity between susceptibility alleles and phenotypic features that fall short of the full phenotype in other highly heritable disorders, such as autism, is still open to question. One might anticipate that there would be (Skuse 2000b) but the evidence is against it at present (Pickles *et al.* 2000).

In both linkage and association studies (see McGuffin & Rutter, Chapter 12), the aim is to find a measure of dysfunction that is closely and causally linked to the genetic anomaly. Realistically, no cognitive or behavioural feature is likely to be unique to a single genetic disorder, nor is that feature likely to be found in all instances of the disorder. By what means, then, is the choice of marker made? The difficulty in using gross behavioural measures (e.g. hyperactivity, self-injury, impulsiveness, clumsiness) or personality characteristics (e.g. aloofness or a tendency to express anxiety) is that these features are found in association with many genetic disorders and have low specificity. Broad cognitive measures, such as IQ, are little better. Ideally, one wishes to find phenotypic markers that are unlikely to have been substantially modified by experience, and which are aetiologically linked to the genetic anomaly. The choice of a phenotype to designate someone who is presumably at high risk of possessing the genotype of interest requires the identification of phenotypic features that reliably discriminate those with the genotype from those without it. It is very difficult, even in family studies of individuals at known genetic risk—let alone in an association study of a population sample—to make this discrimination on the grounds of cognitive or behavioural characteristics.

Turner syndrome, with the classic 45,X karyotype, is associated with a gross genetic anomaly and, in most non-mosaic cases, with a striking phenotype. Affected individuals are known to have cognitive deficits including a relatively specific problem with visuospatial skills. Ross *et al.* (1997) used discriminant function analysis to find what set of neurocognitive tests could distinguish reliably between a sample of females with the condition and a comparison group who were matched for age, height, IQ and socioeconomic status. The best discrimination identified just 45% of the 45,X females as belonging to the case group, although only 3% of comparison females were so identified. Such heterogeneity in cases of genetic anomalies with cognitive or behavioural phenotypes is likely to be the rule rather than the exception. Few investigations of the sensitivity and specificity of the behavioural and neurocognitive profile of such disorders have been published. Why is the result of this study so

important? Because if we want to link the behavioural or cognitive features to a genetic anomaly we must know who in our patient sample possesses the genetic anomaly and who does not.

Contrast this picture with the study of a family reported by Vargha Khadem *et al.* (1998), known as the KE family. This family had previously generated considerable excitement when Gopnik (1990) claimed that they had a fundamental language disorder involving a mutation in a single gene that affected a component of Universal Grammar (in the Chomskyian sense) which was inherited in a simple autosomal dominant fashion, with full penetrance. The locus of the gene that is mutated in this family (*SPCH1*) has since been mapped to an interval in 7q31 (Fisher *et al.* 1999) and then identified and cloned. This precise mapping was possible because, fortunately for the investigators, members of the family with the mutation could be distinguished reliably from those who did not. It is rather unusual for a behavioural phenotype to characterize carriers of the mutation so precisely. Yet, failure to take account of variability in the genetically modified population can make interpretation of data for deletion mapping very difficult indeed.

Limitations of the behavioural phenotype approach

It is often very difficult to discover how the genotype of an individual with a naturally occurring genetic anomaly contributes to the behavioural manifestations of that condition. Conceptual flaws in study design and interpretation are widespread. The key point is related to Bayesian statistical theory. In other words, given the phenotype, what is the probability that this individual has the genotype of interest? Bayesian statistics is used in genetic counselling, where the risk of carrier status can be calculated given certain parameters and assumptions about the mode of inheritance of the condition of interest. It is quite a different matter, to take a condition that is not inherited in any simple Mendelian fashion, and to infer from some aspects of the phenotype that a particular genotype is present. We may be able to do this fairly successfully with the physical features of Down syndrome, for example, but we certainly could not infer trisomy 21 from the cognitive profile of Down syndrome alone. This is not only because there is variability within the Down syndrome population but, more importantly, because only a very small proportion of individuals with that degree of mental retardation will have trisomy 21.

Take Williams syndrome as an example. A few years ago Frangiskakis *et al.* (1996) claimed to have discovered that deletion of the *LIMK1* gene, in the Williams syndrome critical region of chromosome 7, led to visuospatial deficits in affected children. The implication was that *LIMK1* was involved in the development of areas of the brain that were important for visuospatial abilities. A series of children with Williams syndrome in whom the gene was deleted had such deficits, and colleagues with a partial phenotype and no visuospatial deficits did not have the gene deleted on the affected chromosome 7. The variability of the visuospatial phenotype within Williams syndrome was not known, and so the extent to which it correlated in gen-

eral with the size of the microdeletion was not known. Furthermore, visuospatial deficits are found in a substantial minority of the general population, for reasons that probably have nothing to do with *LIMK1*. Accordingly, in some children the deficits could have been a chance finding, and the lack of deficit could have also been a chance finding for an equivalent reason. In other words, a drop in visuospatial IQ of 20 points in a child who was, in the absence of Williams syndrome, destined to have a verbal IQ of 100 and a non-verbal IQ of 120, would result in apparent absence of deficit. Failure to take account of these variables is probably why successes such as those claimed by Frangiskakis *et al.* (1996) have subsequently been countered by other data (Tassabehji *et al.* 1999).

Variation in behavioural phenotypic manifestations may be either relatively direct, resulting from the genetic anomaly itself, or indirect, arising for instance from the impact of the genetic anomaly upon the affected child's social immaturity. A condition that results in very small stature may be associated with a tendency for both adults and peers to treat the exceptionally short child according to the age they appear, rather than their chronological age (Gilmour & Skuse 1996), possibly evoking such immaturity in behaviour functioning.

Once an alleged behavioural phenotype has been described, subsequent studies have often failed to confirm the stereotypes proposed by the clinical observer who first described the behavioural, or cognitive dysmorphology of a condition with a known or suspected genetic aetiology. Take, for instance, Prader–Willi syndrome, which is characteristically associated with hyperphagia (Cassidy 1984). It is possible nowadays to make the diagnosis on the basis of molecular tests, rather than relying on the presence of the full clinical phenotype (Mann & Bartolomei 1999). Although many clinicians believe that hyperphagia is an invariable feature of the condition, that is not the case (Gilmour *et al.*, 2001), although the reasons for the variability have yet to be defined, and may not have a genetic origin.

One of the most common complicating features of any study of behavioural phenotypes is ascertainment bias. Cases of any condition with a distinctive behavioural characteristic are more likely to be detected if that characteristic is present. Thus, the key behavioural features are likely to be more common in an identified clinical population than in unidentified cases from the general population. Examples could be hyperphagia in Prader–Willi syndrome or autistic features in association with fragile X syndrome. On the other hand, if it can be demonstrated that the reason for ascertainment is never, or hardly ever, the cognitive or behavioural features, such bias would not apply. Many studies also fail to take account of the need to recruit comparison subjects: both to find out the degree to which the behavioural feature of interest is directly linked to the genetic anomaly rather than associated with some other non-specific factor, such as low IQ; and to control for the possibility that the behavioural feature is linked to some other specific characteristic of that syndrome, so confounding the relationship of interest.

In a study of behavioural phenotypes in children, the interpretation of cognitive or behavioural data is complicated by devel-

opmental considerations. A comprehensive account will include factors such as whether all features manifest at all ages, or whether various manifestations are developing in an invariable progression, and whether the progressive change in the cognitive and behavioural picture is itself genetically programmed (rather than depending on the influence of environmental contexts). Genes are switched on and off over time, according to both an internal clock as well as in response to environmental influences (Skuse 2000a). Their effects will depend on their pattern of expression during any given period of development. The natural history of genetically specified disorders with relatively circumscribed cognitive deficits (e.g. early stages of Huntington chorea; Lawrence *et al.* 1998) shows how dysfunction can develop in later life; it is by no means always present during infancy, or even childhood. In Huntington chorea there appears to be a deficit in inhibitory control mechanisms that are under the influence of striatofrontal circuits. Individuals with Huntington chorea also demonstrate a remarkably specific failure to recognize the facial expression of disgust (Gray *et al.* 1997). On the other hand, remarkable talents in certain cognitive skills may also be observed to develop over time in disorders with a strong genetic component, such as the enhancement of certain visuospatial skills in some boys with autism (Hermelin *et al.* 1999).

In summary, the concept of 'behavioural phenotypes' is fraught with difficulties, and falsely implies that there are characteristic patterns of behaviour that are specific to particular chromosomal anomalies. This assumption is hardly, if ever, justified. For instance, Hodapp (1997) reviewed the notion of 'total specificity' and quoted Flint & Yule (1994) as judging only the self-mutilation in Lesch–Nyhan syndrome, the hyperphagia of Prader–Willi syndrome, and the hand-wringing of Rett syndrome as being unique to that syndrome. There are no data on the uniqueness of the Lesch–Nyhan phenotype, but the Prader–Willi phenotype is certainly not unique (Skuse *et al.* 1997; Gilmour *et al.*, 2001), although the Rett phenotype might be (Mount *et al.*, 2001). To a limited extent, one may tell from genetic variation within a syndrome, as indexed by the degree of mosaicism for the aberrant cell line or the extent of a microdeletion, what degree of behavioural anomaly will arise in later life. However, precise prognostication is likely to be impossible for the great majority of conditions currently regarded as having 'behavioural phenotypes'. Nevertheless, the study of genotype–phenotype correlations should lead to the identification of genes that influence the development of cognitive brain systems. This will be greatly facilitated by the study of animal models. In some cases the cognitive brain systems will be important for the integrity of psychological domains that, if disrupted, lead to phenotypes resembling common conditions such as autism or ADHD. Accordingly, it should be possible, by a 'bottom-up' approach, to work out how those systems normally operate, so gaining insights that could lead to the development of new treatments.

In this section we review some of the most widely recognized and more common genetic disorders that are associated with

cognitive or behavioural characteristics that could be considered to constitute a phenotype. In most instances the phenotype has been reasonably well characterized, and in some cases there has been considerable work published on these aspects of the syndrome. However, for a variety of reasons, not always connected with the rarity or otherwise of the condition, there is rather little information available. We review a selection of intensively researched and less well-investigated syndromes. A summary of the findings is shown in Tables 13.1–13.3. These also give the reference number for the putative genetic aetiology of the disorders, which can be accessed from the Online Mendelian Inheritance in Man website ([HTTP://www3.ncbi.nlm.nih.gov/Omim](http://www3.ncbi.nlm.nih.gov/Omim)).

Behavioural phenotypes associated with single gene mutations

Duchenne muscular dystrophy

This X-linked condition comprises a range of muscular dystrophies with associated degrees of handicap from mild to severe.

Genetic anomaly

Muscular dystrophies are X-linked myopathies that result from mutations on the dystrophin gene, lying on the short arm of the X chromosome at Xp21.2. This gene encodes a protein that is involved in cytoskeletal development. There are many possible mutations (usually deletions) of exons (transcribed segments) in the huge dystrophin gene, which is the largest gene yet discovered on the human genome.

Cognitive and behavioural phenotype

There is a mild to moderate degree of mental retardation in one-quarter to one-third of cases (Bresolin *et al.* 1994) and, rarely, there is familial segregation with schizophrenia in families (Zatz *et al.* 1993).

Genotype–phenotype relationships

The dystrophin gene is expressed in the brain, but deletions that remove the brain-specific promoter are compatible with normal intelligence (Bushby *et al.* 1995). Recently, Bardoni *et al.* (1999) found evidence that deletions in the Dp140 regulatory sequences are specifically linked to cognitive impairments. This finding is compatible with previous work (Moizard *et al.* 1998) and therefore may be reliable.

Kallman syndrome

Kallman syndrome is a sex-linked condition in which affected males have anosmia because of agenesis of the olfactory lobes, and hypogonadism which is secondary to a deficiency of

Table 13.1 Syndromes with behavioural phenotypes.

	Single gene mutations				Microdeletion and duplication syndromes				Sex chromosome aneuploides	
	Duchenne muscular dystrophy	Tuberous sclerosis	Fragile X female carriers (full mutation)	Neuro-fibromatosis type 1	Williams syndrome	Prader-Willi syndrome	Smith-Magenis syndrome	Velocardio-facial syndrome	Turner syndrome	Klinefelter syndrome (47,XXY)

hypothalamic gonadotrophin-releasing hormone (GnRH). Hardelin *et al.* (1992) described additional phenotypic features including renal agenesis, and mirror movements of the hands, as well as pes cavus, a high-arched palate and cerebellar ataxia.

Genetic anomaly

The *KAL1* gene is located just proximal to the pseudoautosomal region at the tip of the short arm of the X chromosome. It escapes inactivation on the X chromosome in the female, although it is a pseudogene, and non-functional, on the Y chromosome in the male. Mutations in or loss of the single-expressed *KAL1* gene in males results in the phenotype of Kallman syndrome. There are also rare autosomal dominant and recessive forms of the disorder (*KAL2* and *KAL3*).

Cognitive and behavioural phenotype

Kallman syndrome has behavioural correlates. In about 85% of cases there are mirror movements, which comprise involuntary, non-suppressible movements of the contralateral upper limb. They are provoked by voluntary movement that is intended to be unilateral, and are maximal in distal hand and finger muscles (Krams *et al.* 1999). Interestingly, they are seen only among Kallman patients with the X-linked form of the disorder. Recent evidence has attributed these movements to abnormal development of the ipsilateral corticospinal tract (Krams *et al.* 1999).

The fact that affected individuals have both impaired development of the olfactory system and delayed sexual maturation links the two aspects of our everyday functioning to the same genetic system, in which the Kallman gene plays a part (Rugarli 1999). There is, as yet, no mouse model of the disorder. Affected individuals may have mental retardation, but this is usually mild. They have a range of odd social behaviours, some of which may be attributable directly to the loss of the Kallman gene, others to the loss of contiguous genes in cases where there has been a microdeletion, and yet others to the endocrinological abnormalities found in association with the syndrome.

Genotype–phenotype relationships

Is the Kallman gene dosage sensitive? Female carriers of the Kallman mutation have one functioning copy of the gene (as do normal males) yet are reported to have partial or complete anosmia, a key phenotypic feature of the condition. On the face of it, this finding is hard to explain; it suggests that although males can manage perfectly well with one copy of the gene, females need to have two functioning copies. Quinton *et al.* (1996) described a range of mutations at the *KAL* locus, but these did not correspond in any obvious way to phenotypic variability.

Tuberous sclerosis

Tuberous sclerosis is heterogeneous in both genetic and phenotypic terms (Harrison & Bolton 1997). The condition is charac-

terized by lesions in many parts of the body, including the brain. Indeed, the name of the syndrome refers to the potato-like growths seen in the brains of affected individuals which develop in early fetal life and appear to be static (Gomez 1995). The syndrome's phenotypic heterogeneity is probably caused in part by the seemingly random distribution of the areas of abnormal cell proliferation (Flint 1996). Epilepsy is common, affecting 60–80% of cases (Webb *et al.* 1996). The prevalence of tuberous sclerosis is estimated to be about 1 in 10 000 (Osborne *et al.* 1991).

Genetic anomaly

The condition is inherited in an autosomal dominant fashion. Approximately 60% of cases are caused by a spontaneous mutation, in one of two genes. These include the *TSC1* gene on chromosome 9q34, which encodes a protein known as hamartin. The *TSC2* gene lies on chromosome 16p13.3 and codes for tuberin. It is now known that there is an interaction of these two proteins at every stage of the cell cycle, and both seem to play a part in attenuating cell proliferation (Cheadle *et al.* 2000).

Cognitive and behavioural phenotype

About 50–60% of people with tuberous sclerosis have mental retardation, although precise estimates are hard to obtain because of lack of standardized IQ assessments (Harrison & Bolton 1997). There is some suggestion that mental retardation may be more common among affected males than females (Clarke *et al.* 1996). The number of tubers and the type and age of onset of epilepsy seem to be associated with the risk for mental retardation. Little is known about the exact nature of specific cognitive deficits in tuberous sclerosis, but problems such as dyspraxia, dyscalculia and visuomotor disturbance have been observed in affected individuals without general cognitive impairment (Jambaque *et al.* 1991). Harrison *et al.* (1999) conducted a detailed neuropsychological assessment of seven individuals with tuberous sclerosis and nine matched controls. Although all the patients had IQ scores in the normal range, five of them showed significant specific cognitive impairments. The individuals with tuberous sclerosis were particularly likely to perform poorly on a spatial planning task and a task involving cognitive shift, whereas none of them showed impairment on tests of semantic or phonological fluency or on tests of spatial span capacity.

Epidemiological studies indicate an association between tuberous sclerosis and pervasive developmental disorders. Compared to the general population, the risk of autism and atypical autism is 200–1000 times greater in individuals with tuberous sclerosis. Conversely, the risk of tuberous sclerosis is 100–300 times higher in individuals with autism (Wing & Gould 1979; Osborne *et al.* 1991; Hunt & Shepherd 1993; Gillberg *et al.* 1994; Smalley 1998). A neuroimaging study of a clinic sample of individuals with tuberous sclerosis obtained

evidence of an association between localized, structural abnormalities in the brain and the development of pervasive developmental disorders (Bolton & Griffiths 1997). The association between tuberous sclerosis and pervasive developmental disorders was related to the presence of tubers in the temporal lobes.

Fragile X syndrome

Fragile X syndrome is often quoted as being the single most common form of inherited mental handicap after Down syndrome, but it is probably far less common than was once thought. In the general population its prevalence is between 1.5 and 2.5 per 10 000 males (DeVries *et al.* 1997; Turner *et al.* 1997). In a large population of children at schools for those with learning difficulties, the prevalence could be as high as 1.3% (DeVries *et al.* 1997), with no difference in prevalence between those with mild and those with moderate to severe mental retardation.

Genetic anomaly

The mutation underlying the disease is a CGG triplet repeat expansion occurring within an untranslated portion of the *FMR1* gene. The clinical severity of the disorder, which is far greater in males than females, is substantially more marked if there are more than 200 CGG repeats, for this is associated with transcriptional silencing of the gene. Expansions in the number of CGG repeats occur exclusively during female transmission of FRAXA.

Cognitive and behavioural phenotype

Females with fragile X syndrome have a more variable clinical picture than affected males. They are said to show similar difficulties in social interaction, including shyness, gaze avoidance and poor modulation of interpersonal communication (Lachiewicz & Dawson 1994; Sobesky *et al.* 1996). They may also be more prone to sadness, and even depression (Thompson *et al.* 1994), and have poor attention skills (Franke *et al.* 1999).

Both males and females can have a degree of cognitive and behavioural abnormality that is related to the degree to which the trinucleotide CGG repeat is methylated, and hence the amount of fragile X protein that is produced (Tassone *et al.* 1999). If no *FMR1* protein is produced there will be moderate to severe mental disability; this situation is found virtually exclusively in males, for females have two copies of the *FMR1* gene, and even if one is mutated the other can compensate to a degree in certain circumstances. If the male is a mosaic, or if his full mutation is only partially methylated, the IQ deficit will be less marked. The phenotype in females depends on the inactivation pattern of the X chromosome. If the normal X is the active one, in any particular clone of cells, the functions of those cells will be relatively unimpaired and the corresponding phenotypic feature will not be found (Wolff *et al.* 2000). The full mutation (fM) is associated with deficits in short-term visual memory, visuospatial skills,

visuomotor co-ordination, the processing of sequential information, and in executive function skills. Attention deficits and hyperactivity are found in most cases of both referred and non-referred subjects (Baumgardner *et al.* 1995). It has been suggested that many such problems with activity and sensory stimuli may relate to anomalies in the posterior cerebellar vermis and caudate nucleus (Reiss *et al.* 1995). However, the neuropsychological deficits are associated with rather non-specific brain changes on magnetic resonance imaging (MRI), especially within the temporal cortex and hippocampus. However, there is no simple relationship between neuropsychological test performance, CGG triplet repeat lengths and structural brain abnormalities (Merenstein *et al.* 1996).

The notion current some years ago that fragile X syndrome is commonly associated with autism has not been supported by more recent rigorous analyses (Dykens & Volkmar 1997). The consensus seems to be that a minority of fragile X males do have classical autism (from 15 to 25%; McCabe *et al.* 1999) but the majority show behavioural characteristics that could be regarded as 'autistic-like' in character. These include gaze avoidance, shyness, social anxiety and withdrawal. Some of them could be regarded as having an autistic spectrum disorder, or the broader autistic phenotype (LeCouteur *et al.* 1996). A proportion is found to have stereotypies, impulsivity and be oversensitive to certain perceptual experiences. In contrast to males with classical autism, they are able to recognize facial expressions and emotions in others (Turk & Cornish 1998).

Genotype–phenotype relationships

Flint (1999) commented that the mutation in the *FMR1* gene was detected 10 years ago (Verkerk *et al.* 1991) and was the first of the trinucleotide repeat expansions to be discovered and yet we still do not know its physiological function. He argued that research has told us nothing about how the mutation results in mental retardation. We do know that the protein is associated with ribosomes, and it is believed to bind to specific RNAs and to regulate their expression so as to ensure that neurones develop correctly (Inoue *et al.* 2000). We also have a mouse model of fragile X, and these mice have certain of the features of the human condition including macro-orchidism and impaired spatial learning abilities. However, the degree of learning impairment in the mouse has not been as marked as is found in humans. The reason appears to be related to the strain of mouse used in the investigation (Dobkin *et al.* 2000). Despite this range of knowledge, we still know nothing specific about what the gene actually does.

Mental retardation associated with thalassaemia

Inherited disorders of haemoglobin are the most common monogenic disorders worldwide and amongst the most intensively studied. Weatherall & Clegg (1999) estimated that 6–7% of the global population are carriers. They serve as a paradigm of our state of knowledge about the relationship of molecular

pathology and the associated clinical phenotype (Weatherall 1999). The major phenotypic differences can be attributed to the actions of mutational variability at a single locus (Higgs 1993), and the interactions of this locus with two other major modifying loci. Yet, the complexity of the genetic mechanisms involved is far greater than was initially anticipated (Weatherall 1999).

Genetic anomaly

There are two syndromes in which mental retardation is associated with α thalassaemia, which occur in European rather than tropical populations (Wilkie *et al.* 1990a,b). One is associated with structural rearrangements of the short arm of chromosome 16, including microdeletions, and constitutes an aspect of a contiguous gene syndrome in which variable numbers of genes are deleted, each of which may have rather specific functions (Weatherall 1999). The other disorder is X-linked, and is known as ATR-X syndrome. It is associated with a mild form of α thalassaemia, a characteristic facial appearance, profound developmental delay, neonatal hypotonia and genital abnormalities. The mutated gene is *ATR-X*. This syndrome is of particular interest because the effects of the single gene mutation are pleiotropic and it was one of the first disorders in which mutations of a putative transcriptional regulator have been described (Gibbons *et al.* 1995). *ATR-X* is widely expressed in the brain, heart and in skeletal muscles, and is very likely to have a key role in the regulation of other genes. Mutations of transcription factors are likely to result in complex phenotypes, and potentially such mutations may account for a small proportion of behavioural phenotypes (Skuse 2000a).

Rett syndrome

Rett syndrome is a progressive neurodevelopmental disorder of females, which occurs in no more than 1 per 10 000–15 000 live female births (Hagberg *et al.* 1993). It is devastating in its consequences upon normal development.

Genetic anomaly

Interest in the genetic aetiology of the syndrome was heightened recently when two families possessing more than one affected member were studied. As the condition is manifest only in females, the X chromosome is the likely location of the susceptibility locus, probably the long arm (Willard & Hendrich 1999). Males with a mutation in the gene usually cannot survive beyond birth. The variability in the female phenotype suggests the gene is likely to be subject to X inactivation, and thus is like fragile X syndrome in this respect. The female expression pattern will depend on whether the X chromosome carrying the abnormal gene is active in critical tissues, especially the brain, and some reports have suggested skewing of X inactivation does occur in females with the syndrome or their mothers (Kirchgesner *et al.* 1995; Sirianni *et al.* 1998). Amir *et al.* (1999) reported

that there are mutations in a gene known as *MECP2* in a proportion of Rett females, a gene that is involved in transcriptional regulation of other genes, which appears to have very widespread influence. Genes that are targets of MeCP2 protein in the brain need to be identified. An important lesson from this research is that although the key mutation may be in *MECP2*, it is the failure of this regulatory gene to act normally on other genes that causes the symptoms of Rett syndrome (Willard & Hendrich 1999). We already know from studies of females with ring X chromosomes, in which functional disomy of X-linked genes may occur (Dennis *et al.*, 2000), that impaired dosage regulation of such genes can result in a severe cognitive and behavioural phenotype (Kuntsi *et al.*, 2000).

Behavioural phenotype

Although affected girls appear to be quite normal for the first few months after birth, there is a failure to gain new skills during early infancy and subsequent deterioration between the ages of 1 and 4 years. There is progressive loss of speech, purposeful hand use, microcephaly and epilepsy (Hagberg *et al.* 1993). Following this period of loss of skills, various behavioural and cognitive features become evident which, taken together, are quite characteristic of the clinical features of the syndrome (Mount *et al.*, 2001). They include breathing difficulties and involuntary movements, especially 'hand-wringing' or washing movements, and a jerky truncal ataxia. Interest has been heightened by the fact that a number of affected girls display autistic-like behaviours, and some commentators think it could be regarded as a subtype of autism (Gillberg 1994; Rutter 1994b). Given the degree of mental retardation associated with the condition, and the fact that autistic features are rather more common among moderate to severely mentally retarded individuals (Bailey *et al.* 1995), a comparison between Rett syndrome and mentally retarded comparisons was clearly needed. Mazzocco *et al.* (1998) conducted such a study, and concluded that the autistic features of Rett syndrome are not simply a consequence of severe mental retardation.

Genotype–phenotype relationships

It is too early to know if the Rett mutation that has been identified will be associated with a phenotype that differs to any significant extent from the majority of cases that do not share this mutation. We may learn more from the study of an animal homologue of the disorder. Mice in which the *mecp2* gene has been knocked out have been produced (Chen *et al.* 2001). Such mice have a behavioural phenotype but unlike humans they are only viable if they contain only a small proportion of cells with the *mecp2* mutation. As the severity of the human phenotype varies according to whether the X chromosome containing the Rett gene is inactivated or not, the chimeric mouse model could be a parallel to the presumed human mosaicism for the mutation, based upon the pattern of X inactivation.

Behavioural phenotypes associated with chromosomal deletions and duplications

Spontaneously occurring chromosomal aberrations can provide a useful pointer to the existence and location of genes that are important in the development of normal cognition and behaviour, although to date the study of such anomalies has been mainly in the study of cancers (Strachan & Read 1999). Abnormalities of chromosomes that can be observed under the microscope are known as cytogenetic abnormalities. Several important discoveries were made simply because rare cytogenetic abnormalities in a few patients led to the 'disease' gene. These included dystrophin (MIM 310200), retinoblastoma (MIM 180200) and neurofibromatosis 1 (MIM 162200). Central to this approach is the need to identify a candidate gene, and discovering the correct candidate can be very time consuming.

Even microdeletions can disrupt a large number of genes, any one of which could be the candidate of interest. Once the Human Genome Project is completed the task should be rather easier because it will be possible to use unique markers (short sequences of DNA) to define the boundaries of the deleted or reduplicated segment. It should then be a straightforward matter to look up which genes are known to be expressed in the candidate region. If we are interested in genes that are expressed in the brain, there are ways of discovering whether our candidate is expressed in fetal brain. However, merely finding that a gene is expressed in the brain at some time during fetal development does not actually tell us as much as might at first appear, for up to 70% of all genes in the human genome are probably expressed in fetal brain at some time (Andrew Copp, personal communication).

Chromosome abnormalities can occur in all the cells of the body if they originated in the germ-line, or during formation of the zygote. Alternatively, they may come about as a consequence of some acquired insult, such as exposure to a carcinogen. Structural abnormalities do not always result in disruption to genetic function; they may be benign.

Microdeletion and duplication syndromes

Williams syndrome

Williams syndrome is a rare sporadic disorder with an incidence estimated to be about 1 in 20 000 live births (Perez Jurado *et al.* 1996). The condition is associated with a relatively distinctive cognitive profile. Affected individuals have both a superficial facility with language and with facial recognition, but they possess poor visuospatial skills (Bellugi *et al.* 1999).

Genetic anomaly

In over 90% of cases, there is a submicroscopic deletion of one copy of chromosome 7. The region of chromosome 7 most com-

monly deleted contains the following genes, the list of which is not exhaustive:

- 1 homologue of the drosophila gene *frizzled* (*fzd3*);
- 2 the syntaxin 1 A gene (*STX1A*);
- 3 the elastin gene (*ELN*), which accounts for some aspects of the physical phenotype, especially the associated cardiac anomaly supravalvular aortic stenosis (SVAS);
- 4 the LIM-kinase gene (*LIMK1*);
- 5 *WSCR1*;
- 6 *RFC2*; and
- 7 *GTF21* (Bellugi *et al.* 1999).

In total at least 20 genes may be deleted, including a number of highly repetitive DNA sequences. The deletion arises because occasionally recombination occurs between misaligned repeat sequences either side of the critical region (Baumer *et al.* 1998) during gamete formation. The replication factor C2 (*RFC2*) and syntaxin 1 A (*STX1A*) genes have also been mapped to the Williams syndrome critical region. The extent of the deletion is variable, but the classic Williams syndrome phenotype is associated with deletion of *ELN*, and usually *LIMK1* too. Although it was reported that haploinsufficiency for *LIMK1*, which is widely expressed in the brain, was likely to be responsible for the non-verbal cognitive deficits (Frangiskakis *et al.* 1996), subsequent research has suggested this is unlikely. Patients with hemizyosity for this gene may not have any detectable cognitive deficits. Furthermore, it appears that *LIMK1*, *STX1A* and *RFC2* are not dosage sensitive.

Cognitive and behavioural phenotype

The overall IQ of patients with Williams syndrome is low, on average about 60, but this disguises a discrepancy between verbal and non-verbal abilities. Non-verbal abilities are much more seriously impaired (Udwin *et al.* 1987). One of the most difficult tasks for affected individuals is pattern construction, such as the block design subtest of the Wechsler scales (Wechsler 1986, 1992). Verbal fluency is similar in quantitative terms to normal age-matched individuals, although it is qualitatively abnormal (Bellugi *et al.* 1999). In contrast to children with fragile X syndrome, those with Williams syndrome do not have social deficits of an autistic character. Indeed, it is often said that their social interactions are relatively unimpaired in character. They are described as outgoing, with good eye contact, and they may be friendly and have good empathic skills (Gosch & Pankau 1997; Dykens & Rosner 1999). However, it would be a mistake to assume their social interactions are normal. Rather, the abnormality is of a different character to that found in conditions where the impairment to social skills is autistic-like. Children with Williams syndrome are often strikingly disinhibited and relate indiscriminately to unfamiliar children and adults, which may put them at social risk (Davies *et al.* 1997; Dykens & Rosner 1999). The social disinhibition found in association with this syndrome, as occurs in many cases of ADHD of unknown origin, is correlated with poor performance on standard tests of attention. There is also overactivity, impulsivity and anxiety.

Several research groups have examined the Williams syndrome cognitive phenotype (Howlin *et al.* 1998; Jarrold *et al.* 1998; Bellugi *et al.* 1999). Their current view is that the discrepancy between relatively preserved verbal skills and poor non-verbal abilities, previously reported as being common in the condition, has been exaggerated. Nevertheless, there continues to be considerable interest in their odd use of language (Karmiloff-Smith *et al.* 1997; Sacks 1995). Paterson *et al.* (1999) reassessed the claim that the uneven cognitive profile of children with Williams syndrome provides evidence for an innate inherited faculty for understanding and using grammatical constructions (Pinker 1994). In its simplest form, the theory of modularity, based upon a superficial study of the Williams syndrome cognitive and behavioural phenotype, predicts that innately specified modules are impaired at birth as a consequence of the genetic disorder. Only those modules of ability that are linked to the genetic anomaly will be impaired, others will be spared. Paterson *et al.* (1999) showed that some language skills are poor among toddlers with Williams syndrome, whereas some numerosity skills are relatively good. Yet in adulthood the opposite pattern of discrepancies is observed. Hence, they concluded, neither numerosity nor language skills can be innately specified modules, or the same pattern of impairment would have been present since infancy. Some would argue the evidence for a radical shift in the cognitive phenotype of Williams syndrome during development is not as strong as was claimed (Bishop 1999). Others might feel it is naïve to imagine that genetically specified cognitive modules would be laid down at birth and would be unchanging over time, in any event.

Some earlier reports suggested a selective preservation of face recognition abilities in Williams syndrome (Bellugi *et al.* 1988; Udwin & Yule 1991), despite the visuospatial deficits. On closer inspection it appears that face processing in individuals with Williams syndrome is in fact atypical. Karmiloff-Smith (1997) obtained preliminary evidence suggesting that individuals with Williams syndrome perform well only on those face processing tasks that require feature-by-feature componential analysis. More recently, Deruelle *et al.* (1999) compared configural and local processing of faces in children with Williams syndrome to that of both age- and mental age-matched controls. Inverted faces are in general harder to recognize than faces presented upright, which is taken as a sign of configural processing. The control children showed the normal inversion effect for faces (and not for houses), but no such effect was observed in the Williams syndrome group. On a matching-to-sample task the control children showed a bias toward a configural mode of face and geometrical shape processing, whereas the children with Williams syndrome did not show any bias. These results not only suggest an impairment in configural processing of faces in Williams syndrome, but also indicate that this impairment may generalize to other visual objects too. Other studies using visuospatial tasks similarly indicate difficulties in performing part integration tasks in Williams syndrome (Bihrlé *et al.* 1989; Bertrand *et al.* 1997).

Brain development of Williams syndrome subjects has been

investigated, both *in vivo* with the aid of MRI scans and at post-mortem. So far, there have not been any published attempts to link variations in genotype with variations in brain phenotype, although that is clearly an interesting and potentially valuable line of enquiry. The cognitive profile is but a crude measure of changes that occurred in brain development because of haploinsufficiency for the gene(s) responsible. It is certainly possible that rather more extensive abnormalities will be found in the brains of Williams syndrome individuals with partial deletions than would be suspected from their cognitive abilities. Neuro-anatomical studies have contrasted Williams syndrome subjects with normal and with Down syndrome controls (Bellugi *et al.* 1999). There seems to be relative preservation of the anterior cortical areas, and enlargement of neocerebellar areas, together with preservation of the mesial temporal lobe. Galaburda *et al.* (1994) studied Williams syndrome brains at autopsy and reported microencephaly and relatively small volumes of occipital and posterior parietal areas of several brains.

Finally, anxiety may be a common feature of the syndrome, although the reasons for this are not clear. Dykens & Rosner (1999) reported 'anticipatory anxiety' in over 50% of a sample of both children and adults. They also showed that up to 95% had persistent or marked fears that lasted up to 6 months or more. Others had phobic symptoms too. In a minority of cases these fears could be connected to the hyperacusis that is characteristic of the syndrome.

Gene-phenotype relationships

Frangiskakis *et al.* (1996) claimed, in a sophisticated piece of research, that hemizyosity for a specific gene was responsible for the impairment in visuospatial constructive cognition in Williams syndrome. They identified two families with 13 members who had a partial Williams syndrome phenotype, associated with one of two differing deletions of limited extent that incorporated both the *ELN* and the *LIMK1* genes. These individuals did not suffer from the general cognitive impairment usually associated with the syndrome; instead, they had a marked deficiency only in visuospatial constructional abilities. On the basis that targeted disruption of protein kinases in mice results in impaired spatial learning (Ashkenas 1996), the investigators hypothesized that *LIMK1*, which is widely expressed in human cerebral cortex, was of particular significance for this aspect of the phenotype. Individuals from the families with the partial phenotypes who had the typical cognitive profile were found to have a microdeletion that incorporated this gene, as did 62 individuals with classic Williams syndrome. In a further sample who had only the cardiac anomaly (SVAS), which is thought to be associated with deletion of the elastin gene, there was no such abnormal profile. *ELN* is not expressed in the brain.

Whereas the findings were undoubtedly appealing, and were claimed to herald the discovery of the first human gene to be associated with a specific cognitive ability, subsequent studies have failed to support this conclusion. Tassabehji *et al.* (1999) pointed out that for most genes a 50% decrease in gene dosage

has no phenotypic effect, which is obvious when we consider the large number of recessive characteristics we harbour in our genome. Secondly, they suggest mouse knockouts are of limited relevance to human cognitive function. Certainly, the spatial deficits seen in mice with protein kinase knockouts are of quite a different character to the visuoconstructional problems found in individuals with Williams syndrome. Finally, Tassabehji *et al.* (1999) drew attention to the confounding issue of genetic background when interpreting phenotypes in limited samples of (wild-type) individuals. They reported an intensive investigation of three individuals who, despite deletion of one copy of the *LIMK1* gene, did not have the impairment in pattern-construction that would have been predicted from the Frangiskakis *et al.* (1996) report. Why would this anomalous result be found? Tassabehji *et al.* (1999) claimed that ascertainment of Williams syndrome is not influenced by the associated cognitive impairment, and that almost every individual with the physical phenotype has the typical cognitive profile. Biased ascertainment remains, however, an important consideration to be firmly excluded. The jury is out on whether the gene responsible for the fascinating cognitive profile of the condition has yet to be discovered. However, it would be conceptually muddled to claim that because the disorder is associated with impaired visuospatial abilities, the critical gene is responsible for the specific development of such skills. Visuospatial deficits are found in association with a variety of microdeletion syndromes (Skuse 1999), although not with Down syndrome which is a favourite comparison group in Williams syndrome investigations.

Prader–Willi syndrome

Prader–Willi syndrome is a distinctive disorder, associated with a genetic anomaly on the long arm of chromosome 15, in which hyperphagia, mild to moderate mental retardation and obesity combine with a typical developmental history. In the great majority of cases there is no inherited predisposition, but a sporadic event during meiosis leads to the failure to express the paternal copy of some as yet unidentified critical gene, or set of genes. There is debate about the true incidence of the condition. Donaldson *et al.* (1994) suggested that former estimates of 1 in 10 000 births were too high, because of overdiagnosis of Prader–Willi syndrome. Unless a molecular investigation is confirmatory, caution should be exercised in making the diagnosis (Chu *et al.* 1994). Using molecular techniques in combination with the clinical diagnostic criteria developed by Holm *et al.* (1992), a more accurate prevalence rate may now emerge.

Genetic anomaly

This disorder is associated with structural rearrangements of the long arm of chromosome 15. The anomalies include deletions, translocations, inversions and supernumerary marker chromosomes, as well as uniparental disomy. Such anomalies can be found not only among patients with Prader–Willi syndrome but also those with the much rarer condition, Angelman syndrome.

Deletion or disruption of the Prader–Willi/Angelman critical region (PWACR) within the 15q11–q13 region may result in either Prader–Willi or Angelman syndrome, when the affected homologue is paternal and maternally inherited, respectively. This parent-of-origin effect has been explained as a consequence of oppositely imprinted genes within this region (Feil & Kelsey 1997). Occasionally, there is inheritance of a cytogenetically detectable interstitial duplication of proximal 15q. Those that do not contain the PWACR are not associated with any specific phenotype, and are equally likely to be maternally or paternally inherited. Duplications that are maternal in origin, and include the PWACR, are associated with developmental delay and speech difficulties in all probands (Browne *et al.* 1997).

Submicroscopic duplications of this region could also exist, and they may account for some cases of developmental delay and/or learning difficulties, despite an apparently normal karyotype. A report by Bunday *et al.* (1994) demonstrated that the presence of a *de novo* duplication of part of the long arm of the chromosome 15 of maternal origin was associated with autism and severe mental retardation. Other reports of autism in association with duplications of this region have recently been made (Cook *et al.* 1997), as well as with a microdeletion in 15q11–12 (Schroer *et al.* 1998). In all cases reported to date, the abnormality has been maternally derived, whether it was a duplication or deletion of the region. Interestingly, the results of linkage studies are also consistent with involvement of the long arm of chromosome 15 in the predisposition to childhood autism (Maddox *et al.* 1999).

Prader–Willi syndrome is probably not the result of a deficit in a single gene, as there have been seven genes (and candidate genes) identified in the Prader–Willi syndrome region, all of which appear to be brain-specific (Nicholls *et al.* 1998; Nicholls 1999). The function of these genes is unknown, but one that has been identified, *IPW*, does not even code for a protein and is therefore similar to two other imprinted non-translated RNAs, *H19* and *Xist*. Potentially then, the phenotype arises from deficits in all these genes, but it is not known how the genetic defect causes intellectual impairment. Mice that have chromosomal deletions in the equivalent region to the PWACR, or uniparental disomy for the region, or imprinting mutations, have a severe phenotype leading to early postnatal death (Gabriel *et al.* 1999; Tsai *et al.* 1999).

Behavioural phenotype

Dysmorphic features include a disproportionately narrow forehead, almond-shaped eyes, downturned mouth and abnormally shaped ears (Cassidy 1992; Holm *et al.* 1993). There is hypogonadism in 90–100% (Butler 1990; Cassidy 1992). Small hands and feet are found in 70% of typical cases and hypopigmentation in 40% (Holm *et al.* 1992). A squint occurs in 60–70% and scoliosis in 40–60% (Cassidy 1992).

Ninety-seven per cent of Prader–Willi syndrome affected individuals have an IQ below 70 (Butler 1990), with an average IQ of about 60, in the moderate retardation range (Dykens *et al.*

1992). Cognitive strengths and weaknesses may be uneven. For example, visual processing skills could be relatively strong (Curfs *et al.* 1991; Holm *et al.* 1992; Taylor 1992), although that finding is not consistent (Gabel *et al.* 1986). There may be deficits in attention, perceptual-motor integration and motor control too—all of which exacerbate the Prader-Willi syndrome group's poorer performance on IQ testing. Dykens *et al.* (1992) suggested sequential processing was relatively weak whereas attainment and achievement were relatively strong. Although just under half of children with Prader-Willi syndrome attend a mainstream elementary school, by secondary school age the proportion in mainstream education may drop. Whether this shift is because of a developmental decline in IQ is uncertain. Dykens *et al.* (1992) reported that in contrast to Down syndrome, there was no evidence of IQ decline in Prader-Willi syndrome on the basis of both cross-sectional and longitudinal data. Dykens & Cassidy (1995) found no relationship between IQ and maladaptive behaviour.

Poor muscle tone (hypotonia) is evident in almost 100% of infants with Prader-Willi syndrome. Between 90 and 100% have feeding problems and failure to thrive (Butler 1990; Cassidy 1992). The feeding problems appear to be caused by hypotonia, with poor sucking and gagging reflexes (Holm *et al.* 1992). Tube feeding is often necessary (Ehara *et al.* 1993) until 10–18 months, after which weight gain increases dramatically. Motor milestones are delayed to approximately twice the equivalent age of normal children (Butler 1990; Cassidy 1992).

The most distinctive feature of Prader-Willi syndrome is hyperphagia; 80–90% of children become hyperphagic, which often results in obesity (Cassidy 1992), although this outcome is not inevitable, but depends in part on parental management style (Holland *et al.* 1995). Its onset occurs at an average age of 2 years (Butler 1990), and in most cases before the child is 6 years old (Holm *et al.* 1993; Holland *et al.* 1995). A number of studies have attempted to identify the physiological basis of this appetite disorder, and to find ways of controlling it with medication. These have not, on the whole, been very successful (Zipf & Berntson 1987; Dech & Budow 1991; Tu *et al.* 1992; Benjamin & Buot-Smith 1993). The reason why people affected with Prader-Willi syndrome seem to experience hunger to a greater degree than the general population remains unclear. Taylor & Caldwell (1985) reported that sweet foods are often preferred and would be chosen over larger amounts of less preferred food. High-preference foods have been used successfully as positive reinforcement, to encourage activity in one sample of adults with Prader-Willi syndrome (Caldwell *et al.* 1986). Taylor (1992) cautioned that hyperphagia is not invariable in Prader-Willi syndrome and that the eating behaviour demonstrated by individuals with Prader-Willi syndrome might be similar to any other individual who is living in an environment of continuous food restriction. Obesity is usually found in association with hyperphagia and there seems to be a characteristic body fat distribution, with weight often distributed around the trunk (Cassidy 1992). Obesity can become so severe that there may be physical (and life-threatening) complications, in addi-

tion to a poor quality of life (Holland *et al.* 1995). Maintaining a reasonably low body mass index (BMI) is the key to successful management of Prader-Willi syndrome.

Other behavioural phenotypic features include skin picking, observed in up to 85% of cases (Greenswag 1987; Clarke *et al.* 1989; Cassidy 1992), temper tantrums (Cassidy 1992; Butler 1990), belligerence and stubbornness (Greenswag 1987), aggression (Taylor 1992) and poor judgement relative to measured IQ level (Sulzbacher *et al.* 1981). However, just how specific these behaviours are to Prader-Willi syndrome, rather than to moderate mental retardation, is hard to assess. Many studies lack an appropriate comparison group and have other methodological limitations. Butler (1990) suggested that some behavioural difficulties, such as temper tantrums, may begin as a consequence of the food restriction imposed upon the individual. Whitman & Greenswag (1992) noted that individuals with lower BMIs, subjected to greater restrictions on eating behaviour, were more likely to have behavioural problems. Other studies have reported no relationship between BMI and behavioural disturbance in adults (Clarke *et al.* 1989).

Children and adults with Prader-Willi syndrome are commonly described as hypoactive and lethargic. Their lack of activity may be exacerbated by co-ordination problems, resulting from hypotonia. Problems with obesity following excessive eating will be increased by inactivity (Nardella *et al.* 1983). Davies *et al.* (1992) used doubly labelled water isotopes in a study of free living children in their home environment. Children with Prader-Willi syndrome showed a significantly lower total energy expenditure than non-obese comparisons.

Sleep architecture studies have indicated that there may be a neurological basis to the reports of disruptive sleeping patterns in Prader-Willi syndrome. Helbing-Zwanenburg *et al.* (1993), using objective measures, note that 95% of their sample of Prader-Willi syndrome affected children and adults had excessive daytime sleepiness, as compared with 10% in the adult normal comparison group. During night sleep, the Prader-Willi syndrome group showed a significantly lower proportion of rapid eye movement (REM) and slow-wave sleep than the comparisons, but there was no evidence of the sleep apnoea syndrome in any Prader-Willi syndrome cases tested. Excessive daytime sleepiness is also commonly reported (Clarke *et al.* 1989) which may be exacerbated by sleep interruption during the night.

Speech difficulties occur in around 80–90% of cases (Cassidy 1992). Kleppe *et al.* (1990) found articulation problems, difficulties in terms of expressive and receptive language, including difficulties with syntax. The battery of tests in this study was extensive, with most instruments having standardized norms for the general population, but an IQ-matched control group may have been more informative in order to identify Prader-Willi syndrome-specific speech problems.

Short stature is usual. Children with Prader-Willi syndrome are usually on the 10th centile for height or below, in contrast to non-affected obese children who are usually tall for their chronological age (Donaldson *et al.* 1994). Butler (1990) noted

the lack of growth spurt in adolescence results in Prader–Willi syndrome affected adults being proportionately smaller than Prader–Willi syndrome affected children. However, short stature is not invariable. There is debate whether Prader–Willi syndrome is associated with growth hormone deficiency or whether the short stature is caused by growth hormone dysregulation. Angulo *et al.* (1992) examined the 24-h growth hormone profile in obese and non-obese children aged 1–15 years who had Prader–Willi syndrome. They reported abnormally low levels in all the children regardless of BMI. Blichfeldt *et al.* (1992) found 66% with growth hormone levels below the 25th centile of the levels reported in the general population. Other studies have cast doubt on the growth hormone insufficiency theory (Ritzen *et al.* 1992). Other endocrine disturbances may also be associated with the condition (Muller 1997).

Genotype–phenotype relationships

Interest has been expressed in whether the form of Prader–Willi syndrome caused by uniparental disomy differs in any aspect of the cognitive or behavioural phenotype from that caused by a microdeletion of the paternally derived chromosome 15 (Cassidy *et al.* 1997). There do seem to be some significant differences, but they are not large. In general, those with a deletion have a lower verbal IQ (Roof *et al.* 2000) and there may be rather less skin-picking behaviour and fewer articulation problems among those with uniparental disomy (Cassidy *et al.* 1997). Genotype–phenotype correlations have also been investigated in the mouse model for the disorder, in which a variety of mutations and deletions of the PWACR have been induced. Certain of these deletions can lead to a paternally inherited pattern of severe growth retardation and hypotonia, with partial lethality (Tsai *et al.* 1999). Nicholls (1999) commented that in the equivalent mouse chromosome 7C region, there is a novel gene (*SNURF-SNRPN*) that encodes two independent proteins, and these may play a part in the phenotype. He suggested that colocalization of *SNURF* and *SNRPN* within the imprinting control region could be a critical factor, and says evolutionary arguments would suggest that this genetic locus is a prime candidate for mutations producing the failure-to-thrive phenotype of neonates with this syndrome and of corresponding mouse models.

Angelman syndrome

Angelman syndrome is phenotypically quite unlike that of Prader–Willi syndrome, despite the fact that it is also caused by anomalies in the PWACR. The mental retardation is very severe, and most individuals do not develop spoken language. There is also ataxia, seizures, hyperactivity and paroxysms of laughter. The term by which the condition used to be known ('the happy puppet syndrome') is not regarded as appropriate nowadays. The prevalence of the disorder is much the same as that of Prader–Willi syndrome, about 1 in 15 000 live births (Clayton-Smith & Pembrey 1992).

Genetic anomaly

The genetic disorder is variable (Mann & Bartolomei 1999), and comprises deletions of the PWACR, uniparental disomy for the paternally derived chromosome 15, intragenic mutations and also imprinting mutations (Nicholls *et al.* 1998). In stark contrast to Prader–Willi syndrome, for which no single intragenic mutation has been discovered, about 20% of cases of Angelman syndrome are associated with presumed mutations as no other abnormality in the PWACR can be discovered. Mutations in a ubiquitin protein ligase gene (*ube3a*) have been found in a few rare families with Angelman syndrome (Kishino *et al.* 1997), and it has been proposed that the *ube3a* gene is maternally expressed. Even if we learn that mutations in this gene are the cause of Angelman syndrome they are unlikely to tell us much about the origin of the cognitive phenotype. The gene product is part of a widely used ubiquitin-mediated protein degradation pathway, and the deletion almost certainly will have pleiotropic effects that will be 'hard if not impossible to disentangle'. Flint commented (1999): 'An immense amount of work has gone into the characterization of the small deleted region in Prader–Willi syndrome/Angelman syndrome. The basic deficit is not simply a dosage effect. However, the molecular deficit seems to be the same in both instances, but it looks increasingly unlikely that the genes act directly or specifically on the CNS.'

Genotype–phenotype relationships

It has been possible to generate a mouse model of Angelman syndrome, with disruption of the *ube3a* gene (Jiang *et al.* 1998). The deficits displayed by these mice include a context-dependent learning deficit, motor dysfunction and inducible seizures. The central part of mouse chromosome 7 is homologous to human 15q11–q13, with conservation of both gene order and imprinted features. Gabriel *et al.* (1999) conducted a transgene insertion into mouse chromosome 7C, which has resulted in mouse models for both Prader–Willi syndrome and Angelman syndrome dependent on the sex of the transmitting parent.

Smith–Magenis syndrome

Smith–Magenis syndrome is caused by an interstitial deletion involving 17p11.2. It is associated with some degree of mental retardation, measured IQs being in the range 40–54 (Greenberg *et al.* 1996) and cognitive and behavioural profiles have recently been described (Dykens *et al.* 1997).

Genetic anomaly

It is one of the most frequently observed human microdeletion syndromes, and seems to be caused by homologous recombination of a low-copy-number repeat region (a repeated gene cluster) flanking the junction of the deletion (Chen *et al.* 1997).

Cognitive and behavioural phenotype

Over half of those with the syndrome are likely to have disobedient behaviour, to be hyperactive, to be attention-seeking, with sleep disorder and toileting abnormalities including enuresis (diurnal and nocturnal) and soiling (Dykens & Smith 1998). Impulsivity, irritability and temper tantrums may also occur (Clarke & Boer 1998). Self-injurious behaviours include biting, head banging and also inserting objects into bodily orifices and pulling out finger- or toenails (Dykens & Smith 1998; Smith *et al.* 1998b). There are motor stereotypies, including inserting hands or other objects into the mouth, grinding teeth, and other repetitive behaviours, such as flipping pages of books (Dykens *et al.* 1996; Dykens & Smith 1998).

Profound sleep disturbances include reduced or absent REM sleep (Smith *et al.* 1998a,b) and Dykens & Smith (1998) claim this is a strong predictor of behaviour problems. It is not known whether it is the lack of REM sleep that leads to the associated behavioural problems, but Dykens & Smith (1998) claim that increased length of daytime napping is associated with fewer maladaptive behaviours.

Velocardiofacial syndrome

There is psychiatric interest in the velocardiofacial syndrome (VCFS) (Shprintzen *et al.* 1981) which is characterized by cardiac defects, cleft palate, learning disabilities and a characteristic facial appearance, together with a genetic anomaly on chromosome 22 at q11. The incidence is estimated to be between 1 in 3000 and 5000 live births (Papolos *et al.* 1996). Most cases are sporadic but, when inherited, it has an autosomal dominant pattern of transmission. There is an increased risk of severe behavioural problems in children with the condition, and of major psychiatric illness in adulthood including mood disorders and psychosis (Papolos *et al.* 1996). Up to 30% of adults with VCFS will develop a major psychiatric illness, with the majority fulfilling diagnostic criteria for schizophrenia (Murphy *et al.* 1999). The risk of mental health problems increases with age (Goldberg *et al.* 1993; Papolos *et al.* 1996; Carlson *et al.* 1997a). ADHD and bipolar affective disorder are the most common diagnoses in childhood, although there has yet to be published a thorough investigation of the psychiatric phenotypes at that stage of development. Much of the current literature focuses on the physical manifestations of the condition, which comprises a range of related disorders including DiGeorge syndrome (OMIM 188400). The cognitive and behavioural phenotypes of individuals with VCFS, and children in particular, have been poorly described and are largely based on clinical observation rather than systematic assessment.

Genetic anomaly

About four out of five patients with VCFS have a deletion of the VCFS critical region, with a proximal breakpoint that is similar in most cases. The distal breakpoint is variable (Morrow *et al.*

1995; Scambler 2000). The size of the deletion is usually about 3 million base pairs, so there is clearly loss of a large number of genes from the deleted chromosome. It has been proposed that a number of genes in the deleted segment are needed in two functioning copies for normal development to occur. If only one copy is present, on the intact chromosome 22, there will be insufficient gene dosage (known technically as haploinsufficiency; Fisher & Scambler 1994).

Cognitive and behavioural phenotype

The condition is associated with learning difficulties that are apparent from childhood (Goldberg *et al.* 1993; Motzkin *et al.* 1993), although up to half have an IQ within the normal range (above 70) (Swillen *et al.* 1999). There is no clinically or statistically significant verbal vs. performance IQ discrepancy (Golding-Kushner *et al.* 1985; Swillen *et al.* 1999). Some reports suggest general cognitive ability falls over time, from preschool, through middle childhood to adolescence (Golding-Kushner *et al.* 1985). Deterioration amounts to about one standard deviation on average, and is similar in verbal and non-verbal abilities. Gross and fine motor problems are frequently noted (Goldberg *et al.* 1993; Lynch *et al.* 1995) and perceptual problems may be relatively severe, although the evidence is presently lacking (Golding-Kushner *et al.* 1985; Swillen *et al.* 1999).

Children with VCFS have speech and language problems for a number of reasons. There are physical problems, secondary to the cleft palate abnormalities, with forming speech sounds and these are characteristically hypernasal (Shprintzen *et al.* 1978). Speech development is often delayed and impoverished in content (Kok & Solman 1995; Lynch *et al.* 1995; Swillen *et al.* 1999). Qualitative descriptions of poor expressive language skills include immature grammar and syntax and low utterance length (Golding-Kushner *et al.* 1985). Poor language comprehension may also occur, and language skills tend to be worse in general than would be predicted from verbal IQ measures alone (Moss *et al.* 1999). Affected children may have poor concept formation and do not develop past the concrete operations phase in problem-solving (Golding-Kushner *et al.* 1985; Motzkin *et al.* 1993; Kok & Solman 1995; Swillen *et al.* 1999). Sight-reading ability may be markedly superior to reading comprehension skills.

A relatively low level of arithmetical ability and mathematical reasoning is also suggested from anecdotal reports (Golding-Kushner *et al.* 1985; Motzkin *et al.* 1993; Kok & Solman 1995). Poor performance on this type of task requires abstract problem-solving skills and so supports the clinical observation of poor concept formation. Remedial help for mathematics is required in a high proportion of cases. However, no analysis has been made as to whether these abilities are simply commensurate with each child's general ability level.

Many children with VCFS are described as socially immature (Goldberg *et al.* 1993), with poor social skills, impulsivity or shyness (Golding-Kushner *et al.* 1985). Anecdotal reports from parents include descriptions of rigid behaviour, difficulty with changes in routine, obsessional traits and lack of emotional

responsiveness. There are no systematic studies of these children's social cognition skills. It is not known to what extent the physical features of VCFS underlie the social difficulties. For example, it is important to partial out the effects on social difficulties of poor language development and articulation from primary social cognition problems. Parents report that affected children avoid using conventional instrumental gestures, such as waving goodbye. They have unresponsive facial expressions (Swillen *et al.* 1999).

None of the studies that describe the VCFS neuropsychological profile includes a comparison group with similar levels of cognitive abilities, so any conclusions drawn must be made cautiously. The most consistently reported deficits include: arithmetic and maths; poor reading comprehension in relation to decoding skills; and possible expressive and receptive language problems. Motor and perceptual problems, visual spatial deficits, abstract reasoning and attention problems are also suspected to be characteristic of the syndrome, although they may simply be aspects of generalized learning difficulties. None of the studies has controlled for IQ in analyses exploring group deficits. However, psychiatric problems are common in childhood. For instance, Carlson *et al.* (1997b) found 4 of 6 children under 10 years had ADHD, 13 of 20 older subjects had symptoms of bipolar affective disorder (10 bipolar II and 3 bipolar I), and 4 of 6 in those over 20 years had psychotic symptoms. Only 2 of 26 had no psychiatric phenotype. These findings are astonishing, even allowing for a degree of ascertainment bias.

Genotype–phenotype correlations

No correlation seems to exist between the size of the 22q11 deletion and aspects of the phenotype, including psychiatric symptoms. There have even been cases of monozygotic twins with seemingly identical deletions and different phenotypes (Vincent *et al.* 1999). This indicates that other factors act in concert with the genetic anomaly to give rise to the clinical picture. Occasionally (~5%), patients with a VCFS phenotype have no FISH-detectable deletion. In such cases there may be a point mutation in a critical gene in the 22q11 region, or at another genetic locus altogether, indicating that the same developmental processes can be disrupted by multiple genetic or non-genetic means. One or several of the 50 genes within the typically deleted region may be implicated in the syndrome. Haploinsufficiency of *Tbx1*, a transcription factor, has been shown accurately to mimic the cardiac phenotype in mice (Lindsay *et al.* 2001a). Whether the same gene is responsible for the cognitive and behavioural features of VCFS has yet to be determined. Interestingly, it has been shown that all mice with a heterozygous deletion that includes *Tbx1* show abnormal aortic arch development early in embryogenesis, but only 32% of embryos still show abnormalities at birth (Lindsay & Baldini 2001b). This indicates that some form of compensatory mechanism can ameliorate early developmental disruption to a mesenchymal structure. Whether this is also true of the neuroectoderm that eventually becomes the central nervous system is not known.

Lesch–Nyhan syndrome

This devastating disorder, a recessive X-linked genetic anomaly that affects purine synthesis, was first reported over 30 years ago (Lesch & Nyhan 1964). Although the phenotype is usually caused by simple Mendelian inheritance of the recessive alleles, occasionally spontaneous mutations occur (Davidson *et al.* 1991). It is rare, occurring in no more than 1 in 10 000 live male births. Patients with the syndrome present with hyperuricaemia, choreoathetosis, dystonia and aggressive or self-injurious behaviour. The root cause of the disorder is the virtual absence of the enzyme hypoxanthine-guanine phosphoribosyltransferase (HPRT), which plays a crucial part in a pathway of purine synthesis. The effect of the disruption to purine metabolism is a serious deficit in dopaminergic functions in the brain (Ernst *et al.* 1996). The diagnosis is made by assaying fibroblast HPRT activity.

Genetic anomaly

The condition is caused by a mutation in the *HPRT* gene, which is found at Xq26-Xq27.2. Mutations may occur more frequently among males than females. Davidson *et al.* (1991) summarized the variety of known mutations, and found very many that can result in the Lesch–Nyhan syndrome. There is evidence that insertions and deletions, as well as point mutations can also be responsible for the phenotype (Renwick *et al.* 1995). There have been attempts to produce a mouse model of the disease, by means of inducing HPRT deficiency, and some success in evoking self-injurious behaviour (Wu & Melton 1993).

Cognitive and behavioural phenotype

At birth, children with the disorder (who are almost exclusively male, because of its sex-linked character) appear normal. There may be no evidence of motor or other developmental delay until the second or even the third year of life, when there is regression and often the onset of choreoathetotic movements. Affected infants are initially hypotonic; subsequently they become hypertonic and hyper-reflexic (Matthews *et al.* 1995). In middle childhood, the characteristic self-injurious behaviour is first manifested, and by the second decade nearly all children will display a range of neurological abnormalities including spasticity, choreoathetosis, opisthotonos, and facial dystonia together with pseudobulbar palsy. There has been some debate about the degree to which these clinical features are associated with mental retardation. Scherzer & Ilson (1969) took the view that intelligence was often in the normal range, and that specific impairment in expressive language could give a false impression, for receptive language skills were within the normal range; this view has been supported by more recent work (Anderson *et al.* 1992). On the other hand, Christie *et al.* (1982) found a significant range of problems on standardized IQ testing, in a moderately large sample of 19 individuals. Matthews *et al.* (1995) made a careful study of seven patients aged between 10 and 22

years. They found, on a wide range of tests carried out over several sessions, that intellectual levels varied from moderate global delay to low-average intelligence. Attention span was generally poor, as was working memory in a variety of domains. The authors suggested that although visual and verbal abilities are acquired during the first decade or so of life, there appears to be a ceiling on further development. The same team conducted a follow-up study 4 years later on the sample (Matthews *et al.* 1999), using standardized tests of verbal reasoning, abstract and verbal reasoning ability, quantitative and short-term memory skills. They confirmed their initial hypothesis that abilities did improve up until a mental age equivalent of about 13 years, but no further. This was reflected in a decline in age-standardized scores for the raw scores tended to remain constant over time. A relative strength was found in verbal reasoning ability and in vocabulary.

The self-injurious behaviour that is seen in this disorder presents a major challenge for management. Characteristically, the onset is in the preschool period, at 3 or 4 years of age. The child starts by biting lips and fingers, but in time the range of self-injurious behaviour increases and it is usually necessary to employ splints or other restraints for at least half of the time. Many children ask to be restrained. Strangely, punishment is ineffective and may even make the behaviour worse (Anderson *et al.* 1992). Anderson & Ernst (1994) reviewed the range of self-injurious behaviour found in a large sample of individuals with the syndrome. They found that there was no correlation between the degree of self-injury and age, but that it was severe and persistent in the great majority (at least 90%) of individuals with the confirmed diagnosis. Although biting of lips was one of the most common forms of self-injury it was not the only common form, and non-biting activities such as back arching and head snapping were equally prevalent. Finger biting was likely to be the first such behaviour to be observed in childhood. The majority did not show any cyclical variability in severity. Medical management may be most effectively provided with anticonvulsants, although there has not been any systematic evaluation of such treatments. Control of the excessively high purine levels by the prescription of allopurinol does not appear to have any beneficial effect on behavioural abnormalities (Christie *et al.* 1982).

Olson & Houlihan (2000) concluded that the most effective therapeutic interventions included differential reinforcement of (and especially incompatible) behaviours. The most common intervention is restraint which, interestingly, does not necessarily have to be unduly restrictive (e.g. light gloves may be as effective as splints). There is evidence that these steps can be successful, but the generalizability of techniques that are effective for single cases is open to question.

Genotype–phenotype correlations

Dopaminergic dysfunction lies at the heart of the disorder, as indicated by a variety of studies that have examined neurotransmitters and metabolites in brain tissues, blood and cerebrospinal fluid (Ernst *et al.* 1996). A mouse model for the

condition has been produced (Jinnah *et al.* 1994), which shows dopamine deficiency too. Ernst *et al.* (1996) concluded that the HPRT deficiency results in the loss of dopa decarboxylase activity, and reduced dopamine storage in dopaminergic brain regions. There was a neuropathological process that affected both dopaminergic nerve terminals and cell bodies, and probably involved mesocortical, mesolimbic and nigrostriatal dopaminergic pathways. As these pathways are believed to play a part in the regulation of cognitive, emotional and motor functions the authors suggested that their dysfunction could account for the wide range of abnormalities associated with the syndrome. They hypothesized that the profound decrease in dopamine is contributory to both the cause and the mediation of the aggression shown by many such patients towards self and colleagues. However, this cannot be the only explanation and they went on to speculate that it is the maldevelopment of certain neural pathways, beginning early in infancy, which are necessary for the full clinical picture to appear.

Cri du chat syndrome (5p syndrome)

Cri du chat syndrome is a microdeletion syndrome, with the loss of chromosomal material on the short arm of chromosome 5 at 5p15 (the name 5p syndrome is now preferred). The incidence has been estimated to be no more than 1 in 50 000 live births (Niebuhr 1978). The syndrome is associated with mental and developmental retardation from birth. There are several characteristic aspects of the physical phenotype, including slow physical growth, microcephaly, hypertelorism, epicanthic folds, a high-arched palate, and microretrognathia. The hallmark of the disorder is the infant's cry, which is high-pitched and has a mewling character that is quite distinctive once heard. The full phenotypic picture seems always to be associated with the deletion of at least 1–2 Mb at the 5p15 location, and it is assumed this is a classic contiguous gene syndrome. The location of the gene whose deletion leads to the cat-like cry may be distal to the other loci that account for the physical phenotype (Church *et al.* 1995). Most cases are caused by *de novo* deletions (which may be terminal or interstitial), with 80% paternal in origin (Church *et al.* 1995), or to structural rearrangements involving unbalanced translocations. The cognitive phenotype is very variable, even among those with an apparently identical deletion, and families have been reported with multiple affected generations in whom the anomaly was detected by chance (Kushnik *et al.* 1984).

Genetic anomaly

A molecular analysis of 17 cases of 5p deletions has been made by Church *et al.* (1995) in order to identify correlations of genotype with phenotype. Because the aim of the study was to link variability in the 5p phenotype to the location and extent of the genetic anomaly, virtually all the subjects studied had partial syndromes. A number of reasons were suggested for the phenotypic heterogeneity associated with the syndrome. These

potential reasons apply to a range of conditions that are associated with aneuploidy. There was the possibility that allelic variability of the normal chromosome affected the phenotype—and this was most strikingly evident from familial cases where the deletion was presumably identical in every instance. For example, recessive mutations on the equivalent part of the normal chromosome would be expressed phenotypically in regions that are hemizygous, and recombination would influence the characteristics of those regions. In order to discover just which genes contribute to the phenotype of this syndrome, it will be necessary to clone the genes lying within the critical region. These candidates could then be studied for their temporal and spatial expression; we would expect those that are associated with the cognitive and behavioural features of the disorder to be expressed early in development in the brain, for instance.

Cognitive and behavioural phenotype

The characteristic picture of profound retardation with minimal verbal abilities and severely delayed psychomotor development may partially reflect ascertainment bias (Cornish & Pigram 1996). One of the most careful evaluations of the cognitive abilities of children with 5p syndrome was conducted by Cornish *et al.* (1999). A group of 26 children between 6 and 15 years was studied, using standardized measures. Most were found to have both verbal and performance IQs below 50, and none was greater than 65. Both receptive and expressive language skills were retarded, the latter much more severely. Age-equivalent scores for expressive language among those who reached a baseline level ranged from 4 to 6 years, but receptive language was rarely better than a 2 year age equivalent. Articulation problems were severe, and limited the usefulness of the spoken language even among those who possessed it. In general, the results of this investigation mirrored those of previous studies (Dykens & Clarke 1997). Clearly, children with this condition should be encouraged to communicate by non-verbal means, and up to 50% are able to do so to a limited extent. Not surprisingly, the syndrome is associated with high levels of intrafamilial stress, and such stress is worse when children show high levels of maladaptive behaviours (Hodapp *et al.* 1997). Dykens & Clarke (1997) examined the correlates of such behaviour in a study of 146 individuals aged from 2 to 40 years. They found that the most frequent problems included excessive distractibility, restlessness and overactivity, intrusiveness, impulsivity and demanding behaviours. Many were aggressive and disobedient or unco-operative with instructions. Treatment with stimulants for hyperactivity and inattention sometimes resulted in an exacerbation of undesirable symptoms, including stereotypical behaviours and aggression to self and colleagues.

Both the physical and the cognitive/behavioural phenotype change quite markedly over time in this condition. The facial appearance changes from a round shape with hypertelorism to a longer slender face with normalization of the inner canthal distance (Niebuhr 1978). With advancing age, the hyper-

telorism becomes less marked, and the mandibular hypoplasia becomes less evident, although the microcephaly is more striking than before and the mandible becomes more prominent (Van Buggenhout *et al.* 2000). The outcome in early adulthood is also associated with spasticity in a minority, and with gait problems. Few adults with the condition are able to communicate verbally other than by means of very simple expressions, and it may be that frustration consequent upon the difficulty of making their needs known underlies the outbursts of aggressive and destructive behaviour that are observed from time to time.

Genotype–phenotype correlations

Dykens & Clarke (1997) found that those whose syndrome was caused by a translocation were less severely affected than those in whom it was caused by a microdeletion. In particular they were less likely to be socially withdrawn, although they were equally hyperactive, impulsive and irritable. Church *et al.* (1995) attempted to map the various phenotypic features of the syndrome to the location of the deleted segment of 5p15, and found the following. Speech delay was associated with distal deletions (down to the telomere) of 5p15.3. On the other hand, deletions in the more proximal band at 5p15.2 were associated with a cat-like cry, and the facial dysmorphology was probably associated with an even more proximal deletion within this same band. There have been attempts to map candidate genes within the critical region (Simmons *et al.* 1997). Simmons *et al.* (1998) suggested the human semaphorin F gene could play a part in the aetiology of the syndrome, for it seems to be involved with neuronal migration. Certainly, there is evidence for structural brain abnormalities in 5p syndrome (Kjaer & Niebuhr 1999), so this is a reasonable hypothesis. Nevertheless, we are still some way from identifying the number and identity of the genetic loci contributing to the complex range of phenotypes encountered in this rare but tragic condition.

Chromosomal aneuploidies

Down syndrome

The publication in 2000 of the DNA sequence of human chromosome 21 (Hattori *et al.* 2000) represents an enormous scientific leap in knowledge, from the original discovery in 1959, that an extra copy of chromosome 21 causes Down syndrome (Lejeune *et al.* 1959). The chromosome 21 gene catalogue reflects the realization of a longtime goal for many Down syndrome researchers (Reeves 2000). It also suggests that the total number of human genes may have been overestimated: in comparison to the previous estimates of between 70 000 and 140 000 genes (Fields *et al.* 1994), the chromosome 21 consortium accurately predicted approximately 40 000 genes (Hattori *et al.* 2000).

Down syndrome is the most common identifiable cause of learning disability, which is typically moderate to severe. The

estimated second trimester prevalence is currently approximately 1 in 500 (Egan *et al.* 2000), the risk increasing with maternal age. Physical features are well recognized: they include a shortening of all parts of the body; with a wide and flat face containing a small nose; abnormally shaped ears which may be low-set; and irregular teeth. The little finger is incurved, and the feet often display a wide gap between the first and second toes. Muscle tone is usually poor, and hypotonia is common. There are characteristic dermatoglyphic patterns, including the well-known single palmar crease. Down syndrome is associated with congenital heart disease, and an increased risk of specific leukaemias, immunological deficiencies and other health-related problems. Males have poorly developed genitalia, and they are invariably sterile; in females, ovarian structures are abnormal and menstruation is irregular (Mange & Mange 1990).

Genetic anomaly

The majority of individuals with Down syndrome have trisomy 21, resulting from chromosomal non-disjunction. In a small minority (1–5%) of cases the disorder results from a translocation of a portion of chromosome 21 to other chromosomes. The translocation may be inherited, whereas the most common Down syndrome genotype is non-familial. Mosaicism, with one trisomic and one normal cell line, is seen in approximately 1–2% of cases, and may be associated with a milder phenotype.

Chromosome 21 is the smallest human autosome, representing around 1–1.5% of the human genome. The sequencing of the chromosome provided evidence for 225 genetic loci: 127 known genes, 98 predicted genes and 59 pseudogenes (Hattori *et al.* 2000). The small number of untranslated genes may explain why Down syndrome is one of the only viable human autosomal trisomies (Hattori *et al.* 2000). Studies on transgenic mice suggest that dosage imbalance of only a proportion of the genes on chromosome 21 contribute to the Down syndrome phenotype (Kola & Hertzog 1997).

Cognitive and behavioural phenotype

The most notable aspect of the cognitive phenotype in Down syndrome is the marked mental retardation, with IQs typically in the 30–70 range (averaging around 50; Chapman 1999). Relatively poor expressive language and impaired verbal short-term memory are predominant aspects of the cognitive phenotype (Chapman & Hesketh 2000).

Tests of verbal short-term memory, such as digit or word span, consistently indicate impaired performance in individuals with Down syndrome, relative to mental-age-matched controls (Jarrold *et al.* 2000). In contrast, visuospatial short-term memory is relatively spared (Jarrold & Baddeley 1997; Jarrold *et al.* 1998). These findings have often been interpreted as indicating a specific deficit to the phonological loop component of Baddeley & Hitch's (1974) model of working memory in which the phonological loop component represents the system for processing verbal material, which is considered separate from the

system for processing visuospatial material (the visuospatial sketchpad). The phonological loop is fractionated into a limited capacity store and an articulatory loop. In Down syndrome, a deficit to the articulatory loop—absent or inefficient subvocal rehearsal—does not seem to explain the poor verbal short-term memory (Jarrold *et al.* 2000). This leaves a reduced capacity phonological store as a possible explanation for the poor verbal short-term memory in Down syndrome, though encoding difficulties have not been ruled out (Jarrold *et al.* 2000). As the phonological loop has a role in language development, particularly in vocabulary acquisition (Baddeley *et al.* 1998), there might be a link from the verbal short-term memory impairment to the language deficits in Down syndrome.

Infants with Down syndrome tend to reach early language milestones (first words, first two-word combinations) at an appropriate rate, given their overall retardation in cognitive development, but there are slower rates of development in expressive lexicon and syntax subsequently (Cardoso-Martins *et al.* 1985; Miller 1995; Caselli *et al.* 1998). Poor speech intelligibility, which is caused by problems with articulation (Pueschel & Hopman 1993; Kumin 1994), is common, as are associated hearing deficits (Roizen *et al.* 1993) which might play a minor part in the impaired development of speech skills (Chapman & Hesketh 2000).

Parents express rather fewer behavioural concerns about children with Down syndrome than do parents of age-matched children with mental retardation of unknown origin, or parents of children with other syndromes associated with equivalent degrees of learning difficulty, such as Prader–Willi syndrome (Chapman & Hesketh 2000). Compared to typically developing siblings, parents report more problem behaviours overall and, specifically, more attentional problems among children and adolescents with Down syndrome (Cuskelly & Dadds 1992; Stores *et al.* 1998). Adaptive behavioural skills are overall consistent with general intelligence (Chapman & Hesketh 2000).

It has been suggested that older adults with Down syndrome are subject to two stages of cognitive decline (Chapman & Hesketh 2000). The first stage, thought to correspond to the accumulation of senile plaques, involves problems in forming new long-term memories. A loss of overlearned behaviours characterizes the second stage, which is thought to result from marked neuronal cell loss.

In adulthood, Down syndrome is also associated with an increased risk of Alzheimer disease. Autopsy studies indicate the presence of brain amyloid (senile) plaques and neurofibrillary tangles that are characteristic of this disease (Wisniewski & Silverman 1998). Neuroimaging data show that dementia in older individuals with Down syndrome is associated with volume reductions in the amygdala and hippocampus, regions known to be affected in Alzheimer disease (Aylward *et al.* 1999). Despite the presence of the neuropathology of Alzheimer disease, observed in all individuals with Down syndrome over the age of 40 (Wisniewski *et al.* 1985), many of them demonstrate clinical features of dementia only when much older (Lai &

Williams 1989). Positron emission tomography data on older individuals with Down syndrome indicate abnormalities in cerebral metabolism in the parietal and temporal cortical areas (the first cortical regions typically affected in Alzheimer disease), when the functional demand on the brain is increased through audiovisual stimulation (Pietrini *et al.* 1997). These effects were observed before the onset of dementia and despite normal metabolism at rest.

Genotype–phenotype correlations

Duplication of a small region of the distal part of the long arm of chromosome 21 (21q22.1-22.3), termed the Down syndrome critical region, is associated with several of the physical features. These include the facial features, congenital heart disease and duodenal stenosis as well as some aspects of the learning difficulties. Candidate genes located within this region whose over-expression may be linked to the learning difficulties include *DRYK*, *DSCR1*, *DSCAM*, *TPRD* and *SIM2* (Chapman & Hesketh 2000). However, genes outside the Down syndrome critical region also seem to contribute to the full behavioural phenotype (Antonarakis 1998) so the picture is a complex one.

Genes that may contribute to dementia of the Alzheimer type in Down syndrome include the superoxide dismutase gene (*SOD-1*), which is associated with rapid ageing, and the beta-amyloid precursor protein gene (*APP*), which is associated with Alzheimer disease (Chapman & Hesketh 2000). Apolipoprotein E (*APOE*) alleles on chromosome 19 also influence the risk for Alzheimer disease: the E2 allele offers a protective effect in both Down syndrome (Lai *et al.* 1999) and in the general population (Corder *et al.* 1994). Although the reason for the protective effect of the E2 allele is not completely understood (Lai *et al.* 1999), it seems to be associated with the extent of beta-amyloid protein deposition (Polvikoski *et al.* 1995). In Down syndrome the *APOE* genotype seems to be linked to language ability too. Alexander *et al.* (1997) reported that language function was inversely related to *APOE* genotype in a sample of non-demented Down syndrome adults. The E2 allele, relative to the E4 allele, was associated with better language skills.

Transgenic mice with three or more copies of the mouse homologues of human chromosome 21 genes can serve as models for overexpression of particular genes. Segments of mouse chromosomes 16, 17 and 10 have homology to human chromosome 21. Mouse chromosome 16 includes the entire Down syndrome critical region. Several mouse models have been generated, which demonstrate some features similar to those observed in Down syndrome (Antonarakis 1998). Transgenic mice that overexpress individual human chromosome 21 genes have also been produced. The new techniques will enable the testing of hypotheses about the contributions of single genes, combinations of genes, or combinations of human chromosome 21 syntenic regions (Antonarakis 1998).

It is in these attempts to assess the contributions of specific genes to traits seen in Down syndrome that the chromosome 21 gene catalogue will have its greatest impact (Reeves 2000). The

catalogue now enables the hypothesis-driven selection of candidate genes, as well as a systematic search for sets of candidates without pre-existing hypotheses (Hattori *et al.* 2000).

Turner syndrome

Turner syndrome was first described by the endocrinologist Henry Turner in 1938, but it was not until 20 years later that the genetic basis of the syndrome was discovered. About 50% of clinically identified cases of Turner syndrome are associated with a single X chromosome, and subjects therefore have 45 rather than the usual 46 chromosomes (Jacobs *et al.* 1997). In the majority, there is loss of the sex chromosome donated by the father, and so the single normal X is maternal in origin. Nevertheless, the diagnosis of Turner syndrome is clinical, rather than based on the result of a genetic investigation.

The most striking physical characteristics include short stature, which is not caused by growth hormone deficiency as such but is associated with the deletion of the distal portion of the short arm of the X chromosome, which contains genes that are important for normal growth in stature (Rao *et al.* 1997). There is a failure of secondary sexual characteristics to develop in most cases, and oestrogen replacement therapy is now given routinely in adolescence. The ovaries fail to develop, and the uterus and vagina are often small and immature. Other physical features are much more variable, and include a webbed neck, a wide carrying angle, and broad chest, together with a characteristic facies (Lippe 1996).

The verbal intelligence of females with Turner syndrome is usually normal (Lippe 1996). Although specific cognitive deficits may exist, especially in visuospatial skills (McCauley *et al.* 1986; Ross *et al.* 1995; Skuse *et al.* 1997), the accepted view is that there is no increased risk of moderate or severe mental retardation. The exception is relatively rare cases with a small ring X chromosome (Dennis *et al.*, 2000; Kuntsi *et al.*, 2000). On the other hand, scattered reports over the past 20 years have also suggested that Turner syndrome is associated with psychosocial difficulties (Garron *et al.* 1978; McCauley *et al.* 1986; Downey *et al.* 1989), immaturity and poor self-concept (Hier 1980; Bender *et al.* 1987; Swillen *et al.* 1993; Rovet & Ireland 1994; McCauley *et al.* 1995). Some of these social adjustment difficulties persist into adult life (Downey *et al.* 1989).

Genetic anomaly

Most investigators believe that the phenotype in Turner syndrome is the result of a deficiency of specific genes, most of which are as yet unidentified, rather than to the consequence of a single X chromosome (45,X) *per se*. One-half of clinically identified cases possess part of a second X chromosome too, which is structurally abnormal, usually in association with some 45,X cells (Jacobs *et al.* 1997). Phenotypic features of Turner syndrome are thought to be caused by haploid (single and insufficient) dosage of these specific genes, rather than to the complete absence of gene products or the presence of abnormal products.

Monosomy (loss of one complete chromosome) in humans is normally lethal. It is thought that Turner syndrome is an exception because, in normally developing females, one X chromosome normally undergoes condensation and transcriptional silencing (X inactivation) very early in embryogenesis. Thus, only *one* X chromosome is normally active during most of development. If a single X chromosome is associated with a phenotype (Turner syndrome) this implies that in humans X inactivation is incomplete, and some essential gene products are transcribed from the 'silent' X chromosome too. A relatively large number of such genes are now known (Brown *et al.* 1997). It therefore seems likely that the genes involved in most features of Turner syndrome are X-linked and are not subject to X inactivation. They are needed in two expressed copies (diploid dosage) for normal development to take place (Zinn *et al.* 1993).

If X-linked genes are required in diploid dosage for normal development, how can we account for the situation in males who develop normally yet have only a single X chromosome? One possibility is that there are functionally equivalent genes on the Y chromosome. Rao *et al.* (1997) identified *SHOX*, a gene that contributes to the short stature associated with the syndrome, by molecularly characterizing a region at the tip of the X and Y chromosomes that is active on both sex chromosomes and contains homologous genes. They did this by studying a small series of male and female individuals with structural abnormalities and short stature, and comparing them to an equivalent series in which there was *no* height deficit.

In genomic imprinting the allele inherited from one parent is silenced, so that normal development is dependent solely on the function of the allele from the other parent. This imprint is normally erased at some time between generations. Female mammals have a maternally derived X chromosome (X^m) and a paternally derived X chromosome (X^p) in each cell, but in males the single X is invariably maternal in origin (X^m). Until very recently no imprinted gene had been described on the X chromosome in humans. However, there is now evidence suggesting imprinted X-linked genes play a part in the aetiology of some aspects of the behavioural phenotype of Turner syndrome. In 70% of monosomic (45,X) Turner syndrome the single X chromosome is maternal in origin (Jacobs *et al.* 1997); in the remainder it is paternal in origin. The single X chromosome in X monosomy is never inactivated. The strongest evidence is for an imprinted locus on the X chromosome that is preferentially expressed from the paternally inherited chromosome. If such a mechanism exists, it would lead to the preferential expression of a genetic locus in females, which was always normally silent in males (whose single X chromosome is always maternally derived). The imprinting mechanism is deceptively simple. The genetic locus is silenced when it is transmitted by a mother and is switched on when transmitted by a father. A mother passes a silent copy of the locus to both her sons and daughters, but fathers will only pass on an expressed copy to their daughters. There are various mechanisms by which an imprinted X-linked locus could result in sexual dimorphism in phenotypic characteristics. The nature of the dimorphism would depend not only

on the parental allele from which the imprinted genes were expressed. It would also depend on whether or not the alleles in question were subject to X inactivation (Lyon 1996) and whether or not there was a gene homologue (which was not imprinted) on the Y chromosome (Skuse 1999).

Cognitive and behavioural phenotype

Deficient visuospatial functioning is a reliable finding in Turner syndrome, first noted by investigators using standard IQ tests, who reported that performance IQ was impaired relative to verbal IQ, the latter being normal. Deficits in performance IQ, in copying complex designs, and in a speeded peg-moving task (a motor task with visuospatial demands) are seen in 45,X subjects. The underlying nature of the visuospatial deficit remains poorly understood (Temple & Carney 1995). 45,X subjects have substantial impairment in simple numerical tasks, including biologically based abilities to subitize and to compare number magnitudes (Alexander & Money 1966; Rovet *et al.* 1994; Temple & Marriott 1998; Butterworth *et al.* 1999). Face recognition ability is impaired, and this includes both the ability to recognize a familiar face and the detection of facial emotions (Ross *et al.* 1997). Buchanan *et al.* (1998) suggested there is a working memory deficit for visuospatial information in Turner syndrome that links impaired facial recognition to poor performance on arithmetic tasks.

Certain aspects of social behaviour are relatively less adaptive in 45, X^m compared to 45, X^p subjects on a 'social cognition' questionnaire (Skuse *et al.* 1997). Adjustment of 45, X^m females is poorer than for those with a 45, X^p karyotype in several aspects of behaviour (Skuse *et al.* 1999), as rated by parents, teachers and by the girls themselves on standardized instruments. Approximately 5% of all subjects have been found to have either childhood autism, or autistic features compatible with a broader phenotype. In all confirmed cases the normal X chromosome was maternal in origin. It is possible that there is increased vulnerability to autism in females who lack a normal paternally derived X chromosome (Creswell & Skuse 1999; Skuse 1999, 2000a; Thomas *et al.* 1999).

In an investigation contrasting the cognitive abilities of 45,X females whose single X chromosome was either paternal or maternal in origin, intriguing differences in memory dysfunction were discovered (Bishop *et al.* 2000). There was no significant impairment in immediate recall of verbally encoded information, presented in the form of a story, in either group, compared to normal females. However, those with a 45, X^m karyotype forgot the information relatively easily, whereas 45, X^p females did not differ from controls. On a non-verbal memory task, the Rey figure (Waber & Holmes 1985, 1986), the complementary pattern was seen. Both 45, X^m and 45, X^p females had visuospatial problems that affected their ability to copy the complex figure. However, those with a 45, X^p karyotype showed a disproportionate amount of forgetting when asked to redraw it from memory after a delay, whereas those with a 45, X^m karyotype did not differ from normal controls. The implication from these

findings is that imprinted X-linked genes may contribute to the development of distinct cognitive brain systems, and that verbal and visuospatial memory can be genetically disassociated.

Investigations of the neuropathology of Turner syndrome are limited to a small number of autopsy studies with heterogeneous findings, including abnormalities of cerebral cortical organization and developmental deviation of structures in the posterior fossa (Reske-Nielsen *et al.* 1982; Della Giustina *et al.* 1985). Brain structure in Turner syndrome has also been investigated with imaging techniques. These have reported changes in the parieto-occipital region (Reiss *et al.* 1993), and also in subcortical structures, especially the hippocampus (Murphy *et al.* 1993; Reiss *et al.* 1995). Attempts to link the findings of structural brain imaging to deficits in cognitive functioning have not previously been fruitful. One potentially confounding variable is ovarian dysgenesis, which is almost invariable in cases of X monosomy (Lippe 1996). Exogenous oestrogen has to be provided to induce secondary sexual characteristics, and this may have independent structural and functional effects on the central nervous system (Ross *et al.* 1995). Other potential confounding variables include X chromosome mosaicism, an excessively wide age range, and sociocultural or educational heterogeneity.

When contrasts are made between individuals with Turner syndrome and normal females, it is not possible to distinguish the behavioural effects of former oestrogen deficiency from that of haploinsufficiency for X-linked genes (Zinn & Ross 1998). Ross *et al.* (1997) showed that some non-verbal tasks and motor-related skills are performed more rapidly by oestrogen-treated subjects. Structural changes consequent upon oestrogen deficiency have been demonstrated in the hippocampus of the rat (Gazzaley *et al.* 1996) and the hormone could have a broader role in gene regulation in the brain (Toran-Allerand *et al.* 1999). However, differences in brain structure and associated cognitive functions between Turner females whose single X is paternal or maternal in origin could not be caused by oestrogen, or any other endocrine deficiency. Growth hormone treatment does not influence the cognitive function of Turner females (Ross *et al.* 1997).

Genotype–phenotype relationships

Many phenotypic features of Turner syndrome are caused by haploinsufficiency for a gene, or several genes, that are expressed from both X chromosomes in normal females (and not subject to X inactivation) and which may have homologues on the Y chromosome. Using molecular methods, it is possible to map the breakpoints in structural anomalies of the X chromosome, in samples of isochromosomes (James *et al.* 1997; Dalton *et al.* 1998), partial deletions of the short arm of the X chromosome (James *et al.* 1998), and also ring chromosomes (Dennis *et al.*, 2000). More detailed information is needed on the cognitive and behavioural phenotypes of these structural anomalies, in order to correlate systematic variations with the nature and extent of chromosomal material that has been lost. This technique is known as deletion mapping, and was successfully

applied in a study of minor X-linked structural anomalies by Rao *et al.* (1997). The methods they employed for deletion-mapping an X-linked gene (*SHOX*) that influences growth in stature, is also potentially applicable to phenotypes such as cognition (Ross *et al.* 1997).

Klinefelter syndrome

Klinefelter syndrome, first described in the 1940s, is caused by an extra X chromosome in males that can be either maternal or paternal in origin. It occurs with remarkable frequency, perhaps as many as 1 in 500 male live births (Smyth & Bremner 1998). The physical phenotype is often not apparent until after puberty, and it is very variable. Tall stature is usual, with long limbs. Testis development is characteristically inadequate, and the majority of affected men are infertile. Learning difficulties may lead to identification in childhood but, if not, diagnosis is likely to be delayed until infertility raises concerns. Our own cytogenetic laboratory data suggest that very few cases are identified in childhood, with the majority probably never identified clinically at all.

Genetic anomaly

There is considerable variability in the cognitive and behavioural phenotype, but this is not caused by mosaicism. In fact, mosaicism for a normal 46,XY cell line is unusual in Klinefelter syndrome, indicating that the genetic anomaly must have occurred at an early stage of development. The great majority are thought to be a result of non-disjunction, either in the formation of gametes in mother or in father. There is no paternal age effect, but there may be a slightly increased risk of non-disjunction in older mothers.

Cognitive and behavioural phenotype

Klinefelter syndrome is not closely associated with mental retardation, although there is a tendency for cases that have been detected in childhood, other than by antenatal screening, to have learning difficulties. Bender *et al.* (1999) reported a follow-up into young adulthood of an unselected sample determined from a consecutive birth cohort. The mean full-scale IQ was 91, significantly lower than a comparison group.

Features such as ‘more tender-minded, passive’ (Mandoki *et al.* 1991) have been reported for some, whereas others are said to be aggressive with poor impulse control (Netley 1991). To date there have been no systematic attempts to link the phenotype to the parental origin of the additional X chromosome, which is maternal or paternal in equal proportion. A preliminary investigation by Ratcliffe *et al.* (1990) found no relationship between the parental origin of the additional X chromosome and either verbal or non-verbal abilities. Most studies of the syndrome have recruited children and adolescents, although it would be important to have follow-up information on adult outcomes.

Geschwind *et al.* (2000) reviewed the neurobehavioural phe-

notype. There is a tendency for verbal abilities to be lower than non-verbal abilities (Mandoki *et al.* 1991; Rovet *et al.* 1996). This provides an interesting contrast to the situation in X monosomy (45,X), in which the reverse pattern is found. Geschwind *et al.* (2000) commented that there is an association with specific impairments in language, arithmetic and frontal-executive functions—such as the tendency to make perseverative responses on the Wisconsin Card Sort test. However, others have not found this (Bender *et al.* 1995).

Longitudinal studies show fundamental language processing difficulties in up to 80% of Klinefelter males and a specific reading disability in up to one-half (Graham *et al.* 1988). Besides a general language delay, there may be more specific difficulties in articulation, verbal fluency and possibly auditory working memory. These latter problems may persist into adulthood.

The condition seems to be associated with introversion and social withdrawal (Sorensen 1992), but also with aggressive behaviour and social maladjustment (Bender *et al.* 1999). Geschwind *et al.* (2000) speculated that the more disinhibited forms of Klinefelter syndrome, which are associated with attention deficits and hyperactivity in many cases, are caused by dysfunction in frontal brain neurocognitive systems. Testosterone is used clinically to encourage sexual maturation, but the impact on behaviour or cognition is uncertain. In Bender *et al.*'s (1999) unbiased sample, there was no evidence on standard measures of maladjustment but about half had been diagnosed with mild to moderate psychiatric disorders during adolescence (Bender *et al.* 1995). The evidence on motor skills is contradictory, with some reports suggesting impairment (Salbenblatt *et al.* 1989; Geschwind *et al.* 2000), but others not (Bender *et al.* 1995).

Patwardhan *et al.* (2000) published the first detailed report on brain morphology in the condition. Inevitably the sample size was small (just 10 subjects) because they recruited an unbiased sample. In general, the Klinefelter syndrome group had a significant reduction in the grey matter of the left temporal lobe compared with 46,XY normal comparison subjects. The extent to which this reduction occurred appeared to be associated with testosterone supplementation. These findings echoed, to some extent, those of another structural MRI study conducted by Warwick *et al.* (1999), who compared 10 47,XXY males with 47,XYY and 46,XY males. They found Klinefelter males had smaller brains than normal controls, and bilaterally enlarged lateral ventricles relative to whole brain volume. There were no significant differences in right or left temporal lobe volume between all three groups. However, inspection of the data shows the mean volume of the left temporal lobe was approximately 12% less in the Klinefelter group than normal males, and the magnitude of difference was slightly greater on the right. If these findings are generalizable, it is possible that they do provide some basis for understanding the origin of the verbal deficits associated with the syndrome.

Other sex chromosome aneuploides

There have been relatively few reports on Klinefelter syndrome,

given how commonly it occurs in liveborn males, but there are even fewer on the other relatively common sex chromosome aneuploides, 47,XXX and 47,XYY syndromes. In the classic Edinburgh-based UK study of sex chromosome anomalies 34 380 consecutive live births were screened (Ratcliffe 1994). This showed the prevalence of both XYY and XXX syndromes to be about 1 in 1000, slightly less common than Klinefelter syndrome, but far less likely to be encountered in clinical practice. Boys with an XYY karyotype are likely to be taller than average (probably caused by overexpression of the *SHOX* gene; Rao *et al.* 1997; Ogata *et al.* 2000). They may have slightly poorer motor co-ordination than control males, and are also more likely to have delayed speech development, although intelligence is virtually normal (Ratcliffe 1994). There is an increased rate of overactivity and impulsivity. It may be that a form of ADHD impairs their ability to cope with an educational curriculum, and there is evidence of a reading level significantly behind that of their peers. Remedial support, especially in reading, was required for about half the cohort identified by Ratcliffe (1994) and in a comparable study in Boston (Walzer *et al.* 1990).

Boys with an XYY karyotype are not much more aggressive or difficult to manage than other children (Ratcliffe 1994) but there is some increase in antisocial behaviour and psychiatric referral (nearly half of cases)—usually for oppositional/defiant or conduct problems. Sexual development is normal. In the only study to have examined brain structure in this condition, Warwick *et al.* (1999) report no significant differences from controls.

Females with 47,XXX syndrome are likely to be smaller than normal at birth, in terms of birth weight, length and head circumference (Ratcliffe 1994). The size of the head correlated with later IQ, and no catch-up in this variable was observed as Ratcliffe's cohort was followed into adulthood. As is the case for boys with additional sex chromosomes, stature is significantly greater than for typically developing females at the same age. In this sample, there were associated problems in fine motor co-ordination and balance.

47,XXX syndrome is associated with a degree of mental retardation which amounts to about one standard deviation below normal, in respect of verbal IQ (Bender *et al.* 1995). Performance IQ is less impaired—an interesting comparison with Klinefelter syndrome—and quite distinct from the situation in X monosomy. There is no evidence of a deterioration over time in cognitive skills. Remedial help at school was required for over two-thirds of the sample in the Ratcliffe (1994) cohort study, and that was mainly concerned with reading retardation as a consequence of the lowered IQ.

There is little objective information on the behavioural and emotional adjustment of 47,XXX females. Anecdotally, they are said to be emotionally less mature than their peers, and to have particular difficulty relating to others in group situations. They will be taller than their peers throughout childhood, and adult stature is also a little above average. Pubertal development takes place at the normal time, and the condition is not associated with infertility. It is worth bearing in mind that adults tend to use

stature as a yardstick by which to judge children's age. Those children who are tall for their age, as will be the case for most 47,XXX females, will be judged older than they actually are and will be expected to behave accordingly. As it is likely that the girls in question are going to have relatively poor verbal skills in comparison with their peers, and perhaps also to be somewhat emotionally less mature, the discrepancy between expectations and behaviour could lead to conflict, and other undesirable consequences. However, there is no evidence of any specific forms of behaviour problem being associated with this syndrome, and the vast majority of cases go undetected throughout their lives.

Conclusions

The challenge in developing a truly scientific nosology of child psychopathology is to bring together expertise from multiple complementary disciplines. Such a plea has already been expressed in respect of adult psychiatric disorders, and the study of schizophrenia in particular. Andreasen (1999) argued that the phenotype of this archetypal psychiatric illness should be defined in terms of abnormalities in neural circuits and fundamental cognitive processes. Cognitive psychology has aimed to divide the adult mind into component domains, such as perception, language and executive functions, often employing evidence from lesions to determine localization by observing the absence of function after injury. It is arguable that the very plasticity and flexibility of the developing child's central nervous system makes it less susceptible to study by that approach (Karmiloff-Smith 1998). If we could identify the genetic mechanisms that guide neurobiological systems of development, we could begin to understand the origins of the cognitive dysfunction that underlies much child psychiatric disorder. In a discipline for which there are few if any clear boundaries between 'disease' and 'normal' states of mind, categorical disease (or disorder) models may not be appropriate for the investigation of these putative genetic mechanisms. We suspect the genetic predisposition to certain cognitive deficits, particularly those underlying social communicative skills, will eventually be found to underlie a wide range of neurodevelopmental disorders.

Accordingly, in the search for genes that predispose to the development of child psychiatric disorders it may make little sense to seek the genetic components of relatively amorphous diseases (still less 'comorbid' disorders). Rather, we should look for the genetic basis of cognitive processing deficits that may be common to a number of diseases or disorders. Creating a heuristic cognitive model of developmental disorders will in due course lead to the integration of disciplines, and this is already happening in child psychiatry to some extent. We need to learn how genes control neurobiological development and, in so doing, increasing use will be made of animal models (Skuse 2000a). The appropriate use of behavioural phenotypes could guide the development of such models. Studies of the genetic influences upon specific cognitive processes could reveal 'double dissociations', analogous to the procedure used by cognitive

neuroscientists to contrast cognitive profiles among groups with distinct brain lesions (Young *et al.* 2000). In other words, we could discover, through the appropriate use of behavioural phenotypes, that certain cognitive systems are influenced by relatively independent genetic mechanisms. Were it possible to generalize this technique with the discovery of other genes for specific cognitive functions (which may in turn have neuro-behavioural consequences), a more rational and scientific basis for the classification and treatment of child psychiatric disorders could be developed.

In conclusion, specific cognitive phenotypes can be found in individuals with genetic disorders, but they are not isolated deficits. They are associated with behavioural, personality and other psychological characteristics, which make the identification of features which are causally related to the genetic anomaly difficult. It is rare to find examples of such phenotypes in which the cognitive deficit is explicit, and such specificity is likely only to be found in association with a single gene mutation (such as the language disorders in the KE family, see above).

We may be sceptical about the degree to which even very well-studied disorders with a known genetic aetiology and cognitive or psychiatric phenotypes have yet told us much about the development of the brain. Flint (1999) discussed autosomal Mendelian disorders that have cognitive disabilities in their phenotype. He commented that the study of these disorders has told us nothing about how genes affect cognitive processes. Take, for instance, the neurodegenerative disorders, such as cortical and subcortical dementias. The relatively specific deterioration in memory in Alzheimer disease might suggest that genetic analysis could lead to new advances in our understanding of the biology of memory, but this has not been the case. Nor, he commented, has the cause of the cognitive decline in Huntington disease been explained, despite the fact that there is a relatively specific neuropathology, which affects the caudate nucleus, the putamen and the globus pallidus. A mouse model has been developed, which apparently shows that there is altered expression of multiple neurotransmitters in the condition which cannot be explained on the basis of the dysfunction of a particular cell type (Cha 2000). Molecular genetics, developmental neurobiology and cognitive neuroscience have not yet been integrated into a satisfactory causal model of disease in any single condition, but the potential is there.

Introduction

This chapter focuses on the psychiatric consequences of childhood brain disorders, including epilepsy. It offers no more than a few glimpses of the interesting but largely unexplored territory that has variously been called ‘organic child psychiatry’, ‘paediatric behavioural neurology’, and ‘developmental neuropsychiatry’. Our current knowledge of the childhood links between brain and behavioural disorders is extremely sketchy, partly because of limitations in the ‘parent’ disciplines of child psychiatry and paediatric neurology. Readers who appreciate how little is known about the classification, aetiology, course and management of child psychiatric disorders may be surprised to learn that the situation is no better for most of the common neurological disorders of childhood. The classification of seizure disorders has changed repeatedly, and the existence and nosological status of many named syndromes (such as the Lennox–Gastaut syndrome) remains controversial. The classification of cerebral palsy is also problematic. Everyone agrees that cerebral palsy should be thought of as a group of disorders rather than a single disorder, but there is much less agreement about what to include under that rubric, or how to subclassify the varieties of cerebral palsy. In these areas, paediatric neurology has lagged at least two decades behind child psychiatry in the use of epidemiological samples and multivariate statistics to refine clinical classification. Cerebral palsy also exemplifies many of the uncertainties in paediatric neurology about aetiology, course and management. What causes cerebral palsy? What becomes of children with cerebral palsy when they grow up? Is very intensive physiotherapy more effective than less intensive alternatives? None of these questions can be answered satisfactorily at present.

This dismal account of the state of paediatric neurology is not the whole story. In some areas, much has already been learned and progress is rapid. This is true, for example, of the biochemistry and molecular genetics of many neurodegenerative and neuromuscular disorders. However, most of these disorders are rare and advances in the assessment and management of common neurological and neurosurgical problems are less impressive. In this context, it is bound to be difficult to make sense of the links between brain and behavioural problems in childhood. For example, given the crude and changing classifications of both psychiatric disorders and epilepsy, it is obviously harder to examine the psychiatric correlates of epilepsy. These difficulties are not mentioned to discourage readers, but to put them on

their guard against simplistic conclusions drawn from inadequate data.

Brain damage?

This chapter is deliberately entitled ‘brain disorders’ rather than ‘brain damage’. The term ‘damage’ suggests that the brain was developing normally until something happened to damage it. This is accurate in some instances: athetoid cerebral palsy following rhesus haemolytic disease; hydrocephalus following tuberculous meningitis; epilepsy following a penetrating head injury; and so on. In other instances, however, brain development may have been abnormal from the beginning, rather than proceeding normally until derailed by some insult. Brain abnormalities can be caused by inherited disorders, new mutations and chromosomal aberrations. The power of language is such that an ill-chosen term, such as ‘brain damage’, can seriously distort clinical and scientific reasoning. Once children with cerebral palsy or mental retardation are labelled as ‘brain damaged’, parents and researchers tend to assume that the cause must be some insult, such as a difficult birth, and the possible role of genetically or chromosomally determined malformations tends to be forgotten. As far as the common brain disorders in childhood are concerned, we do not even know if acquired or intrinsic aetiologies are more important.

Another disadvantage of the term ‘brain damage’ is that it suggests permanence to anyone who has been taught that the brain cannot regenerate lost or damaged parts. This connotation of irreversibility is potentially misleading (see also Rutter, Chapter 19). For example, children do commonly grow out of epilepsy and may even grow out of cerebral palsy (Taudorf *et al.* 1986). In some instances, reversible brain disorders may arise not from fixed abnormalities of neuronal organization but from delayed or precocious neuronal maturation. It is plausible but unproven, for instance, that transient childhood epilepsy reflects temporarily delayed development of inhibitory neurotransmitter systems, or prematurely accelerated development of excitatory systems. Once again, ‘damage’ is too narrow a concept to embrace all possible brain disorders.

Birth damage

The best known ‘brain damage’ theories are those that

emphasize birth damage. Generations of medical students have been taught that cerebral palsy, epilepsy and severe learning difficulties (mental retardation) are commonly caused by perinatal complications. This view is almost certainly false. Obstetric and neonatal complications are common but are generally innocuous. Thus, in one study based on detailed records, over half the *normal* controls had experienced one such complication (Jacobsen & Kinney 1980).

Even severe perinatal complications are usually harmless. In one prospective study, for example, children who had an Apgar score of 3 or less at 5 min after birth were roughly 30 times more likely to be neurologically normal at the age of 7 years than to have cerebral palsy (Freeman & Nelson 1988). The same study showed that only 21% of children with cerebral palsy had at least one of three markers suggestive of birth asphyxia (Nelson & Ellenberg 1986). Even among the children with cerebral palsy who did experience birth asphyxia, many had congenital malformations or microcephaly at birth, suggesting that these fetuses were already abnormal before labour began (Nelson & Ellenberg 1986). This suggestion is reinforced by Miller's (1989) study of 36 patients with ataxic cerebral palsy: 25 of these patients had multiple minor congenital anomalies, suggesting that development had already gone awry in the first half of pregnancy, and 16 of these 25 also experienced perinatal or early postnatal complications.

Because the fetus is an active participant in the delivery process, and not simply a passive passenger who is expelled when his or her time is up, it is not surprising that an abnormal fetus is particularly liable to an abnormal birth. It is possible that perinatal complications compound whatever damage has already occurred prenatally, just as labour may compound the existing damage in spina bifida (Luthy *et al.* 1991). Alternatively, perinatal complications may simply be harmless markers for an abnormal fetus. This 'harmless marker' possibility is supported by findings that cerebral palsy rates in children born at term have been fairly steady over the recent past, despite major advances in perinatal management and a dramatic fall in perinatal mortality (Paneth & Kiely 1984; Hagberg *et al.* 1996). If perinatal complications commonly converted normal or vulnerable fetuses into children with cerebral palsy, improvements in obstetrics and neonatal paediatrics should have resulted in a clear fall in the rate of cerebral palsy—and this does not seem to have occurred.

Although this account has focused on the extent to which birth complications are largely irrelevant to cerebral palsy, probably accounting for fewer than 10% of cases (Nelson & Ellenberg 1986), similar considerations may apply to severe learning difficulties (mental retardation). Thus, Rantakallio & von Wendt (1985) described a high rate of perinatal complications in children whose severe learning difficulties were genetic or chromosomal in origin. Had the prenatal origin not been established in these cases, it is easy to imagine that the perinatal complications would have been blamed for the learning difficulties. For epilepsy too, prenatal risk factors seem far more important than perinatal risk factors (Wallace 1992).

These new views on the relationship between birth complications and brain damage are clearly relevant to obstetricians, paediatricians and their lawyers. The findings also carry two important lessons for child psychiatrists. First, neurological theories about aetiology are as error-prone as psychiatric theories—psychiatrists should not be too willing to take neurological theories on trust simply because neurology is a high-status discipline. Secondly, if birth complications are not common causes of overt brain disorders, such as cerebral palsy, it is even less likely that birth complications commonly result in 'minimal brain damage' manifesting solely in behavioural or learning difficulties. Child psychiatrists who make detailed enquiries about obstetric and neonatal complications will often elicit positive histories from the parents of their patients (as they would from the parents of normal children). This information may be clinically useful, e.g. when it reveals that the father blames the mother for their child's behavioural problems because she chose to have an epidural and this made a forceps delivery necessary. It is important that child psychiatrists do not fall into the same sort of trap, pinning the blame on birth complications without scientific justification. The combination of birth complications and psychiatric problems will often occur by chance because both are common in the general population.

Is there any truth in the notion of 'minimal brain damage'? Do birth complications sometimes cause brain damage that results in psychiatric symptoms but no neurological signs? There is no reason to suppose that this sort of causal link is at all common (Goodman 1993), except in the special case of children born very prematurely. Follow-up studies of children born weighing less than 1500 g show that even when those with overt neurological disorders are excluded, there is a consistently higher rate of attention deficit hyperactivity disorder (ADHD), with less evidence for an increase in the rate of conduct or emotional disorders (Breslau 1995; Chapieski & Evankovich 1997; Wolke 1998). The increased rate of ADHD primarily reflects problems with inattention rather than with hyperactivity or associated behavioural problems (Wolke 1998). Szatmari *et al.* (1993) suggest that the excess of ADHD is entirely explained by the lower IQ of very prematurely born children; the children are no more inattentive than would be expected for their IQ. By contrast, the findings of Whitaker *et al.* (1997) suggest that the excess of ADHD is only partly explained by the link with lower IQ; after adjusting for gender and social disadvantage, very prematurely born children of normal intelligence had elevated rates of ADHD as well as tics and separation anxiety. Studies using neonatal ultrasound scans have shown that the periventricular white matter damage that particularly commonly occurs in children born before 28 weeks' gestation is strongly associated with subsequent cognitive and psychiatric problems, even when the children do not develop overt neurological disorders (Whitaker *et al.* 1996, 1997). When the white matter damage in very prematurely born children results in cerebral palsy, this is associated with an especially high risk of comorbid psychiatric problems (see below).

How to recognize a hardware defect

If a computer is not working properly, three sorts of explanation need to be considered:

- 1 the computer is being used inappropriately;
- 2 there is a 'software' problem in the way the computer has been programmed; or
- 3 there is a 'hardware' fault in the electronic circuits.

Although the analogy is crude, three similar sorts of explanation need to be considered, singly or in combination, for a child's psychiatric problems:

- 1 the child's social world is making inappropriate demands on him or her;
- 2 the child has learned or internalized maladaptive ways of being in the world; or
- 3 the child has an abnormal brain.

This is an oversimplification, of course, but it is a useful starting point. Parents and professionals have a shared interest in establishing how far a child's problems can be attributed to underlying 'hardware' defects in the child's brain. The issue is potentially relevant to further investigations, referral to a paediatrician or paediatric neurologist, prognosis and treatment—not to mention the question of blame. There are several sorts of pointers to a hardware defect. Some of these pointers are persuasive while others are best ignored. In a rough and ready sort of way, it is worth distinguishing between six sorts of pointers.

1 Brain abnormalities are most convincingly inferred from the sorts of evidence acquired in a standard neurological assessment, e.g. a clear-cut history of seizures, the signs of a spastic diplegia, an unequivocally abnormal electroencephalogram (EEG), or a focal lesion on computed tomography (CT) or magnetic resonance imaging (MRI) scanning.

2 Less weight can be placed on 'soft neurological signs' (mostly reflecting immature motor development), abnormal neuropsychological profiles, or abnormalities of derived neurophysiological measures. In each case, abnormalities add extra weight to the suspicion that something is wrong with the child, but these abnormalities do not prove that the something is the child's brain (Goodman 1993).

3 Brain abnormalities may also be inferred from a history of exposure to the sorts of insults that can damage the brain, e.g. a head injury, an encephalitic illness or high-dose cranial irradiation. There are several potential problems with this sort of inference. First, some members of a high-risk group may escape unscathed. Secondly, changes in behaviour after a potential brain insult may be mediated by maladaptive parental responses (such as overprotectiveness or inconsistent discipline) rather than by biological damage. After mild head injuries, for example, the increased rate of child psychiatric disorders seems to owe more to disrupted parenting than to acquired brain damage (Hjern & Nylander 1964). Finally, when risk factors for brain injury are associated with psychiatric problems, it may be unclear what is cause and what is effect. For example, it is equally plausible a priori that head injury leads to hyperactivity, that hy-

peractivity and impulsiveness lead to head injury, or that some third factor, such as psychosocial disadvantage, independently predisposes a child to both head injury and hyperactivity.

4 There is accumulating evidence that genetic factors play an important part in at least some child psychiatric disorders (Rutter *et al.* 1999; see McGuffin & Rutter, Chapter 12). Although this genetic liability may be mediated by an inherited hardware fault in the child's brain, this is not necessarily the case. In a prejudiced society, for example, genes for skin pigmentation, short stature or adiposity may be risk factors for peer rejection, low self-esteem, and secondary behavioural problems that have nothing to do with brain abnormalities.

5 When a child develops psychiatric problems despite apparently favourable home and school circumstances, it is tempting to suppose that the child's problems are biological in origin. This is a very weak argument. Until relatively recently, this sort of argument led to the consequences of child sexual abuse being attributed to constitutional factors in the child. Absence of proof of psychosocial causation is not proof of absence.

6 The presence of a specific behavioural syndrome is sometimes taken as suggestive or even sufficient evidence that the child has an abnormal brain. This is rarely warranted because few behavioural syndromes are commonly associated with *independent* evidence of underlying brain abnormalities—the exceptions being progressive dementia, severe learning difficulties (mental retardation), and perhaps autism. Inferring 'minimal brain damage' or 'minimal cerebral dysfunction' from common child psychiatric problems is currently no more than an exercise in faulty reasoning. Thus, although it is true, as described later in this chapter, that neurologically impaired children are particularly prone to hyperactivity, it does not necessarily follow that all hyperactive children have brain damage. (Consider the logic of: people with strokes are prone to limp, so anyone with a limp must be suffering from a stroke or a 'minimal stroke'.)

Given the potential difficulties in deciding whether or not a child does have a hardware defect, the following sections on the links between brain and behavioural problems are based on studies of children with the best authenticated brain abnormalities, as established by the first set of criteria on the preceding list.

Brain disorders increase the risk of child psychiatric disorders

The neuropsychiatric component of the classical Isle of Wight epidemiological study showed that brain disorders are powerful risk factors for psychiatric disorders: the rates of psychiatric disorders were 44% among children with structural brain disorders and 29% among children with idiopathic epilepsy, as compared with just 12% among children with non-cerebral physical disorders and 7% among children free from physical disorders (Rutter *et al.* 1970). The finding that cerebral disorders carry a much higher psychiatric risk than non-cerebral disorders strongly suggests direct brain-behaviour links in addition to the risks attendant on any chronic or stigmatizing

disorder. This conclusion was supported by a companion study (Seidel *et al.* 1975) that compared children who had cerebral disorders with a matched group of children disabled by other disorders (mainly musculoskeletal). The children with cerebral disorders were twice as likely to have psychiatric problems, even though children with an IQ of under 70 were excluded from both groups, and the two groups were well matched for social background and degree of physical incapacity. Many other studies have since confirmed that psychiatric problems are more likely to result from brain disorders than from other physical disorders (Breslau 1985; Howe *et al.* 1993; Austin *et al.* 1996). Different brain disorders increase psychiatric risk to different extents, e.g. the higher risk associated with structural brain disorders than with idiopathic epilepsy in the Isle of Wight study.

Although the evidence that brain abnormalities increase the risk of child psychiatric disorders is persuasive, it is important to remember not only that many children with brain disorders are free from psychiatric problems, but also that the great majority of children with psychiatric problems are free from overt brain disorders. In the Isle of Wight study, for example, 65% of the children with cerebral palsy or epilepsy had no psychiatric disorders, and fewer than 10% of the children with psychiatric disorders also had definite brain disorders (as judged by the presence of epilepsy, severe mental retardation, cerebral palsy and related disorders).

At risk for which psychiatric disorders?

There is a long-running controversy about the extent to which brain disorders are specific risk factors for particular sorts of psychiatric problems, as opposed to non-specific risk factors for all types of psychiatric problems. It is now clear that the truth lies between these two extremes: brain disorders increase the risk of most psychiatric problems, but not to the same extent. For example, hyperkinesia was particularly over-represented among children with cerebral palsy or epilepsy in the Isle of Wight study (Rutter *et al.* 1970). Thus, while the overall prevalence of psychiatric disorders was about seven times higher in children with brain disorders than in neurologically intact children, the prevalence of hyperkinesia was about 90 times higher. The conclusion that neurological factors do influence the type of psychiatric disorder is supported by numerous studies reporting associations between particular brain abnormalities and specific psychiatric disorders, e.g. between tuberous sclerosis and pervasive developmental disorders (Hunt & Dennis 1987; Hunt & Shepherd 1993), between Sydenham's chorea and obsessive-compulsive disorder (Swedo *et al.* 1989; Asbahr *et al.* 1998), between developmental abnormalities of the temporal lobe and schizophrenia (Taylor 1975; Ounsted *et al.* 1987), and between hemiplegic (but not diplegic) cerebral palsy and hyperkinesia (Ingram 1955). When the neurological disorder is genetic, as in the case of tuberous sclerosis, the associated psychiatric problems are increasingly referred to as part of the 'behavioural phenotype'

of the underlying genetic disorder (see Skuse & Kuntsi, Chapter 13)—a term that would be misleading if it was taken to refer to an invariable link rather than some degree of statistical association.

Left vs. right hemisphere syndromes?

As asymmetrical specialization of the two cerebral hemispheres is evident in early childhood and even in prenatal life (Goodman 1994), it is certainly plausible that unilateral brain disorders could have different effects on the rate and type of associated psychiatric disorder depending on which side of the brain is affected. Such laterality differences have indeed been reported, but these positive reports have typically derived from small series of children, often attending specialized clinics. Such reports may well be capitalizing on the effects of chance in small and atypical samples—a possibility that is rendered all the more plausible by the contradictory nature of these reports. Thus, while Voeller (1986) described a high rate of hyperactivity in children with right-sided lesions, Stores (1977) reported that boys (but not girls) were more likely to be hyperactive if they had left-sided epileptic foci. Similarly, while Sollee & Kindlon (1987) found an association between left hemisphere lesions and externalizing problems, Nass & Koch (1987) found an association between right hemisphere lesions and the sort of difficult temperament associated with later conduct problems.

Studies of larger or more representative samples have not generally suggested any laterality effects on child psychopathology. Thus, the rate of hyperactivity was not influenced by the laterality of lesion in several large studies of children with brain disorders (Ingram 1955, 1956; Ounsted 1955; Rutter *et al.* 1970; Uvebrant 1988). A study of 98 children with localized brain injury caused by penetrating head injuries did not find an association between laterality of lesion and liability to any type of psychopathology (Rutter *et al.* 1984). Goodman *et al.* studied an epidemiological sample of over 400 children with left- or right-sided hemiplegias, all of whom were assessed by behaviour questionnaires, and 149 of whom were assessed by detailed parent and child interviews. The rate of psychiatric problems in this group was high but did not vary significantly by laterality (Goodman & Graham 1996). Neither did laterality of lesion influence the type of psychopathology as judged by a variety of dimensional and categorical measures (Goodman & Yude 1997). Children with left- and right-sided hemiplegias did not differ on measures of affective or interpersonal problems (including autistic problems), contrary to the results of several small studies that have linked developmental lesions of the right (or non-dominant) hemisphere with persistent affective or interpersonal difficulties (Weintraub & Mesulam 1983; Voeller 1986; Sollee & Kindlon 1987). The absence of laterality effects in childhood hemiplegia is evident in the cognitive as well as the psychiatric domain. Whereas damage to the left hemisphere in adult life is specifically linked to verbal deficits, and adult-onset damage to the right hemisphere is specifically linked to visuo-

spatial deficits, comparable unilateral damage sustained early in life does not have laterality-specific effects on memory or intelligence (Vargha-Khadem *et al.* 1992; Goodman & Yude 1996).

Is there any strong evidence that the laterality of childhood brain disorders can influence psychiatric consequences? The best evidence for such an effect comes from studies linking temporal lobe epilepsy in childhood with subsequent psychosis in adult life. Although the literature is contradictory, there is growing evidence that adults with schizophrenia have structural and functional abnormalities that are more prominent in the left cerebral hemisphere, including tissue loss in the left temporal lobe (Gur & Chin 1999; Highley *et al.* 1999; Petty 1999). In line with this, children with temporal lobe epilepsy seem more likely to develop schizophrenia in adult life if their temporal lobe lesion is on the left rather than the right (Taylor 1975; Ounsted *et al.* 1987).

In summary, early brain lesions probably can have side-specific psychiatric consequences, but these seem to be the exception rather than the rule. Further advances in this field will probably depend on studies that correlate psychopathology with detailed information from structural and functional brain scans, while avoiding the trap of extrapolating from small or unrepresentative groups of patients.

How do neurological and non-neurological risk factors interact?

As described in the rest of this volume, a multitude of psychosocial and genetic factors influence a child's liability to psychiatric disorders. How do these 'ordinary' risk factors interact with neurological risk factors? The first point to note is that children with brain disorders are not generally immune to ordinary risk factors. In the Isle of Wight study, for example, children with brain disorders were more likely to have a psychiatric problem if they also came from a 'broken home' or had an emotionally disturbed mother (Rutter *et al.* 1970). The most obvious explanation for this finding is that parental discord or distress resulted in child psychiatric problems, although a plausible alternative is that neurologically determined behavioural problems in the child had an adverse impact on the parents' marriage and mental state. The direction of causality is clearer in the prospective study of childhood head injury carried out by Rutter *et al.* (1984). Although the severity of head injury was the most powerful single predictor of whether a child would develop a psychiatric problem, ordinary risk factors were also influential. Thus, considering just children with severe head injuries, new psychiatric disorders developed in 60% of children who also experienced high levels of psychosocial adversity, but only in 14% of the children who experienced low levels of psychosocial adversity. In this instance, the child's behavioural problems could not have created the psychosocial adversity because the presence or absence of adversity predated both the head injury and the psychiatric problem.

There is one instance in which the presence of brain disorders may 'override' an ordinary risk factor for child psychiatric problems. Among prepubertal children without neurological problems, boys are at considerably greater psychiatric risk than girls (Rutter *et al.* 1975). This male vulnerability is not evident in several studies of children with brain disorders. Psychiatric disorder was equally common in the two sexes in the Isle of Wight sample of children with brain disorders (Rutter *et al.* 1970), and in a sample of children followed prospectively after a severe head injury (Rutter *et al.* 1984). Similarly, the rate of autism in tuberous sclerosis seems to be roughly equal in boys and girls (Hunt & Shepherd 1993).

If a child's liability to psychiatric problems can be increased both by brain abnormalities and by ordinary risk factors, it is important to consider whether neurological and non-neurological risk factors act independently or synergistically. For the sake of clarity, it is worth distinguishing between 'vulnerability' and 'separate paths' models, although hybrid models are certainly plausible. According to the vulnerability model, neurological abnormalities are relatively or totally innocuous on their own, but amplify the effects of any coexistent non-neurological risk factors. By contrast, the separate paths model suggests that there are independent routes into psychiatric disorder: neurological routes that are unaffected by the presence or absence of additional psychosocial or genetic adversity; and non-neurological routes that are unaffected by the presence or absence of brain abnormalities. In statistical terms, the vulnerability model predicts a significant additive interaction between neurological and non-neurological risk factors, whereas the separate paths model predicts separate main effects without an interaction. While there is growing evidence for the separate paths model (Breslau 1990; Whitaker *et al.* 1997), it would be premature to write off the notion that brain abnormalities sometimes act as risk multipliers rather than as risks in themselves.

Our current understanding of the interaction of neurological and ordinary risk factors suggests two lessons for clinicians. First, because children with brain disorders are not immune to ordinary risk factors, the rate of psychiatric problems in this high-risk group could be reduced by tackling coexistent risk factors, such as parental discord or inadequate supervision. Secondly, if there is any truth in the separate paths model, some children with brain disorders will develop psychiatric problems even in the most favourable of environments. Clinicians who bear this in mind will often be able to reassure parents and teachers who blame themselves for not having done enough to prevent the emergence of psychiatric problems. Families and schools who are doing a good enough job with an extremely challenging group of children deserve to feel admired rather than blamed.

What are the mediating links?

Establishing that children with brain disorders have strikingly high rates of psychiatric problems should be the beginning

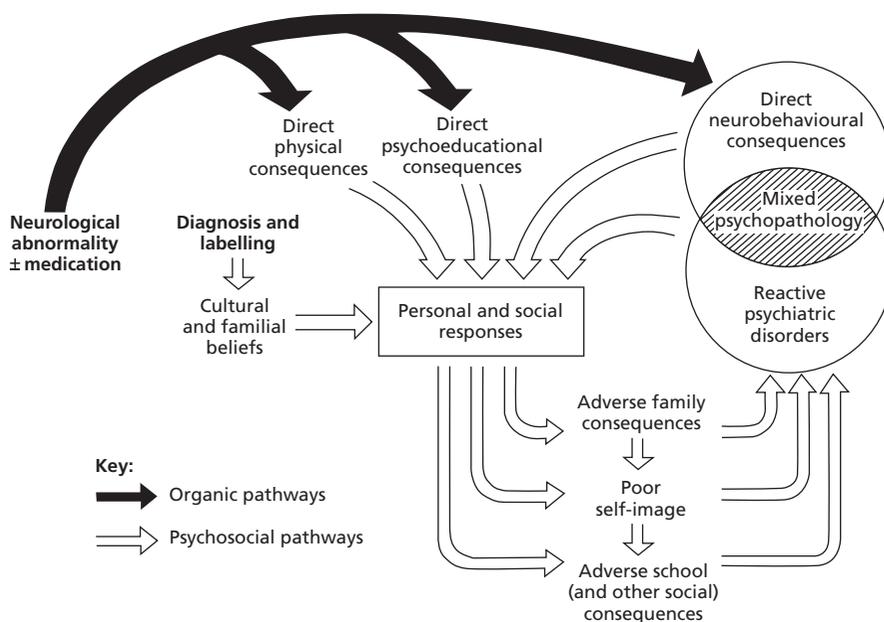

Fig. 14.1 A simplified representation of organic and psychosocial pathways from brain to behavioural abnormalities.

rather than the end of neuropsychiatric inquiry. All too often, however, neuropsychiatrists have been content to call a halt to their inquiries once they have demonstrated that brain-behaviour links exist. This is particularly unfortunate because a better understanding of the mediating mechanisms would be of great theoretical and practical interest. From a theoretical point of view, the links between brain and behavioural disorders in childhood potentially provide a unique window on the biological determinants of psychological development. From a practical point of view, we need to know much more about mediating processes if we are to prevent or treat psychiatric disorders in neurologically impaired children. Imagine, for example, that the main reason brain disorder X leads to psychiatric problems is because it results in specific learning problems that engender marked frustration with schooling, leading on to defiant and disruptive behaviour in class. Imagine also that brain disorder Y leads to psychiatric problems largely as a result of inducing parental overprotectiveness and inconsistent discipline. To be as effective as possible, preventative efforts should mainly be school-based for disorder X but home-based for disorder Y. There are multitudes of possible links between neurological and psychiatric problems, and until we know how to identify the major links for any particular child or group of children, we will misdirect much of our preventative and curative effort.

Given the current dearth of relevant studies, this account of the mediating processes has had to be based largely on clinical plausibility. Before considering the ways in which brain disorders may result in psychiatric problems, it is worth reiterating that just because a child has both neurological and psychiatric problems, it does not necessarily follow that the neurological problems caused the psychiatric problems. It is possible that the two sets of problems are a coincidence, e.g. the child's psychi-

atric problems may be attributable to school stresses that are unrelated to the child's brain disorder. Alternatively, the two sets of problems may reflect a common origin, e.g. the child's head injury and conduct disorder may both be attributable to inadequate parental supervision. Finally, the psychiatric problem may have caused the neurological problem, e.g. when a child with hyperkinesia impulsively runs into the road, gets hit by a car, and ends up with permanent brain damage as a result. With these reservations, it is now appropriate to consider those instances in which the child's brain disorder will have played some direct or indirect part in the origin of the concomitant psychiatric problems. For the sake of clarity, it is helpful to distinguish between the organic and psychosocial consequences of a brain disorder (see Fig. 14.1), acknowledging that these consequences are often intimately interrelated and that the distinction is sometimes impossible in practice.

The organic consequences of a brain disorder may be evident in the physical, psycho-educational and neurobehavioural domains. Physical disabilities, ranging from easy fatigability to lack of independent mobility, may have an indirect impact on psychological well-being, e.g. by influencing self-esteem or peer relationships. In many cases, the treatments of physical problems have their own psychological costs. Children may spend many hours each week in physiotherapy (sacrificing time when they could have been playing and occasioning 'I don't want to' battles), and some children experience repeated hospital admissions, with their attendant separations and disruptions.

Specific learning problems and below-average intelligence are common psycho-educational consequences of brain abnormalities (Rutter *et al.* 1970; Goodman & Yude 1996; Frampton *et al.* 1998). This probably reflects a direct link between brain disorders and impaired cognitive processing, although the situation is

sometimes aggravated by restricted educational opportunities, lower expectations and lengthy absences from school for therapy or operations. For children with epilepsy, cognitive and scholastic skills can be disrupted not only by their clinical and subclinical seizures, but also by the effects of their antiepileptic medication (see below).

The evidence that brain disorders lead directly to some types of childhood psychopathology is largely circumstantial. First, there are adult parallels for direct brain–behaviour links (Lishman 1998), and even some animal models (Robinson 1979). Secondly, various medications have an adverse impact on children’s behaviour, e.g. barbiturates on activity and attention control (Ounsted 1955). Thirdly, organic links seem to provide the best explanation for the wide variety of specific neuropsychiatric associations in childhood, such as the association between Prader–Willi syndrome and characteristic sleep and appetite problems, or the association between Lesch–Nyhan syndrome and severe self-injury (see Skuse & Kuntsi, Chapter 13).

Brain disorders can lead to a multitude of adverse psychosocial consequences. Physical disabilities can result in teasing, poor self-image and reduced opportunities for peer interaction. Repeated hospitalizations may disrupt friendships and predispose to behavioural disorders, perhaps as a result of repeated separations from family. Specific learning problems and low intelligence are associated with a much higher rate of psychiatric problems in children with brain disorders, just as they are in ordinary children (Rutter *et al.* 1970; Goodman & Graham 1996; Frampton *et al.* 1998). There are several possible reasons for this association, including the frustration engendered by school failure, and its impact on self-esteem. If brain abnormalities do have organic neurobehavioural consequences, such as hyperkinesia or an impaired ability to decipher social and emotional cues, then these organic consequences may, in turn, have adverse effects on family relationships and friendship patterns. The beliefs and attitudes of the family and the wider social world also have a major impact. Parents, teachers and peers respond to a neurologically impaired child in the light of their beliefs and prejudices about ‘brain damaged’ children. These beliefs influence the likelihood of overprotection, peer rejection and unrealistic expectations. Beliefs can also interfere with parents’ abilities to set limits to unacceptable behaviours. This can happen, for example, if parents assume that all bad behaviour is neurologically driven and beyond the child’s control, or if they fear that any reproof will trigger off an epileptic seizure and further damage the child’s brain. Family relationships can be disrupted for other reasons too. Sibling rivalry, for example, can be fuelled by the resentment of disabled children who see themselves being overtaken by younger siblings, or by the resentment of non-disabled siblings who feel they are missing out on parental attention. These are only a few of the many possible psychosocial pathways from brain disorders to child psychiatric problems. Others are well described, with a wealth of case histories, in Taylor’s (1989) account of the psychosocial consequences of childhood epilepsy.

It is one thing to describe a mixture of organic and psychosocial pathways from neurological abnormalities to psychiatric disorder, and it is quite another thing to establish the importance of any given pathway in practice. There are disappointingly few good studies in this area, but relevant research strategies can be summarized fairly briefly (with a more detailed account available in Goodman 1993). If we want to establish whether factor X (e.g. marital breakdown, self-esteem, friendships) is an important mediating link between neurological and psychiatric disorders in childhood, several research strategies are available. The most basic strategy, although it is sometimes overlooked, is to establish whether factor X is more common in a representative sample of children with some particular brain disorder than in the general child population. Thus, several studies suggest that the parents of children with chronic physical disorders are *not* at increased risk of marital breakdown (Sabbeth & Leventhal 1984), making it most unlikely that the high rate of psychiatric disorder in neurologically impaired children can be attributed to a high rate of marital breakdown brought on by the strains of looking after a disabled child.

If factor X is more common in a neurologically impaired group, the next step is to examine whether factor X predicts which neurologically impaired children will also develop a psychiatric problem. Once again, the answers may be surprising. There is no convincing evidence, for example, that a high level of physical disability increases the risk of psychiatric problems within a neurologically impaired group (Rutter *et al.* 1970; Seidel *et al.* 1975). By contrast, not only are specific reading retardation and low IQ particularly common among children with brain disorders, but these children with additional learning problems are at considerably greater psychiatric risk (Rutter *et al.* 1970; Goodman & Graham 1996; Frampton *et al.* 1998). When factor X does predict psychiatric risk, multivariate statistical techniques can be used to quantify the possible importance of X as a mediating factor (Breslau 1985). However, it is important to remember that even strong associations are not proof of causation. The presence of factor X may be a consequence rather than a cause of psychiatric disorder, or some third factor may independently increase both X and psychiatric disorder (so that X is a marker for the mediating process rather than the mediator itself).

Longitudinal studies provide a valuable research strategy for investigating the causal mechanisms underlying cross-sectional associations. For example, findings from a longitudinal study of children with hemiplegic cerebral palsy suggested that adverse family factors, including low parental warmth or marital discord, were more likely to be consequences than causes of the child’s psychiatric problems (Goodman 1998). The level of adverse family factors initially did not independently predict whether that child would have improved or deteriorated at follow-up. Intervention studies could also be powerful research strategies for investigating the causal mechanisms underlying brain–behaviour links—although this potential has hardly been tapped in developmental neuropsychiatry to date.

Psychiatric consequences of specific brain disorders

Turning from the general to the particular, the following sections review a range of childhood brain disorders from a psychiatric perspective. It is obviously impossible to cover the whole of paediatric neurology and neurosurgery in a few pages; disorders have been selected on the basis of frequency, severity or particular relevance to child psychiatry. The main clinical features of each disorder are reviewed along with the psychiatric consequences. Readers who want to learn more about specific aspects of paediatric neurology are recommended to turn to Aicardi *et al.* (1998), Brett (1997) or Menkes (1995) for succinct, readable and well-referenced accounts.

Childhood dementias and other conditions involving the loss of skills

A variety of dementing disorders present in childhood with an insidious loss of skills, often accompanied by rather non-specific psychiatric problems. Child psychiatrists have a key part to play in recognizing these disorders at an early stage so that the child can be referred to a paediatric neurologist for detailed assessment. In disorders such as Wilson disease where there is a specific treatment, delayed diagnosis and treatment can result in unnecessary and irreversible damage. In most childhood dementias there is no specific treatment—but that does not mean that delayed diagnosis is trivial. Until the organic basis is recognized, the child's problems may be blamed on his or her laziness, or on parental mishandling, causing unnecessary anguish and subsequent guilt or anger. Occasionally, prompt diagnosis and genetic counselling would have averted the birth of a second affected child. Finally, once the diagnosis has been made, a child psychiatrist may be able to offer useful help to the child, the parents, and the siblings—and this help is much more likely to be accepted if the child psychiatrist referred the case on for physical investigation at an early stage.

Although desirable, prompt recognition of a dementing disorder is undoubtedly difficult. Normal development often involves some degree of 'two steps forward, one step back'; many children revert to more babyish ways when physically ill or under stress; and almost any child psychiatric disorder can interfere with concentration or application at school, leading to a falling off in classroom performance. Even when there is a marked loss of skills in several areas, the cause may be psychosocial rather than organic. For example, Brown & Perkins (1989) described child sexual abuse presenting with marked loss of skills. The presence of psychosocial or organic risk factors can sometimes be misleading in individual cases. For example, the children of prostitutes or drug addicts are clearly at psychiatric risk for psychosocial reasons, but they are also at risk of HIV infection and its associated dementia (see Havens *et al.*, Chapter 49). Conversely, because the children of patients with Huntington disease have a 50% chance of carrying the gene themselves, psychiatric problems in these children could be caused by early

onset Huntington disease—but the problems could also be caused by the abuse, neglect and disorganization that are common in affected families (Dewhurst *et al.* 1970; Folstein *et al.* 1983). In practice, an organic cause needs to be considered (and appropriate referrals or investigations initiated) when the child meets one or more of the following three criteria.

- 1 Progressive loss of well-established linguistic, academic or self-help skills—with performance being well below previous levels even when the child seems content, motivated and not pre-occupied. Psychometric testing is sometimes helpful, particularly if repeated measures are available (Lobascher & Cavanagh 1980).
- 2 Emergence of other features suggestive of a brain disorder, such as seizures, evidence of visual impairment, tremor or postural disturbance.
- 3 Risk factors for relevant genetic or infectious diseases, e.g. father with Huntington disease, mother with AIDS.

Clinicians who make a practice of reviewing their initial diagnostic formulation at regular intervals will be less likely to miss insidiously progressive disorders that initially present with apparently straightforward psychiatric symptoms. The following are the dementing disorders that are most likely to present to child psychiatrists.

Batten disease

Batten disease (which is also known as neuronal ceroid lipofuscinosis) refers to a group of inherited neurodegenerative disorders, most of which are autosomal recessive. Child psychiatrists are most likely to encounter children with the juvenile form, which is the most common neurodegenerative disorder of childhood, affecting up to 1 in 25 000 births. Patients usually present with visual failure at age 5–7 years but disease does not generally result in obvious dementia for a further few years. If no cause is initially found for the visual failure, the child may be referred for psychiatric assessment of 'hysterical' blindness. Alternatively, if the visual impairment is attributed to a non-progressive cause, psychiatric referral may occur several years later when deteriorating schoolwork and non-specific behavioural problems (such as disruptive and aggressive behaviour) are mistakenly attributed to the psychological consequences of blindness or family stresses. Seizures may occur fairly early in the disorder, but the emergence of hard neurological signs is usually a late feature. Exceptionally, dementia and seizures may be the presenting features without any visual failure (Scully *et al.* 1978). The gene has now been located (Mole & Gardiner 1999). Blood tests can be used to diagnose the disorder and carrier status.

Wilson disease

Wilson disease is an autosomal recessive disorder of copper metabolism. As a rule of thumb, children presenting before the age of 10 years do so with progressive liver failure, whereas children presenting after the age of 10 years do so with neurological features, insidious dementia, or non-specific emotional or behav-

itorial problems. Early neurological features include extrapyramidal and cerebellar signs. Dystonic movements and postures can be bizarre, unilateral and exacerbated by stress—so misdiagnosis as conversion hysteria is all too easy. The child's writing may change to a crabbed Parkinsonian style, or may provide evidence of involuntary jerks of the pen. Urinary copper is high, while plasma copper and caeruloplasmin are both low. Ophthalmological examination with a slit lamp may reveal the pathognomonic Kayser–Fleischer ring on the iris. Liver biopsy is necessary in doubtful cases. The disorder can be treated successfully by copper chelation, with earlier treatment resulting in a better outcome.

Huntington disease

Huntington disease is an autosomal dominant disorder that typically presents with chorea and dementia in mid-adult life. The disorder has its onset in childhood in about 5–10% of cases, with early onset cases more often having an affected father than an affected mother. Chorea may occur but a rigid Parkinsonian picture is more common. Epilepsy is an early feature in a substantial minority. The first presentation may be with disturbed or withdrawn behaviour, including loss of interest in games and lessons. These psychiatric features are particularly difficult to interpret in the context of the marked psychosocial disturbance that is common in families where one parent has Huntington disease (Dewhurst *et al.* 1970). The child's fear of developing the same disease may also be important. Just as a positive family history does not make the diagnosis, a negative family history does not rule out the diagnosis because the presence of affected relatives may be concealed, may be masked by misdiagnosis, or may not be apparent as a result of 'non-paternity'. CT or MRI scanning may demonstrate caudate atrophy, and positron emission tomography (PET) scans may show caudate hypometabolism. The disorder is caused by an unstable expansion of a CAG trinucleotide repeat in a gene on chromosome 4 (DiFiglia 2000). The normal number of repeats is between 6 and 34, with more than 37 resulting in a mutated protein product. More trinucleotide repeats result in earlier onset: childhood onset is associated with 55 or more repeats. A simple DNA test can now confirm the presence of the expanded repeat. Harper & Clarke (1990) have discussed some of the ethical issues involved in predictive DNA testing of children.

Adrenoleucodystrophy

Adrenoleucodystrophy is an X-linked recessive disorder. The most characteristic presentation is a combination of adrenal insufficiency, progressive dementia and neurological features. However, even within the same family the presentation can be very variable, with adrenal failure predominating in some affected boys and dementia and neurological features predominating in others. Problems with restlessness, poor coordination, disruptiveness and deteriorating school progress are often the earliest manifestations. Psychotic symptoms may

also be prominent (Corbett *et al.* 1977). Unequivocal neurological abnormalities usually begin at 5–9 years of age, with pyramidal and extrapyramidal signs, convulsions, deafness or visual failure (sometimes caused by cortical blindness). If present, severe adrenal failure results in diarrhoea, vomiting, hypotension and pigmentation. Subtle adrenocortical insufficiency may only be evident from the results of an adrenocorticotrophic hormone (ACTH) challenge. A leucodystrophy with occipital predominance is often evident on CT scan. The combination of leucodystrophy and adrenal failure is pathognomonic. The diagnosis can be confirmed by high levels of saturated very long chain fatty acids in tissues and body fluids, and by DNA mutation analyses (Gartner *et al.* 1998).

Juvenile onset metachromatic leucodystrophy

Juvenile onset metachromatic leucodystrophy is an autosomal recessive disorder with an onset at 6–10 years of age. It often presents insidiously with cognitive decline, deteriorating school performance, and the emergence of oppositional, aggressive or antisocial behaviours. As the disorder progresses, the dementia worsens, Parkinsonian signs emerge, and fits may occur. Optic atrophy and visual failure are late signs. The presence of metachromatic material in the urine can be a reliable test, but the definitive diagnosis is based on markedly reduced arylsulphatase A activity in white cells or cultured fibroblasts.

Subacute sclerosing panencephalitis

Subacute sclerosing panencephalitis is a slow virus infection caused by measles virus. It is much more common after 'wild' measles (particularly if contracted during infancy) than after immunization with live attenuated measles virus. Boys are affected five times more often than girls. Onset is between 5 and 15 years, usually starting with insidious intellectual deterioration and personality change. The emergent behaviours range from irritability to withdrawal, and from defiance to inappropriate affection. Myoclonic jerks without interruption of consciousness begin several months later. Initially these jerks are infrequent and lead to occasional episodes of the child falling or staggering backwards. As the disorder progresses, the jerks become increasingly evident as shock-like movements affecting the head or the whole body, recurring every 5–20s (accompanied by characteristic periodic complexes on the EEG). These myoclonic jerks are accentuated by excitement or loud noises, and are absent in sleep. The serum and cerebrospinal fluid levels of measles antibodies are markedly elevated.

HIV encephalopathy

HIV encephalopathy may now be the most common cause of childhood dementia worldwide. Some congenitally infected children make slow developmental progress, others reach a developmental 'plateau' and fail to advance further, and yet others suffer from a true dementia, with loss of early acquired skills.

Antiretroviral therapies may halt or even reverse neurocognitive decline, although the benefits may not be sustained in the long term. The neurological and psychiatric features of congenital and acquired HIV infections are described in Brown *et al.* (2000; see also Havens *et al.*, Chapter 49).

Pervasive developmental disorders

Pervasive developmental disorders may present with loss of established skills in the domains of communication, social interaction and play—sometimes accompanied by general intellectual deterioration. Loss of skills is always present at the start of disintegrative disorder. In addition, a substantial minority of autistic children also come to medical attention after losing skills in the second year of life (Kurita 1985); such children are particularly likely to be referred to paediatric neurologists to rule out progressive neurodegenerative disorders. Clinical features supporting a pervasive developmental disorder rather than a neurodegenerative disorder include:

- the presence of subtle abnormalities in communication;
- social interaction or play *prior* to the phase when skills were lost;
- the absence of abnormalities on neurological examination and investigation; and
- a resumption of developmental progress and new learning in the months following the initial loss of skills.

The pervasive developmental disorders are described by Lord & Bailey (Chapter 38).

Rett syndrome

Rett syndrome is a progressive neurological disorder that only affects girls. After a period of normal development for the first 7–18 months, there is a phase of developmental stagnation, and then a rapid period of skill loss, commonly accompanied by screaming attacks. The disorder is described in detail in Lord & Bailey (Chapter 38).

Sanfilippo syndrome

Sanfilippo syndrome is the only mucopolysaccharidosis that commonly presents with cognitive decline and behavioural problems; the associated coarsening of the facial features is subtle and may go unnoticed because it occurs so gradually. Measuring urinary mucopolysaccharides is the simplest screening test.

Skill loss and epilepsy

As described in the following section, there are several circumstances in which epilepsy may be associated with cognitive decline. Loss of skills is prominent in some epileptic syndromes, such as the Lennox–Gastaut syndrome. In addition, potentially reversible cognitive decline can be caused by non-convulsive status epilepticus, to toxic levels of antiepileptic medication,

or to the folate deficiency induced by some antiepileptic medication.

Epilepsy

Convulsions are the most common problem encountered in paediatric neurology. Wallace (1995) provides a convenient introduction to childhood epilepsy; the three-volume textbook by Engel & Pedley (1999) provides a more detailed and densely referenced account. References are only provided in this section for topics that are not well covered in the main texts.

At least 1 child in 200 experiences repeated epileptic seizures without a detectable extracerebral cause—the usual definition of epilepsy. This definition excludes children who have hypoglycaemic seizures brought on by their diabetes, or children who have anoxic seizures as a result of faints or breath-holding attacks. The definition also excludes the 3% of preschool-age children who have one or more convulsions provoked by febrile illnesses—these febrile convulsions are generally benign, with about 98% of affected individuals *not* developing true epilepsy. Distinguishing epilepsy from other sorts of paroxysmal disorders (such as faints and parasomnias) can be surprisingly difficult, and misdiagnoses are all too common in both directions. Stores (1985) has summarized the clinical and EEG evaluation of seizures and seizure-like disorders, and has also reviewed possible confusions between sleep disorders and epilepsy (Stores 1991).

Psychiatrists may be asked to help distinguish between true seizures and pseudoseizures. This is not an easy task, particularly because most children with pseudoseizures do also suffer from true seizures, because emotional stresses can precipitate true seizures, and because many children with true epilepsy have psychiatric problems as well. Possible pointers to pseudoseizures include:

- they occur when the child is being observed but not when the child is alone;
- the onset is gradual rather than sudden;
- the paroxysm involves quivering or uncontrolled flailing rather than true clonus;
- there are theatrical semipurposive movements accompanied by loud screaming or shouting;
- painful stimuli are actively avoided during an attack and serious injury does not occur;
- the offset is sudden with an immediate return to an alert and responsive state; and
- the EEG does not show any paroxysmal discharge during an episode.

All these observations are easier to make when the child is assessed with combined EEG and video monitoring. However, none of the pointers is infallible and some sorts of true seizures (most notably frontal lobe seizures) are easily mistaken for pseudoseizures. Williams *et al.* (1978), Holmes *et al.* (1980), Goodyer (1985) and Stores (1999) have written helpful accounts of the assessment and management of pseudoseizures.

The classification of epileptic seizures and syndromes has

changed repeatedly over recent decades. In the current classification of the International League Against Epilepsy (ILAE), the most basic distinction in seizure type is between generalized and partial seizures (Commission on Classification and Terminology of the ILEA 1981, 1989). Generalized seizures are bilaterally symmetrical and the first clinical symptoms do *not* suggest a focal onset. Examples of generalized seizures include generalized tonic-clonic seizures ('grand mal'), absence seizures ('petit mal'), atypical absences, tonic seizures, atonic seizures and myoclonic seizures. In partial seizures, the first clinical symptoms *do* indicate activation of a relatively localized group of neurones, accompanied by a correspondingly localized EEG discharge. Partial seizures are further subclassified as simple or complex. In ILAE's 1969 classification (Gastaut 1970), partial seizures were described as simple when symptoms just involved elementary sensory or motor functions, and as complex when symptoms involved 'higher functions' (e.g. déjà vu, forced thinking). In ILAE's 1981 revision, however, the definition was radically changed: partial seizures were described as simple if full consciousness was retained (even if the symptoms involved 'higher functions'), and as complex if consciousness was impaired (even if the symptoms did not involve 'higher functions'). Either sort of partial seizure can evolve into generalized tonic-clonic seizures. Changes in classification make it difficult to compare studies conducted at different times. Thus studies of psychomotor epilepsy, temporal lobe epilepsy, complex partial seizures (1969 definition), and complex partial seizures (1981/1989 definition) have investigated overlapping but not identical groups of subjects, making it hard to integrate the findings of different eras.

The link between epilepsy and cognitive impairment is complex and controversial. Some of the complexities are illustrated by findings from the National Collaborative Perinatal Project (NCP), which followed a large representative sample of children from before birth until 7 years of age (Ellenberg *et al.* 1986). When tested at 7 years, the children who had experienced one or more non-febrile seizures had an average IQ about 10 points lower than the sample average. When children with seizures were compared with siblings who had never had seizures, the difference was much less marked (4 points), and even this non-significant difference disappeared when the case-sibling comparisons were restricted to cases who appeared neurologically normal prior to the onset of seizures. When cases whose seizures began after the age of 4 years were compared with carefully matched controls, there was no evidence that the onset of seizures led to a fall in IQ by age 7. The results of this study suggest that the average IQ of children with seizures is reduced not because of the seizures themselves but because seizures are often markers either for adverse family factors, whether social or genetic, or for other neurological abnormalities. Children whose epilepsy is associated with other neurological abnormalities have a significantly lower mean IQ than children with idiopathic epilepsy (Rutter *et al.* 1970; Bourgeois *et al.* 1983). Intellectual deterioration as a direct result of the seizures themselves is probably rare, although it may sometimes

occur among the small number of children with frequent treatment-resistant seizures (Rodin 1989).

Clinical studies suggest that cognitive impairment is associated with frequent seizures, multiple seizure types, early onset and chronicity (Corbett & Trimble 1984; Farwell *et al.* 1985; Seidenberg *et al.* 1986). Two other factors are potentially relevant to cognitive impairments in children with epilepsy. First, subclinical seizure discharges in the EEG are sometimes associated with significant impairments in cognitive processing (Binnie *et al.* 1990 and Chapter 11). Secondly, antiepileptic medication may also impair cognition: phenobarbital and phenytoin are the worst offenders, while carbamazepine and sodium valproate seem less harmful, particularly when they are used singly (Cull & Trimble 1989). Folate deficiency induced by antiepileptic medication, particularly phenytoin, may also result in cognitive impairment (Corbett & Trimble 1984). Although most studies of cognition and epilepsy have focused on IQ, there is good evidence that children with seizures have a high rate of specific learning problems *after allowing for their IQ* (Rutter *et al.* 1970; Seidenberg *et al.* 1986). In the Isle of Wight study, for example, children with idiopathic epilepsy had specific reading retardation almost three times more often than children without physical disorders (Rutter *et al.* 1970).

Epilepsy in childhood is a powerful risk factor for emotional and behavioural disorders. In the Isle of Wight study (Rutter *et al.* 1970), 29% of 63 children with idiopathic epilepsy had a psychiatric disorder: four times the rate in children without physical disorders, and over twice the rate in children with physical disorders not affecting the brain. Similarly, Meltzer *et al.* (2000) reported that 37% of an epidemiological sample of schoolchildren with epilepsy had at least one psychiatric diagnosis, as compared with 10% of community controls. Although children with epilepsy have a high rate of psychiatric problems, the nature of these problems is not particularly distinctive (with a few rare exceptions, as described below). In the Isle of Wight study, over 90% of the epileptic children who had a psychiatric problem had either a conduct or an emotional disorder, or a mixture of the two (Rutter *et al.* 1970).

What factors predict which children with epilepsy develop a psychiatric disorder? One powerful predictor is the presence or absence of associated neurological abnormalities. In the Isle of Wight study, for example, psychiatric disorders were twice as common among epileptic children when there were additional neurological problems (Rutter *et al.* 1970). Similarly, in the study of temporal lobe epilepsy (TLE) carried out by Ounsted *et al.* (1966), the rate of hyperkinesia was several times more common if the TLE was secondary to a known brain insult rather than idiopathic. It is possible that many of the other predictors of psychopathology (such as frequency of seizures or presence of cognitive impairment) are primarily markers for the extensiveness of underlying brain abnormalities. The other predictors can be divided into seizure factors, medication, cognitive factors, social factors and family factors, each of which will be discussed in turn.

Possible seizure factors include type and frequency of seizures, and age of onset. As described below, TLE may be associated with a particular rate of psychiatric disorder, although the matter remains somewhat controversial. Stores (1977) reported that boys (but not girls) with TLE had more behavioural problems if the focus was in the left rather than the right hemisphere, but others have not replicated this finding (Camfield *et al.* 1984; Caplan *et al.* 1998; Schoenfeld *et al.* 1999). The existence of a link between frequent seizures and more psychopathology is also controversial, with some studies reporting such a link (Pond & Bidwell 1960; Herman *et al.* 1989; Schoenfeld *et al.* 1999) and others not (Berg *et al.* 1984; Caplan *et al.* 1998). Early onset of seizures may also be a risk factor (Pond & Bidwell 1960).

Choice of medication probably also influences psychopathology, although the evidence is surprisingly weak (Taylor 1991). Phenobarbital has been linked to a variety of behavioural problems, including aggression and hyperactivity (Ounsted 1955). Vigabatrin also seems particularly likely to result in agitation, aggression or hyperactivity—side-effects that are often reduced or abolished by lowering the dose (Luna *et al.* 1989). Polytherapy (treatment with two or more antiepileptic medications at the same time) may also increase psychiatric risk (Hermann *et al.* 1989).

Cognitive predictors of psychopathology include impaired neuropsychological functioning (Hermann 1982) and specific reading retardation (Rutter *et al.* 1970). One possible social predictor is the extent to which the child is rejected or stigmatized as a result of community prejudices about epilepsy. While there can be no doubt that such prejudices are common (Gordon & Sillanp 1997), the study of Rutter *et al.* (1970) suggests that peer rejection is more often a consequence than a cause of psychiatric problems in children with epilepsy. The link with family factors is well illustrated by Grunberg & Pond's (1957) study of children with epilepsy who did and did not have additional conduct disorders. The children with conduct disorders were much more likely to have been exposed to marital friction, disrupted care, and parental hostility or neglect, i.e. the same sorts of adverse family factors that are also associated with conduct disorders in non-epileptic children. Parental separation or divorce has also been linked to more psychopathology in children with epilepsy (Hermann *et al.* 1989). Epilepsy does not render children immune to adverse family factors, but neither does it necessarily accentuate their vulnerability to these factors. (Our current ignorance of the interaction of neurological and psychosocial risk factors is reviewed in an earlier section of this chapter.) Finally, it is worth noting that a child's epilepsy can affect the psychological well-being and coping style of other family members (Hoare 1987), and these effects potentially influence the course of the child's development.

Although child psychiatrists assess and treat children with all varieties of epilepsy, the following epileptic syndromes have behavioural correlates that are particularly relevant to psychiatrists.

Temporal lobe epilepsy

Temporal lobe epilepsy generally involves a mixture of complex partial seizures and generalized tonic-clonic seizures, combined with EEG evidence of a temporal lobe origin. The onset (aura) of seizures may involve a rising epigastric feeling or fear. Déjà vu, forced thinking, and other distortions of 'higher functions' are rare in young children. In the longitudinal clinic-based study of 100 children with TLE carried out by Ounsted *et al.* (1966, 1987), only 15% were wholly free from psychological problems in childhood, and almost half had catastrophic rage outbursts, or hyperkinesis, or both. Rutter *et al.*'s (1970) epidemiological study and Hoare's (1984) clinic-based study also found that children with TLE were at particularly high psychiatric risk (although the number of subjects in the epidemiological sample was small). By contrast, two clinic-based comparisons of children with TLE and primary generalized epilepsy suggest that the two groups may have comparable levels of psychopathology once suitable allowance had been made for confounding factors such as IQ (Whitman *et al.* 1982; Caplan *et al.* 1998). This controversy is unlikely to be resolved without a large epidemiological study.

From a psychiatric perspective, three reported features of TLE are of particular note.

- 1** TLE is a risk factor for a schizophrenia-like psychosis in adult life (Davison & Bagley 1969; Ounsted *et al.* 1987), perhaps particularly when the TLE arises from the left hemisphere (Taylor 1975; Perez *et al.* 1985; Ounsted *et al.* 1987). In two series of children with relatively severe TLE, 10% subsequently developed a psychosis (Ounsted *et al.* 1987; Caplan *et al.* 1998).
- 2** Boys whose TLE persists through puberty are more likely to be sexually indifferent during adulthood, and to remain unmarried (Taylor 1969; Ounsted *et al.* 1987).
- 3** Despite everything, many children with TLE and psychiatric problems grow up to be well-adjusted adults (Ounsted *et al.* 1987).

Frontal lobe epilepsy

Frontal lobe epilepsy is primarily of interest to child psychiatrists because the seizures are easily misdiagnosed as pseudoseizures or sleep disorders (Stores *et al.* 1991). Complex partial seizures arising from the frontal lobe can be very bizarre, with odd movements, postures and vocalizations. Possible features include rocking from side to side, thrashing about, making cycling movements of the legs, punching into the air, turning to one side, arching backwards, squealing, screaming, or swearing. Seizures may occur primarily or exclusively during sleep. Other clinical features that make these episodes hard to recognize as true seizures include short duration (generally under 1 min), absence of tonic-clonic movements, and abrupt termination with prompt return of responsiveness. To make matters worse, the EEG recorded between or even during seizures may be unhelpful. Combined video and EEG moni-

toring can be extremely useful in doubtful cases (Stores *et al.* 1991).

Infantile spasms

Infantile spasms often have psychiatric sequelae. In a typical case, runs of brief jack-knife spasms begin at about 6 months of age, accompanied by the loss of previously acquired skills and the presence of a hypsarrhythmic EEG. A cause, such as tuberous sclerosis or a major brain malformation, can be identified in most cases. Children with no identifiable cause have a better prognosis. Most affected children have severe learning difficulties (mental retardation). In a large follow-up study, Riikonen & Amnell (1981) found that serious psychiatric sequelae were common: autism was diagnosed in 12% of the sample and hyperkinesia in 23% (with considerable overlap between the two diagnoses). Using similar diagnostic criteria, Hunt *et al.* have reported considerably higher rates of autism and hyperkinesia among children whose infantile spasms were caused by tuberous sclerosis (Hunt & Dennis 1987; Hunt & Shepherd 1993). It has yet to be established how far the risk for autistic disorders stems directly from the infantile spasms themselves as opposed to specific aspects of the underlying neuropathology, e.g. presence of tubers in temporal lobes (Bolton & Griffiths 1997). Child psychiatrists should always enquire about infantile spasms when assessing children with severe learning difficulties plus autistic or hyperkinetic features. When there is a history of infantile spasms, the child should be examined particularly thoroughly for the skin signs of tuberous sclerosis—a disorder that may have important genetic implications for the family.

Lennox–Gastaut syndrome

Lennox–Gastaut syndrome accounts for about 3–10% of childhood epilepsy. There are several good paediatric reviews of the syndrome (Beaumanoir 1985a; Livingston 1988; Wheless & Constantinou 1997). Although there are continuing doubts about the nosological validity of the syndrome, both because of its heterogeneity and because typical Lennox–Gastaut syndrome grades off into a wide range of atypical variants and other syndromes, most paediatric neurologists find Lennox–Gastaut syndrome a useful diagnostic category.

The onset of Lennox–Gastaut syndrome is typically between the age of 1 and 7 years, with ‘stare, jerk and fall’ epilepsy, involving frequent myoclonic, tonic and atonic seizures, as well as atypical absences. Generalized tonic–clonic and partial seizures may also occur. EEG accompaniments include diffuse and irregular episodes of slow spike-waves that are more prominent in non-REM sleep (see Binnie *et al.*, Chapter 11). The great majority of affected individuals have severe learning difficulties (mental retardation). In most cases, slow development and neurological abnormalities (including infantile spasms) were evident prior to the onset of Lennox–Gastaut syndrome. In a significant minority, however, early development was normal, with marked cognitive deterioration at the onset of

Lennox–Gastaut syndrome. Incapacitating seizures often persist despite medication, and many affected children need helmets to prevent them being injured by their frequent drop attacks. Although neurological accounts mention problems with social responsiveness, attention and aggression, there have been no systematic studies of psychiatric aspects of Lennox–Gastaut syndrome. One feature of the disorder that may bring a child to psychiatric attention is a tendency to prolonged episodes of minor status. During such an episode, which may last for weeks, the child can still engage in a variety of everyday activities but may appear ‘switched off’, socially unresponsive, aggressive, less articulate than normal, and unusually wobbly, with minor twitching of the face and hands. If the organic basis for the episode is not recognized, the deterioration may be attributed to psychological or social factors, leading to psychiatric referral.

Landau–Kleffner syndrome

Landau–Kleffner syndrome is further discussed by Bishop (Chapter 39) and Binnie *et al.* (Chapter 11). In a typical case, a child of between 3 and 9 years of age loses receptive and expressive language skills, either suddenly or gradually. This acquired aphasia is accompanied by EEG changes, involving paroxysmal discharges that affect both hemispheres, often independently. The EEG abnormalities may be most prominent during non-REM sleep. Seizures occur in approximately 70% of cases, usually starting about the same time as the aphasia, and taking the form of generalized or simple partial seizures that are infrequent and mainly nocturnal. Seizures cease by adulthood, but the prognosis for language recovery is far more variable. It is uncertain whether the likelihood of language recovery is increased by vigorous treatment with antiepileptic medication designed to suppress EEG abnormalities. Neurosurgical treatment is potentially an option for severe and unresponsive cases. Paediatric features of Landau–Kleffner syndrome are reviewed by Beaumanoir (1985b), Gordon (1990) and Appleton (1995). Perplexity, anxiety and tantrums are common at the time of onset. In the longer term, affected children do not generally show autistic impairments in social interactions, but often show some degree of hyperactivity.

Epilepsy and CSWS

Epilepsy and continuous spike-waves during slow-wave sleep (CSWS) usually affects previously normal children, generally beginning between 2 and 9 years, and being associated with mental deterioration and behavioural disorders (Tassinari *et al.* 1985; Perez *et al.* 1993). It may be an acquired epileptic frontal lobe syndrome. Parents typically notice the behavioural deterioration before the cognitive deterioration, although it is possible that subtle neuropsychological deficits predate the emergence of psychiatric symptoms. The main psychiatric manifestations are inattention, hyperactivity, impulsiveness, aggressiveness, labile mood, disinhibition, mouthing of objects, reduced play,

perseveration and lack of a sense of danger. Treatment with antiepileptic medication or corticosteroids may result in marked improvement in behaviour as well as in cognition and seizure control.

Cerebral palsy

Cerebral palsy is the single largest cause of severe physical disability in childhood. The label refers to a heterogeneous group of congenital and early acquired brain disorders that meet three criteria:

- 1 the disorders are chronic rather than transient;
- 2 the underlying brain lesions are static, although the clinical manifestations may change as the child grows up (this criterion rules out progressive neurodegenerative conditions or brain tumours); and
- 3 the clinical manifestations include abnormalities of motor function.

These motor defects are often accompanied by other clinical manifestations of brain abnormalities, including epilepsy, learning problems and sensory impairments.

The American term 'static encephalopathy' is roughly equivalent to cerebral palsy except that motor involvement is not obligatory. The subclassification of cerebral palsy is based on the type and distribution of motor problems, although no one scheme is entirely satisfactory. Spasticity is usually the dominant motor problem: affecting just one side of the body in spastic hemiplegia; affecting both legs to a severe extent and both arms to a mild extent in spastic diplegia; and affecting all four limbs severely in spastic quadriplegia (which is also known as tetraplegia or double hemiplegia). Less commonly, the motor problems are dominated by ataxia, or by dyskinesia (athetosis).

The aetiology of cerebral palsy is largely unknown, although there are some recognized associations: e.g. between severe rhesus disease and athetosis; between cerebrovascular accidents and hemiplegia; and between a variety of severe generalized brain insults and quadriplegia. Heredity seems particularly relevant to ataxia. Prematurity is an important risk factor for diplegia and, to a lesser extent, for other varieties of cerebral palsy too.

In the Isle of Wight study (Rutter *et al.* 1970), psychiatric problems were evident in almost half of the children with cerebral palsy or related disorders. The likelihood of psychiatric problems was significantly increased by two common accompaniments of cerebral palsy: low intelligence and specific reading retardation. When the child with cerebral palsy also had seizures, the rate of psychiatric disorder was higher (58 vs. 38%), although this difference fell short of statistical significance. The type of psychiatric disorder was not particularly distinctive, although there was a hint that hyperkinesia was disproportionately common. Ingram's (1955) large epidemiological study also suggested a link between cerebral palsy and hyperkinesia, with this link being most evident for hemiplegic and ataxic cerebral palsy.

Hemiplegic cerebral palsy has been the focus of a decade of

psychiatric studies (Goodman 1997; Goodman & Yude 2000), making it the best-characterized type of cerebral palsy from a psychiatric perspective. Even though hemiplegia is a relatively mild physical disability and most children with hemiplegia are of normal intelligence and attend mainstream schools, around half of all children with hemiplegia have at least one psychiatric disorder (Goodman & Graham 1996). Conduct and emotional disorders each affect around one-quarter of children with hemiplegia, with hyperkinesia affecting around 10% and autistic disorders around 3%. A more detailed account of clinical presentation and management is provided in Goodman & Yude (2000). The best predictor of which children with hemiplegia develop psychiatric problems is IQ, which is itself well predicted by the degree of neurological impairment (Goodman & Graham 1996; Goodman & Yude 1996). Psychiatric problems are more common in the presence of specific learning difficulties (Frampton *et al.* 1998), but are not related to whether the hemiplegia is left- or right-sided (Goodman & Yude 1997). Questionnaire follow-up suggests that psychiatric problems are often very persistent, with around 70% of children with psychiatric disorders initially still having them 4 years later (Goodman 1998). Children with hemiplegia are at increased risk of peer problems, including victimization, marginalization and lack of friends, perhaps in part because of constitutional problems with social understanding and relatedness (Yude *et al.* 1998; Yude & Goodman 1999). Future studies will need to examine how far lessons learned from these studies of hemiplegia apply more widely to other varieties of cerebral palsy, and indeed to other chronic neurodevelopmental problems, such as hydrocephalus.

Head injury

The nature and consequences of children's head injuries are well reviewed in a chapter by Rutter *et al.* (1984) and in two books (Johnson *et al.* 1989; Broman & Michel 1995). Interested readers are advised to turn to these sources for more detailed accounts and further references.

Head injuries are major causes of hospitalization, severe disability and death in childhood. It is useful to distinguish between open head injuries, which typically involve localized brain damage caused by a penetrating injury, and closed head injuries, which typically involve widespread bilateral damage caused by acceleration–deceleration and rotation injuries secondary to a road traffic accident or a fall. Closed head injuries are more common, are much more likely to result in prolonged unconsciousness and post-traumatic amnesia, and are less likely to result in epilepsy.

The victims are not a random cross-section of children. For example, children who are male, hyperkinetic or of below-average intelligence are more likely to sustain head injuries (particularly mild head injuries), as are children who are poorly supervised because of parental illness or depression. In other words, child psychiatric problems (such as hyperkinesia) may be antecedents rather than consequences of head injury, or may reflect third factors (such as lack of parental supervision) that in-

dependently increase the risk of psychiatric disorder and head injury. This has made it particularly hard to determine if mild head injuries cause psychiatric disorders or cognitive deficits. A review of 40 recent studies of the psychological consequences of mild head injury found that those studies demonstrating no persistent impairment were both more numerous and of higher methodological quality than studies suggesting an adverse effect (Satz *et al.* 1997). However, even if mild head injury generally has no lasting effect on academic or psychosocial outcome, it is still conceivable that mild head injury does result in permanent damage to a small subgroup of susceptible children, depending on the child's age or prior risk factors.

Whatever the residual doubts about the effects of mild head injuries, there is no longer any doubt that severe head injuries often result in cognitive impairments and psychiatric problems (Rutter *et al.* 1984). Closed head injuries that result in at least 2 weeks of post-traumatic amnesia commonly result in impaired performance on a wide range of cognitive tests (affecting visuo-motor and visuospatial tasks somewhat more than verbal tasks). Cognitive recovery may be partial or complete. Catch-up is fastest in the first year after injury, but may continue at a slower pace thereafter. Open head injuries also result in cognitive impairments, with performance IQ being more affected than verbal IQ, whatever the laterality or locus of injury. Damage before the age of 5 years may result in faster but less complete recovery, with persisting impairments in scholastic attainments.

The short-term psychiatric sequelae of severe head injuries are well summarized by Hill (1989). Three overlapping phases may be evident: an early phase of confusion, regression, or denial; a middle phase of demanding and arrogant behaviour or listlessness and depression; and a final phase of gradual accommodation to disability.

In the longer term, psychiatric disorders are evident in roughly half of the survivors of severe closed or open head injuries (Rutter *et al.* 1984; Lehmkuhl & Thoma 1990; Max *et al.* 1998). Within this group, the risk of psychiatric disorder is not related to age, sex, or locus of injury, is only weakly related to the severity of the injury, and is best predicted by preinjury characteristics, social adversity and parental handling. Children who had minor emotional or behavioural symptoms prior to injury are at greater psychiatric risk than children whose preinjury behaviour was normal. Coexistent psychosocial adversities (such as maternal depression, paternal criminality or overcrowding) further increase the child's psychiatric risk. This risk is probably also increased when parents respond to the injury by becoming overprotective and reluctant to discipline their child.

Although the psychiatric disorders of children with head injuries mostly involve the sorts of emotional and conduct problems that dominate ordinary child psychiatric practice, severe closed head injury can result in a distinctive syndrome of social disinhibition resembling an adult 'frontal lobe syndrome' (Rutter *et al.* 1984). These disinhibited children are unduly outspoken, ask embarrassing questions, make very personal comments and get undressed in inappropriate contexts. They may also be forgetful, overtalkative, impulsive or careless about their

own cleanliness and appearance. The localization of an open head injury has little if any influence on psychiatric symptomatology; hints that depression is particularly linked with right anterior or left posterior damage have yet to be confirmed.

Prognosis of psychiatric problems in children with brain disorders

Is the prognosis of a psychiatric disorder worse if the child also has a brain disorder? Clinicians and parents often suppose so, and this pessimism may be self-fulfilling if it leads to inappropriately low expectations and therapeutic nihilism. The pessimism has more to do with theoretical expectations than empirical evidence. If a damaged brain cannot mend, it seems to follow that associated psychiatric problems cannot mend either. This is faulty reasoning. The association between brain and behavioural disorders is sometimes simply a coincidence. For example, the child's psychiatric disorder may reflect stresses at school that have nothing to do with the child's neurological problems; if the stresses at school resolve, so may the child's psychiatric disorder. Even when the psychiatric disorder is secondary to the child's brain disorder, the causal chain may be indirect and easy to interrupt. For instance, if a boy with epilepsy develops a conduct disorder, the mediating link may be the parents' fear that he will have a seizure if they discipline him in any way. Helping the parents to reinstate appropriate discipline may cure the conduct disorder. Even when psychiatric problems are direct consequences of the brain disorder, the psychiatric problems may still be temporary (just as some children with fixed brain lesions have seizures for a few months or years and then grow out of them). As noted earlier in the chapter, brain disorders do not necessarily arise from irreversible brain damage. On theoretical grounds, there is no reason to suppose that psychiatric disorders are bound to be persistent just because the child also has a brain disorder.

There is little empirical evidence on prognosis because there have been so few longitudinal neuropsychiatric studies. In the Institute of Psychiatry study of children with closed head injuries (Brown *et al.* 1981), psychiatric disorders attributable to head injury were somewhat more persistent than psychiatric disorders that were not attributable to head injury, but the difference was not statistically significant. Breslau & Marshall (1985) used a brief screening inventory to assess the stability of psychiatric problems over the course of 5 years in a group of children with a mixture of brain disorders, and in a comparison group of children with cystic fibrosis. Judging from this limited assessment, psychiatric problems were more likely to persist in the children with brain disorders—a persistence that was only partially explained by coexistent mental retardation. Follow-up of children with hemiplegic cerebral palsy also suggests that childhood psychiatric problems are often persistent (Goodman 1998). However, this evidence for persistence needs to be set against the more optimistic findings of Ounsted *et al.* (1987) who followed up 100 children with temporal lobe epilepsy for

over 20 years. Although 85% of the sample had some psychological problems during childhood, the adult outcome was surprisingly good. When individuals with mental retardation were excluded, 70% of the survivors were entirely free of psychiatric disorder in adult life.

Individuals can grow into as well as out of the psychiatric consequences of childhood brain disorders. For example, a child who initially adjusts well to an acquired hemiplegia may subsequently become increasingly depressed as recovery slows down and the implications of lifelong disability sink in. Brain maturation may also be relevant. It is possible, for example, that some psychiatric consequences of head injury do not emerge until the child reaches the age when damaged late-maturing cortex normally comes 'on line' (Goodman 1989).

Prevention and treatment of psychiatric problems in children with brain disorders

Because children with brain disorders commonly develop psychiatric problems, and because combined physical and psychiatric problems impose a severe burden on parents and teachers, children with brain disorders seem an obvious target for interventions designed to prevent psychiatric problems. Unfortunately, few such studies have been conducted. Hjern & Nylander (1964) found that children with head injuries were significantly less likely to develop psychiatric problems if their parents had been counselled that the sequelae of head injury were generally transient, and that children with head injuries benefit from a graded reintroduction to all normal activities. Lewis *et al.* (1990, 1991) compared two educational programmes for children with epilepsy and their parents. Families were randomly allocated either to lecture sessions followed by question-and-answer periods, or to a specially devised series of parent and child groups. The group counselling approach was more likely to reduce parental anxiety and foster children's self-perceptions of social competency. Although the gains were modest, this study does demonstrate the feasibility of randomized controlled trials of preventative interventions in this area.

The psychiatric problems of children with brain disorders can be treated in just the same ways as the psychiatric problems of neurologically intact children. Biological treatments are neither more nor less useful than in ordinary child psychiatric practice. There is no empirical basis, for example, for treating a child's conduct disorder with carbamazepine rather than with behavioural therapy or parent management training simply because the child also has a brain disorder. Individual, family and school-based treatment approaches can all be helpful. As far as drug treatment is concerned, five points are worth emphasizing.

1 The indications for, and choice of, psychotropic medication differs little from standard practice (see Heyman & Santosh, Chapter 59).

2 Epilepsy is not a strong contraindication to using antipsychotics or antidepressants even though these drugs may increase seizure frequency. In practice, an increase in seizure frequency is

rarely a major problem, and can often be countered by adjusting the dose of antiepileptic medication. Of the commonly used antipsychotics, risperidone, sulpiride and haloperidol are probably less likely than chlorpromazine to exacerbate seizures, while olanzapine and clozapine are better avoided if possible because they are associated with a particularly high risk of seizures.

3 Although brain disorders are often mentioned as a risk factor for antipsychotic-induced tardive dyskinesias, the evidence is decidedly weak (Kane & Smith 1982).

4 Stimulant medication can be very helpful for hyperkinetic children who also have a neurological problem, although the risk of a dysphoric reaction to stimulants may be higher than in other hyperkinetic children (Ounsted 1955; Ingram 1956). Both methylphenidate and dexamfetamine are commonly used, and although there are theoretical reasons for supposing that methylphenidate may be more likely than dexamfetamine to lower seizure threshold, methylphenidate does appear to be safe and effective for children with well-controlled seizures (Gross-Tsur *et al.* 1997).

5 When children with epilepsy develop behavioural problems, changing the type or dosage of antiepileptic medication can sometimes help. Behavioural problems may improve dramatically, for example, if toxic levels of phenytoin are reduced, or if phenobarbital is replaced by carbamazepine. Changes in antiepileptic medication should obviously be discussed with the child's paediatrician.

Prospects for the future

Research in developmental neuropsychiatry is gathering momentum and it is likely that studies conducted over the next 10 years will make major contributions to the field. There is still much to be done to chart the psychiatric risk profile associated with common and less common neurological disorders—clinical studies, cross-sectional epidemiological studies and longitudinal epidemiological studies all have important contributions to make. Prevention and treatment trials have the potential to be both practically and theoretically illuminating. At a practical level, they will provide the evidence base for planning neuropsychiatric services, while at a theoretical level, they will provide crucial tests of proposed causal pathways. Advances in molecular genetics and neuroimaging should provide new opportunities to examine possible explanations for the marked heterogeneity of psychiatric outcome after apparently similar brain lesions. For example, if additive 'anxiety' genes can be identified, it will be possible to test directly the hypothesis that brain disorders primarily increase an individual's risk of an anxiety disorder if that individual also has what would normally be a subthreshold dose of these genes. As functional neuroimaging can be used to localize the brain systems involved in specific cognitive processes, this approach provides a window on how brain function may be localized differently when particular areas of the brain are damaged at specific stages of development. Given several lines of evidence that neuronal reorganization can

potentially impair as well as promote adaptive functioning (Goodman 1994), it is possible that the heterogeneity of psychiatric outcome in children with brain disorders will turn out to be related to different patterns of cerebral reorganization.

Introduction

Chronic adversities are environmental stressors that endure for extended periods of time. The intensity of these stressors may wax and wane, but the key characteristic that differentiates them from acute trauma is their pervasive and lasting nature. The most notable chronic adversities—poverty, parental psychopathology, parental death, interparental discord, community violence, child maltreatment, foster care, and child medical illness—are seen as creating environments of persistent stress and challenge to healthy development. The past two decades have witnessed an explosion of research examining the impact of such chronic adversities on children and youth (Garmezy & Masten 1994; Rutter 1996). In addition, a related body of work on children's resiliency has also developed, investigating the factors that promote adaptation under duress (Garmezy & Rutter 1983; Masten *et al.* 1999; Luthar *et al.* 2000).

What can we conclude about the effects of chronic adversities on child and adolescent development? What are the key processes underlying these effects? Why do some children develop healthily despite considerable, ongoing stressors in their lives? These are the questions that we address in this chapter.

We begin by briefly reviewing the empirical literature on four of the above major chronic adversities: interparental discord, poverty, parental psychopathology, and community violence. As child maltreatment, foster care, bereavement and physical illness are the topics of separate chapters in this volume, we do not include them here. Our goal in this brief literature review is to present a summary of the type, extent and severity of negative outcomes related to these chronic adversities. We then move to a discussion of two central cross-cutting themes in these literatures: the role of cumulative risk and the impact of protective factors leading to resilience.

A central goal of this chapter is to address what has largely been missing from the study of chronic adversity: a focus on the pathways leading to the negative effects on children. What are the mechanisms that explain why poor developmental outcomes occur in these problematic contexts? Conversely, what are the mechanisms that explain why some children and youth are not harmed by chronic adversity? Toward this end, we present a heuristic model that outlines the processes involved in both negative and positive outcomes for children and youth under stressful conditions. To present and critique this model, we first consider some of the normative developmental processes that are essential for healthy child development. This

permits an illustration from the model of how chronic adversity interferes with these normative processes. We then evaluate the merits of the model by reviewing the existing evidence, and suggest directions for future research. Finally, we briefly discuss the implications of our review and our model for clinical practice and intervention.

Brief summary of effects of chronic adversities

Marital discord and interparental conflict

One of the most widespread adversities for children is the experience of parental discord and divorce. The annual divorce rate has been rising in the USA since the 1850s, and the rate more than doubled between 1960 and 1980, from about 9 divorces per 1000 marriages in 1960 to about 22 in 1980 (US National Center for Health Statistics 1990). Since then the divorce rate has modestly decreased and stabilized (20.9 in 1990), but the USA has the highest divorce rate of industrialized countries except the former Soviet Union. In Europe, the UK and Denmark are the next highest with rates in 1991 of 13.3 and 12.3, respectively, and Italy has the lowest rate at 2.1 (UN Demographic Yearbook 1995). Of US adults marrying in the first part of the twenty-first century, half will experience divorce over the course of their lifetimes, followed by high proportions of remarriage (75% of men and 66% of women; Cherlin 1992). Second marriages are often more problematic for children and less stable than first marriages (Hetherington *et al.* 1998). In addition, cohabitation has been on the rise in the USA, from 11% of those who married in the 1960s to 44% of those who married in the 1980s, with even higher rates for those entering remarriage (60% in the 1980s; Cherlin 1992). Cohabitation is more prevalent in parts of Europe (Kiernan 1999). Cohabiting unions in the USA dissolve more readily than do marriages, and those marriages that are preceded by cohabitation have a higher likelihood of divorce (Cherlin 1992).

It is not the focus of this review to address all of the changes in children's lives brought about by their parents' marital and partnership transitions. Rather, we address marital discord, or more broadly, interparental conflict, a difficult context for children that often predates the dissolution of marriages and cohabitations, or occurs during the dissolution or in the aftermath of separation and divorce, as well as within enduring marriages

or partnerships. Of the chronic adversities reviewed in this chapter, interparental conflict is the most extensively researched.

Marital discord and interparental conflict expose children and youth to hostility, acrimony, arguments and anger. Witnessing angry adults—whether they are strangers in laboratory-based studies or parents in laboratories or at home—is emotionally disturbing and causes physiological distress in children (Cummings *et al.* 1985; El-Sheikh *et al.* 1989; Hetherington 1999). Two meta-analyses have found that marital conflict is related to child and adolescent behaviour problems, including aggression with peers, poor psychological well-being and inadequate social functioning (Reid & Crisafulli 1990; Depner *et al.* 1992). These links remain when studies are statistically controlled for gender, age, race, socioeconomic status, family structure, family psychiatric history and parenting style (Lorenz *et al.* 1995; Davies & Windle 1997).

Interparental conflict appears to be related to elevated levels of behaviour and adjustment problems for all ages of children and adolescents. In early and middle childhood, interparental conflict predicts emotional disturbance and disruptive behaviour problems (Cummings *et al.* 1994; Davies & Cummings 1998; Kerig 1998a,b; Shaw *et al.* 1999), and these same patterns are found in studies of adolescents (Lorenz *et al.* 1995). Perhaps most important, the few existing longitudinal studies show that the negative effects of interparental discord are lasting. For example, in a study of more than 400 adolescents, marital discord predicted depressive symptoms, delinquency and alcohol problems in girls 6 months later (Davies & Windle 1997). Similarly, in a prospective study of 400 nationally representative families, marital discord early in children's lives was associated with subsequent lower levels of closeness to parents, life satisfaction, happiness and self-esteem, in addition to higher levels of psychological distress and violence in adolescents' later relationships (McNeal & Amato 1998).

Interparental discord is a chronic adversity that is detrimental to the psychological health of children and youth. However, the extent of interparental conflict in the USA and in Europe is not known, and we cannot draw firm conclusions about the prevalence or severity of the poor developmental outcomes in the empirical literature.

Poverty

In 1997, 19% of children in the USA lived in families with incomes below the poverty line (\$16 400 for a family of four). Poverty is an official measure of economic standing, defined by the government as the income necessary for basic support of food, clothing and shelter. The poverty line is a monetary threshold, and those falling just above the poverty line are usually not meaningfully better off than those falling just below it. One study found that 50% of all US children, at some point during childhood, live in families whose income is near the poverty line, and almost one-third of children live below the poverty line by age 15 (Duncan & Rodgers 1988).

For children growing up in poor families, poverty usually

entails a much broader set of challenges than just insufficient economic resources. Children in poor families are more likely to have parents with low levels of education, to live in single-mother households, and to reside in neighbourhoods characterized by overcrowding, substandard housing conditions, high rates of unemployment, inadequate schools and higher levels of crime (Brooks-Gunn *et al.* 1997b). These correlates of economic poverty create an ecological context that may impede social, psychological and educational domains. Distinguishing the relative influences of these different dimensions of poverty has been a central challenge in the area of poverty research (Chase-Lansdale *et al.* 1995).

Poverty is related to poorer physical, cognitive and social outcomes for children and adolescents (Duncan & Brooks-Gunn 1997). Low birth weight and other health problems, such as asthma, have higher prevalence rates in low-income populations (Korenman & Miller 1997; McConnochie *et al.* 1999). Family poverty is linked to more behaviour problems and poorer cognitive functioning during early and middle childhood (Dodge *et al.* 1994; Duncan *et al.* 1994; Bolger *et al.* 1995; Chase-Lansdale *et al.* 1997; Chase-Lansdale 1999). Similarly, neighbourhood poverty is related to cognitive delay, antisocial behaviour and emotional disturbance concurrently and over time (Guerra *et al.* 1995; Chase-Lansdale & Gordon 1996; Brooks-Gunn *et al.* 1997a; Dubow *et al.* 1997; Leventhal & Brooks-Gunn 2000), controlling for gender, age and race (Dubow & Ippolito 1994). Research with adolescents finds a similar pattern, with poverty predicting school behaviour problems, poor achievement, and both emotional difficulties and disruptive behaviour problems (Conger *et al.* 1993; Hanson *et al.* 1997), although some recent work finds that poverty during children's preschool years is the most damaging (Duncan *et al.* 1998). This body of work demonstrates that low socioeconomic status is linked to behavioural, emotional and cognitive problems for children and youth.

Another point of debate in the literature involves causality. For example, Mayer (1997) contends that the major reason why children and youth in poverty fare poorly is because of selection bias. In other words, the same factors that lead an adult into poverty (low abilities, poor education, emotional problems, disabilities) can be genetically shared with offspring and can also limit poor adults' abilities to parent effectively, thus resulting in unhealthy child outcomes. We take the position that both selection bias and experience may be influential causal factors. We liken them to Rutter *et al.*'s (2001) discussion of the effects of cigarette smoking on health; certain genetic and other selection biases contribute to a young person's decision to smoke, but the actual experience of smoking also brings new risks. The same logic may be true for becoming impoverished and experiencing poverty.

Parental psychopathology

Having a parent with a mental disorder is a significant risk to healthy child and adolescent development. Children with men-

tally ill parents are vulnerable to developmental problems because of genetic and environmental characteristics that create a situation of multiple risk. For example, parental psychopathology often co-occurs with marital difficulties, parenting problems and spousal psychopathology (Beardslee *et al.* 1998). Children are additionally at-risk because many forms of psychopathology (e.g. alcoholism, antisocial behaviour, schizophrenia and affective illness) are believed to have varying hereditary components (Rutter *et al.* 1990). A significant proportion of the population is affected by mental health problems (Kessler *et al.* 1994). Although we will discuss various types of parental psychopathology as discrete disorders, many mental disorders actually occur comorbidly and so the differential effects of specific psychopathology are often not clear (Sameroff & Seifer 1990; Garmezy & Masten 1994).

Parental alcoholism, antisocial behaviour, schizophrenia and affective illness are all associated with poorer child development. Children of alcoholics demonstrate heavier drinking (Colder *et al.* 1997), more behaviour problems (Martin *et al.* 1994), and more emotional difficulties (Roosa *et al.* 1988; for reviews see Sher 1991 and Chassin *et al.* 1997). Many of these problems continue on through adulthood (Domenico & Windle 1993). In addition, parental criminality and antisocial personality disorder predict poorer child outcomes. These forms of parental psychopathology are associated with more mental health problems and antisocial behaviour in children (Factor & Wolfe 1990; Patterson & Capaldi 1991; Guzder *et al.* 1999), including conduct problems (Loeber & Dishion 1983; Christ *et al.* 1990), attention deficit hyperactivity disorder (ADHD; Lahey *et al.* 1995), and conduct disorder (Frick *et al.* 1992). Schizophrenia, a rare but severe form of mental disorder, has a strong genetic component and relates to other mental health problems more generally (Sameroff & Seifer 1990).

A review of research in the past decade concludes that children of adults with affective illness are more vulnerable to the development of psychopathology in general and to depression specifically (Beardslee *et al.* 1998). Maternal depressive symptoms in a child's first year of life predict developmental delays at age 1 year (Field 1995) and child behaviour problems at 28 and 36 months (Leadbeater *et al.* 1996). Maternal depression is also associated longitudinally with children's social withdrawal and anxious behaviours at age 5 (Rubin *et al.* 1991), and lower child popularity and higher levels of internalizing and externalizing problems in later childhood (Goodman *et al.* 1993).

A robust literature shows that parental psychopathology poses a combination of negative psychosocial, environmental and genetic conditions that place children at-risk for numerous mental health and behaviour problems.

Violence exposure

As violent crime has become increasingly frequent in many urban low-income US communities, researchers have begun to examine the impact of violence exposure on children and adolescents. According to statistics from the Centers for Disease

Control, the USA has the highest homicide rate of any industrialized country (Fingerhut *et al.* 1998), and police estimates suggest there are many more assaults than homicides (Bell & Jenkins 1993). Some violence exposure comes in the form of acute trauma, such as witnessing shootings and homicides (Pynoos & Nader 1990), but children living in high-crime US communities are often chronically exposed to violence through hearsay, as witnesses and victims, and by the ever-present threat of violence. Most research in this area does not specifically measure chronicity of exposure, but rather asks children about the frequency of exposure to specific violent events as witnesses and as victims. A survey with over 1000 children and adolescents from low-income urban communities found that 75% of boys and 70% of girls reported witnessing a shooting, stabbing, robbery or murder (Shakoor & Chalmers 1991). This work suggests many children living in low-income urban areas repeatedly experience numerous types of violence witnessing and victimization, ranging from drug use, arrests and shootings to assault (Richters & Martinez 1993).

Greater violence exposure is associated with higher rates of psychosocial problems in young children and adolescents. The level of violence exposure in young school-age children living in high crime neighbourhoods predicts higher peer-rated aggression (Attar *et al.* 1994). Frequency of violence exposure also predicts aggression and hopelessness in young children (Guerra *et al.* 1995), as well as internalizing and externalizing behaviour problems in children in early and middle childhood (Osofsky *et al.* 1993; Richters & Martinez 1993; Friedman 1999). Furthermore, older children and adolescents exposed to violence also demonstrate more behaviour problems than adolescents living in the same low-income communities but with lower levels of violence exposure (Fitzpatrick 1993; DuRant *et al.* 1995). The link between violence exposure and academic achievement is less clear. Violence exposure has been found to have no longitudinal relation to achievement over 1 year for young school-age children (Attar *et al.* 1994), but is related to poorer achievement in girls in early teenage years (Spencer *et al.* 1993).

The predominantly cross-sectional nature of this research introduces the possibility that the association between violence exposure and negative outcomes stems from adolescents with more emotional problems self-selecting into environments with greater violence. This explanation might be particularly relevant for older children and adolescents who have more autonomy to choose their peer groups and activities in the community. However, violence exposure is also related to more behaviour problems and adjustment in young children who have less ability to self-select into violent contexts, suggesting that much of the link between exposure and negative outcomes may be attributable to the experience of violence itself.

Risk and resilience

Our brief review chronicles the damaging nature of chronic adversities for children and adolescents. An important question

throughout the literature is the probability of problematic outcomes for children in these contexts. Who are the most vulnerable children: who are the most likely to develop problems? The concept of cumulative risk has been developed to answer this. Conversely, who are the children least likely to develop problems: who are most likely to escape the ravages of these contexts? Resiliency may be able to provide the key. We briefly take up each of these topics.

Cumulative risk

The model of cumulative risk proposes that most children have the resources to cope with one risk without serious developmental consequences. However, the accumulation of many risk factors renders children vulnerable to psychopathology and other negative outcomes (Rutter *et al.* 1986; Sameroff *et al.* 1987, 1993; Garmezy & Masten 1994). Indeed, our brief review of the four chronic adversities—interparental discord, poverty, parental psychopathology and community violence—illustrates that multiple risk factors co-occur within each of these adverse contexts. For example, families with high levels of interparental conflict often evidence parental psychopathology. Similarly, poverty and economic hardship are linked with single parenthood, psychological distress and emotional disorders, low social support, and communities with crime and violence.

Rutter (1985) first proposed the cumulative risk model, and this approach has since been expanded and largely replicated in subsequent investigations (Sameroff *et al.* 1987, 1993; Kolvin *et al.* 1988; Liaw & Brooks-Gunn 1994; Fergusson & Lynskey 1996). The risk factors across the studies are similar, although not identical. They range in number and include such risks as:

- biological risks (physical health, low birth weight);
- socioeconomic risks (race, ethnicity, unemployment, education, income, family size);
- maternal mental health and intelligence (psychiatric disorder, verbal ability, anxiety, depressive symptoms); and
- family dynamics and support (marital discord, negativity, social support, stressful life events).

Similar findings emerge across the studies of cumulative risk: as the number of risk factors increases, the developmental status of the child decreases. The probability of negative outcomes (such as lower IQ, higher levels of behaviour problems or psychiatric disorder) increases significantly, often doubling or tripling for children with higher numbers of risk factors than those with only one risk factor. The concept of cumulative risk has also been assessed by creating an indicator of multiple risk; a construct that combines demographic, family psychosocial and neighbourhood risks. These studies also find that higher levels of the multiple risk indicator predict increased behaviour problems and poorer social competence in early (Seifer *et al.* 1996; Shaw *et al.* 1998) and middle childhood (Dumka *et al.* 1997; Greenberg *et al.* 1999).

Resilience

A rich literature identifies risk factors and demonstrates their association with poorer outcomes for children. Yet many children are able to adapt to stress and to develop adequate or competent social, emotional and cognitive functioning, despite the enormity of stressors often present within contexts of risk. Indeed, it is important to remember that most children faced with stressors and chronic adversity demonstrate competence in at least one domain of functioning, and some even thrive despite the presence of risk factors. But why do some children fare better in extreme circumstances than others? The concept of resilience has been developed to answer this question, partly to determine the best method for prevention and intervention in the lives of children in difficult contexts (Rutter 1979, 2000a).

Resilience refers to the ability to demonstrate successful development and adaptation within contexts of risk. Although there is new discourse on the definition and meaning of resiliency (Luthar *et al.* 2000), most agree that ‘resilient’ children are those who show adequate social and cognitive competence despite the presence of risk factors (Garmezy & Rutter 1983, 1985; Rutter *et al.* 1986; Masten & Coatsworth 1998). Three main dimensions of characteristics distinguish stress-resistant from stress-vulnerable children:

- 1 dispositional attributes (e.g. temperament, cognitive abilities, self-beliefs);
- 2 family characteristics (e.g. warmth, closeness, cohesion); and
- 3 the availability and use of external support systems by family members (Garmezy & Rutter 1985).

The presence of one or more of these protective factors is associated with better child and adolescent outcomes in contexts of risk (Werner & Smith 1982, 1992; Luthar & Zigler 1991; Fergusson & Lynskey 1996; Dumont & Provost 1999; Masten *et al.* 1999).

The identified dispositional characteristics are an easy temperament, at least average intelligence and self-efficacy. A close emotional tie with an adult family member or an organized family with routines and clear expectations buffer children, despite the presence of other negative family characteristics, such as parental discord. Perceived social support for parents or children from outside of the family seems to help protect children from difficult environments. These individual, family and community qualities and conditions are integral to the process of resilience and child development in the context of chronic adversity.

Heuristic model for processes underlying the impact of chronic adversities

A central goal of this chapter is to create a more process-orientated, theory-based understanding of the ways in which exposure to chronic adversities affects child and adolescent development, trajectories and outcomes. Although the field of

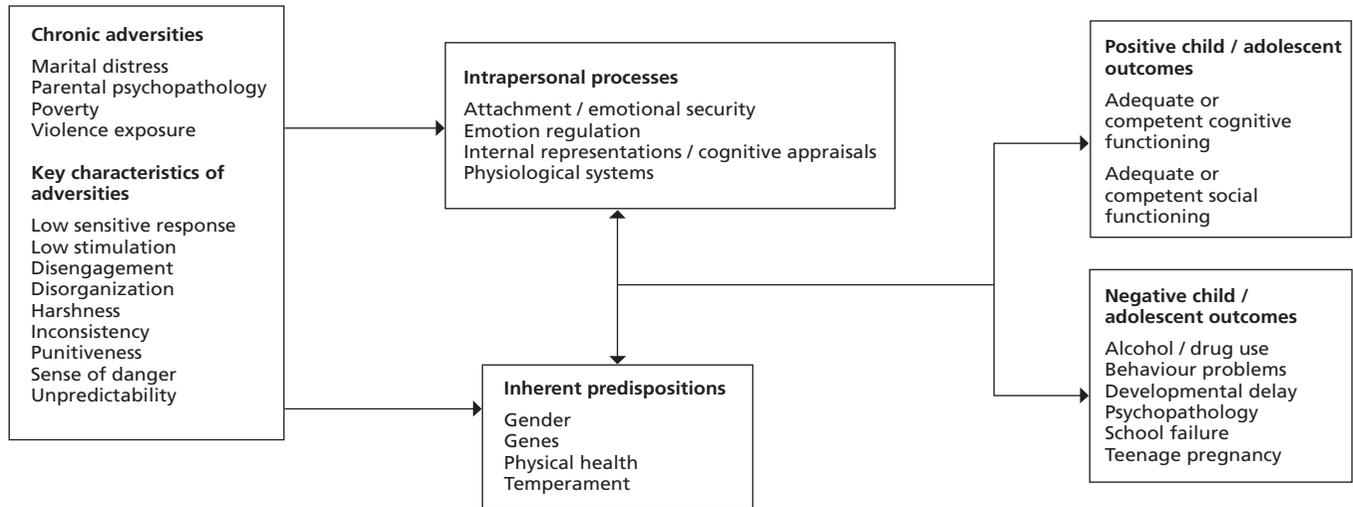

Fig. 15.1 Heuristic model for processes underlying the impact of chronic adversities.

risk and resiliency has grown substantially in the past two decades, it is still missing a unified theoretical model that attempts to explain the underlying mechanisms of resiliency in contexts of chronic risk. We are not the first to point out this gap in the field (Davies & Cummings 1994; O'Connor & Rutter 1996), nor are we the first to propose a theoretical framework for understanding children's reactions to difficult contexts (Grych & Fincham 1990; Egeland *et al.* 1993; Davies & Cummings 1994; Kumpfer 1999; Wyman *et al.* 1999). However, efforts to investigate the processes underlying the development of stress-resilient children remain scarce and disparate.

We believe that the ways in which adversities influence child trajectories cut across many risk contexts and, as such, call for an integrated approach. Therefore, in an effort to push this field forward, we have developed a heuristic model (Fig. 15.1) that proposes an integrated framework for explaining how and why chronic adversities increase the likelihood of poorer behavioural and social outcomes for children. It is our hope that this model promotes a more process-orientated approach to thinking about the meaning of chronic adversities *per se*, as well as a more process-orientated approach to investigating the impact of chronic adversities on children and families. We first turn to a discussion of normative development before presenting our model.

Intrapersonal processes and normative development

To understand the ways in which chronic adversities affect children and adolescents, we first need to consider some of the developmental processes that influence normal trajectories. We view development as a transactional process, as an interplay between the environment and the child's inherent predispositions (e.g. gender, temperament, genes; Collins *et al.* 2000). The role of genetic factors in individual development is important (see

McGuffin & Rutter, Chapter 12; Skuse & Kuntsi, Chapter 13). In recent years, genetic susceptibility for more negative developmental pathways and the interaction between genetic and environmental risk factors have become the focus of considerable research (Pike *et al.* 1996; Plomin *et al.* 1997; Rutter *et al.* 1999; Reiss *et al.* 2000; Shonkoff & Phillips 2000). For heuristic purposes, we will emphasize the role of environmental conditions as part of our framework for presenting our model. For the same reasons, we will not address the role of other biological factors (e.g. physical health and nutrition), but these factors also have a role in the transactional process. We focus on emotion regulation, attachment and emotional security, and internal representations and appraisal systems as the main processes that are fundamental to competent emotional, social and cognitive functioning. Ecological contexts can both foster and hinder the normative development of these core influential systems.

Emotion regulation

Emotion regulation refers to the process through which emotional arousal is controlled and modulated. It is central to an individual's ability to function in emotionally and physiologically arousing situations and is influenced by biological characteristics and environmental conditions (Cicchetti *et al.* 1991; Kochanska *et al.* 1997). In early childhood, caregivers help moderate and regulate arousal states by responding to infants' needs. This interaction is critical to the maintenance of physiological homeostasis and is the foundation for ongoing emotion regulation in infant development. During the first years of life, the maturation of neurological inhibitory systems, cognitive development and parental socialization all influence young children's ability to regulate and differentiate their emotions which, in the long term, influences children's adaptation to stressful situations. Demonstrating effortful control, delay of

gratification and management of disappointment—proxies for emotion regulation—predicts better social and cognitive competence in addition to fewer behaviour problems (Fabes *et al.* 1999). Conversely, poor emotion regulation, often referred to as emotional reactivity, is linked to higher levels of internalizing and externalizing problems (Davies & Cummings 1998). Self-regulation in early childhood is believed to affect coping strategies in adolescence and adulthood (Eisenberg *et al.* 1997). Self-regulation in late childhood is also associated with competent psychosocial development (Lengua & Sandler 1996). Environmental responsiveness, stability and consistency in interactions with parents and peers are integral to the normative development of these systems (Sroufe 1988; Cicchetti *et al.* 1991).

Attachment relationships

The formation of secure attachment relationships is another domain of intrapersonal process with long-term implications for developmental trajectories. Attachments are individuals' representations of their relationships with significant others, usually primary caregivers. The attachment system is based upon the interaction among environmental conditions (e.g. arousing stimuli), internal child states (e.g. distress), and the behaviour and responsiveness of attachment figures (Bowlby 1969, 1982; see Cassidy 1999 for a review of attachment theory; also O'Connor, Chapter 46). Security of attachment refers to the degree to which a child has an internalized sense of significant others as trustworthy, available and loving (Bowlby 1969, 1982; Ainsworth *et al.* 1978) and, as such, can be generalized beyond relationships with parents to relationships with others. Emotional security from attachment relationships reflects a child's confidence in available and responsive attachment figures and is central to emotional well-being (Davies & Cummings 1994). Secure attachments in early childhood predict better peer relations and fewer behaviour problems in later childhood and adolescence (Shaw *et al.* 1997; Greenberg 1999) and healthier relationships and trajectories throughout life (Allen & Land 1999; Thompson 1999).

Cognitive processes

Mechanisms involved in cognitive processing, such as a child's internal representations of the world, are a third developmental domain affecting long-term adjustment and behaviour. In early childhood, children assimilate and integrate observations and appraisals of their experiences into an internalized understanding about cultural rules and expectations regarding behaviour, as well as internal representations of others and self (Zahn-Waxler & Kochanska 1988; Davies & Cummings 1994). Children use these internal working models of human interaction to evaluate and interpret the current behaviour of others and to anticipate future behaviour (Bowlby 1969, 1982; Bretherton & Munholland 1999). Consequently, these internal models, belief

systems and cognitive appraisals play a large part in social competence and peer interactions. Children with expertise in accurately encoding and interpreting environmental cues demonstrate better behavioural competency (Dodge & Price 1994). In later childhood and adolescence, this ability to encode becomes an ongoing complex appraisal system whose balance and accuracy predict better functioning (Kerig 1998a; Kliewer *et al.* 1998).

Conditions that promote healthy intrapersonal processes

Developmentalists and clinicians describe and define the conditions necessary for the healthy development of these processes in different but generally complementary ways. Investigators have stressed the importance of responsiveness, predictability, trust, warmth and sense of security (Bowlby 1969, 1982; Sroufe & Waters 1977; Sroufe 1988; Ainsworth 1990; Davies & Cummings 1994; Chase-Lansdale *et al.* 1995). These experiences are instrumental in facilitating children's emotional, behavioural and physiological abilities to cope with and adjust to stressful and arousing situations. In supportive environmental contexts, children are more likely to learn to regulate their emotions, form close attachments, and develop positive internal representations and accurate appraisal systems. Normative development of these intrapersonal processes greatly increases the likelihood that children will be able to respond to their environment with behavioural, emotional, cognitive and social competence.

We believe that the quality of early relationships is integral to future adaptation, largely through their influence upon these important intrapersonal processes. In early childhood, the family environment is often the context providing the framework for children's early experiences with others. Parent-child interactions reflect a complex bidirectional process of genetic and personality influences (Collins *et al.* 2000; Shonkoff & Phillips 2000). Children's genetically influenced tendencies (such as a sociable or difficult temperament) influence parental behaviour toward their offspring. In turn, parents can act as models of interaction, and their responsiveness, discipline and teaching techniques can directly affect children's emotional and cognitive awareness of others' behaviour and feelings (Zahn-Waxler & Radke-Yarrow 1990). During early childhood, children develop prototypical knowledge of self, others and relationships that serves as a filter for subsequent experiences (Sroufe & Fleeson 1986). The quality of early attachment relationships sets the foundation for the child's sense of effectance, curiosity about the world and, in particular, the ability to engage in intimate relationships (Sroufe 1983, 1996). Primary caregivers' emotional availability and sensitive responsiveness to the infant and growing child are critical factors in the development of secure attachment relationships, and they are important for promoting emotion regulation and providing a beneficial model of behavioural interaction (Ainsworth *et al.* 1978; Lyons-Ruth *et al.* 1989; Bretherton 1996; Eisenberg *et al.* 1997; Bretherton & Munholland 1999). Thus, responsiveness, organization, consis-

tency, safety and warmth are all environmental qualities essential to create a context of security, caring and trust in which children can develop secure attachments, positive models for interaction and emotion regulation.

Although studied extensively in the context of parent–child interactions, relationship quality can and should also be extended to include the child’s broader environment. For example, a child’s interactions with and observations of interadult, peer, and other social behaviour in the home, apartment building or neighbourhood will also influence the scripts and working models they develop to make sense of their world. Furthermore, the sense of predictability and safety that a child derives in the neighbourhood can also influence emotional security and self-regulation, although more distally than from a caregiver relationship.

Later events certainly play an important part in shaping life trajectories. For instance, negative peer groups can have a deleterious effect on behaviour in middle childhood (Rutter, Giller & Hagell 1998b) and adult experiences can influence psychopathology (Brown & Harris 1989; Laub *et al.* 1998). However, early experience appears to have some lasting influences on development, caused in part by the internal structures that the child carries forward through each developmental stage as well as by continuity in environmental contexts (Sameroff 1994; Shonkoff & Phillips 2000). This does not mean that change is impossible at later ages (Nelson 1999), but rather that moving from an unhealthy to a healthy developmental trajectory during adolescence and young adulthood is not as easy as starting off healthily in early childhood (Chase-Lansdale *et al.* 1995).

Processes underlying chronic adversity

Our heuristic model proposes that chronic adversities influence developmental trajectories through the following series of mechanisms. Chronic risk creates environments characterized by disengagement, disorganization, harshness, inconsistency, insensitive responsiveness, poor stimulation, punitiveness, sense of danger and unpredictability. These qualities can exist both for proximal relationships between a child and caregiver and more distal relationships between a child and its broader community. These cross-cutting dimensions in chronic risk environments decrease a child’s sense of emotional security, interrupt attachment relationships, foster emotion dysregulation, modify physiological maturation, distort internal representations and bias cognitive appraisals. The disruption in emotional security diminishes a child’s ability to regulate emotional and behavioural reactions to arousing events. Modified physiological systems limit the body’s ability to cope with stress. In addition, violations of trust, caring and safety negatively influence understanding of relationships and help foster biased appraisals and internal representations. The consequence of these circumstances is an increased likelihood of internalizing and externalizing behaviour problems.

The ongoing interplay between a child’s inherent predisposi-

tions and the environment also serves an important role in this model. Children’s inherent predispositions are conceptualized here as gender, temperament, genetics and physical health. These influence the processes between chronic adversity and child outcomes in a number of ways. First, inherent predispositions are bidirectionally related to the key characteristics of the chronic adversities. For example, certain child temperaments may facilitate greater parental disengagement or negativity. Alternatively, children of affectively ill parents are more likely to have a genetic make-up that predisposes them to poorer mental health outcomes. Secondly, these inherent qualities are bidirectionally related to intrapersonal processes. For instance, genetic predispositions and temperament can influence the development of emotion regulation (Kochanska 1997). Finally, children’s inherent characteristics also have a direct relation to child outcomes. This is consistently seen in the higher rates of disruptive behaviour in males and the higher rates of emotional disorders in females (Canter 1982; Kandel & Davies 1982; Lex 1991; Huselid & Cooper 1994; Nolen-Hoeksema & Girgus 1994).

Empirical evidence

Commonalities across adverse environments

What is the evidence for psychological commonalities across adversities? Chronic interadult conflict creates a home environment in which parents are less emotionally available and where frequent and intense arguments are frightening and threatening to the child (El-Sheikh 1997; Owen & Cox 1997). Discord is related to more coercive parenting patterns (Dadds *et al.* 1990) and less engagement or poorer parent–child relationship quality (Harrist & Ainslie 1998). Poverty entails financial and social strains that interfere with engaged, responsive and consistent parenting (Conger *et al.* 1993; Klebanov *et al.* 1997). The frequent residential mobility and inconsistent routines that are associated with unemployment or transitory employment also can create a sense of unpredictability. Similarly, symptoms of psychopathology can be barriers to effective parenting. For example, parental depression is related to less engaged, less stimulating and less responsive parenting (Field 1995; Leadbeater *et al.* 1996). A chronic violent community promotes a pervasive sense of danger and disorganization as well as creating an environment that is frequently harsh and unpredictable.

The common theme across all of these chronic risk environments is that children are immersed in a context that can be threatening, disorganized, unpredictable, harsh and conflictual. This is also true of other chronic adversities, such as maltreatment, not reviewed in this chapter. Furthermore, environments in which more than one of these adversities is present are even more likely to be characterized by these psychological dimensions.

We do not contend that disorganization, for example, is the same in a household functioning under the strain of poverty as in a household with frequent interparental discord. Rather, we believe that in both cases the environmental disorganization

threatens a child's need for security and predictability. We also do not mean to imply that all of these key commonalities are found in all chronically adverse environments. For instance, inconsistency, harshness and low rates of sensitive responsiveness may figure prominently in certain poverty contexts, while a sense of danger and unpredictability figure prominently in violent communities or in homes characterized by extreme parental discord. It is the pervasiveness of these characteristics, in regard to length of time and extensiveness, which makes the impact of chronic adversities so different from exposure to an acute trauma. Exposure to unpredictability, danger and insensitive responsiveness that is short or limited to one relationship is less likely to influence the developmental path of intrapersonal processes than when those conditions are persistent and pervasive. In comparison to chronic adversities, infrequent or singular acute events can be more easily assimilated as aberrations and are less likely to influence emotion regulation or necessitate the formation of new internal representations. However, chronic exposure to these contextual characteristics can be quite detrimental to these critical developmental processes.

Links to child outcomes

In the previous section, we assembled evidence from the literature for our assertion that varying chronic adversities embody similar psychological experiences for children and adolescents. In this section, we present evidence for our contention that the core features of chronic adversities in fact lead to negative child outcomes. Research across contexts of chronic risk demonstrates the links between problematic child outcomes and the key characteristics of chronic adversities in our model: harshness, inconsistency, punitiveness, unresponsiveness, unpredictability, disengagement, low stimulation and danger. Many, but not all, of these components of chronic adversities are experienced in parental behaviour. For example, parenting quality and practices (e.g. harshness of discipline, low maternal social support and low maternal warmth) explain much of the relation between socioeconomic status and psychosocial problems in children (Dodge *et al.* 1994; Hanson *et al.* 1997; Wyman *et al.* 1999). Maternal responsiveness, rejection and harshness also predict poorer child behaviour and academic outcomes in low-income populations (Conger *et al.* 1997; Myers & Taylor 1998; Shaw *et al.* 1998). Numerous studies also find economic stress influences children and adolescents through disruptions in parental mood and behaviour, which could be proxies for inconsistency, punitiveness and harshness (Conger *et al.* 1993; Duncan *et al.* 1994; McLoyd *et al.* 1994; Masten *et al.* 1995). Moreover, ineffective parental monitoring and discipline, which can reflect disengagement, punitiveness or inconsistency, explain the relation between socioeconomic status and delinquency in early adolescence (Larzelere & Patterson 1990), as well as the relation between parental alcohol abuse and adolescent behaviour problems (Chassin *et al.* 1991). In addition, lower socioeconomic status is associated with children growing up in less cognitively stimulating homes (Klebanov *et al.* 1997),

which in turn mediates the relation between socioeconomic status and child outcomes (Dubow & Ippolito 1994; Duncan *et al.* 1994).

Likewise, some of the work examining the moderating effect of protective factors supports the saliency of the key characteristics of chronic adversities. For example, the relation between maternal depression and problematic preteen outcomes is lessened when the parent-child relationship is warmer and the family demonstrates more cohesion and less conflict (Garber & Little 1999). Warmth, cohesion and low conflict reflect the absence of the key characteristics of chronic adversity we have identified, such as harshness, disorganization, inconsistency, unpredictability and punitiveness. Likewise, family cohesion is a salient buffer in contexts of parental drinking (Roosa *et al.* 1996) and community violence exposure (Friedman 1999). Moreover, children from high-conflict homes are less likely to demonstrate socioemotional behaviour problems if they receive authoritative parenting—a parenting style characterized by high warmth, responsiveness and monitoring (Hetherington *et al.* 1998). Thus, this research shows that resiliency outcomes are more likely to develop in contexts of chronic adversity when the environment is not defined by the presence of some key characteristics.

Role of intrapersonal processes in children's responses to chronic adversity

There is strong evidence that the conflictual, inconsistent and punitive characteristics of the adverse environment influence child outcomes in the context of chronic risk. However, little research examines the saliency of intrapersonal processes as a meaningful underlying mechanism. We now turn to a review of the modest existing empirical evidence for the role of intrapersonal process in children's reactions to chronic adversity.

Several theoretical models address the importance of intrapersonal process (Egeland *et al.* 1993; Crick & Dodge 1994; Davies & Cummings 1994, 1998; Wyman *et al.* 1999), but only a few studies examine this aspect of our model (Dodge *et al.* 1995). For the most part, research demonstrating the links between key characteristics of chronic adversities and child outcomes acknowledges the involvement and potential importance of the intrapersonal processes, but does not directly test them. The few studies examining these intermediary intrapersonal processes support their saliency as an important mechanism within the context of chronic adversity. Yet only a handful of studies addresses the four intrapersonal processes we propose: security, emotional regulation, internal representations and physiological processes. For example, maltreated children evidence internal representations that are more negative (McCrone *et al.* 1994). In addition, marital conflict is related to problematic attachment status in infant-parent relationships (Owen & Cox 1997), and children growing up with severely depressed mothers are more likely to have insecure attachments (Teti *et al.* 1995).

A relatively new area of research suggests that exposure to

chronic adversity may detrimentally affect the physiological systems designed to help humans adapt to arousing and stressful situations (see also Sandberg & Rutter, Chapter 17). The hypothalamic–pituitary–adrenal (HPA) system is one of two systems centrally involved in stress modulation. When a child or adult encounters a stressful or stimulating situation, this system is activated and helps mobilize and regulate the physiological response to stress. Chronic hyperactivity of the HPA, a possible consequence of chronic adversity, is believed to lead to dysregulated functioning of the system, which may impair stress reactivity and regulation (Hart *et al.* 1996). Children with a history of neglect and abuse are more likely to demonstrate altered and dysregulated HPA systems (Hart *et al.* 1996; Rogness & McClure 1996; Kaufman *et al.* 1997). Furthermore, some children in Romanian orphanages, who have experienced severe neglect and lack of stimulation, demonstrate physiological dysregulation (Hart *et al.* 1996). This research suggests that immersion in a chronically stressful environment may lead to alterations in physiological stress responses, which in turn interfere with brain development and emotion regulation (Shonkoff & Phillips 2000).

Evidence for the full model

Up until now, we have tackled separate parts of the model, reviewing evidence for:

- 1 psychological commonalities across adversities;
- 2 links between these psychological commonalities and child outcomes; and
- 3 links between adversity commonalities and the child's intra-personal processes.

The structure of our review reflects the status of the literature. The majority of the empirical work provides evidence for cross-cutting psychological experiences of chronic adversities as well as links to child outcomes. We now highlight two programmes of research that come the closest to examining the complete process model that we propose.

The first exemplar addresses interparental discord, its effects on cognitive appraisals and links to child outcomes. The cognitive–contextual framework developed by Grych & Fincham (1990) proposes that children's understanding of conflict mediates the relation between interparental discord and child adjustment. They hypothesized that children's prior exposure to conflict leads to schemas of beliefs and expectations about what happens in conflict situations. These schemas are then used to interpret behaviour in other relationships (Grych 1998). For example, children exposed to higher levels of interparental verbal and physical aggression view conflict-orientated vignettes as more threatening and have more negative expectations about outcomes of these vignettes than children experiencing lower levels of interparental discord (Grych 1998). Similarly, children from high conflict homes perceive more anger and especially more fear during and after simulated disputes (El-Sheikh 1997). Children's perception of threat has also been associated with negative affective responses (Grych 1998).

Appraisals of conflict properties (perception of frequency, intensity and resolution), self-blame in girls and threat appraisals in boys mediate the relation between marital conflict and child outcomes, with higher levels of conflict interpretations, self-blame and threat appraisals predicting more behaviour problems (Kerig 1998b). This research supports the theory that exposure to interparental conflict distorts children's perceptions of conflict and fear, and that these biased perceptions and appraisals are used to interpret parental behaviour as well as the interactions of others. In turn, the types of appraisals children make are associated with their behavioural adjustment.

The second programme of research that provides empirical support for our heuristic model involves a social information-processing theory of social adjustment. Crick & Dodge's (1994) social information-processing model views behaviour as a function of processing environmental cues in six steps:

- 1 encoding of external and internal cues;
- 2 interpretation and mental representation of cues;
- 3 clarification or selection of a goal;
- 4 response access or construction;
- 5 response decision; and
- 6 behavioural enactment (Crick & Dodge 1994).

Crick and Dodge hypothesized that children's past experiences heavily influence these steps because memories create a general 'mental structure' (which we call internal models) that guide processing of future social cues. For example, early harsh discipline might lead to specific mental representations that would bias children toward hostile and negative interpretations of non-hostile interactions, distracting them from relevant social cues. Hypervigilance to hostile cues would lead children to assume hostile intent in others and because of this misattribution and highly accessible aggressive responses in memory, they would be more likely to behave aggressively (Dodge *et al.* 1997). The authors of this model also suggest that early experiences create neural paths that become activated in future interactions and that emotion is a central influence in each step of processing.

This explanatory model is empirically supported in laboratory studies using videotaped vignettes of social interactions. In school-age children, a history of physical abuse is associated with errors in all steps of information processing—attending to and encoding of relevant cues, interpretation of peers' intentions, accessing possible behavioural responses, and evaluation of consequences—controlling for socioeconomic status and temperament. Furthermore, these types of information-processing cues mediate the relation between abuse history and elevated rates of externalizing problems (Dodge *et al.* 1997).

In a separate longitudinal study that followed a representative sample of more than 500 pre-K children for 4 years, higher numbers of processing errors were associated with more conduct problems. The risk of later conduct problems was four times greater for children with multiple processing errors than for children with no or few processing errors (Dodge *et al.* 1995). In similar but less detailed research, inappropriate or inaccurate inferences about interpersonal situations have mediated the link between maltreatment and behaviour

dysregulation, maltreatment and isolation by peers, and maltreatment and social effectiveness (Rogosch *et al.* 1995).

Toward understanding resilience

Timing

Our model also creates a framework for understanding risk and resiliency and why contexts of chronic adversity do not lead to poor outcomes for all children. One important aspect of this framework is the issue of timing. We believe that children who experience chronic risk later in development are more likely to demonstrate resilience. A relatively low-risk environment during infancy and early childhood would permit normative development of the identified intrapersonal processes. With normative internal representations, emotion regulation and coping systems, older children and adolescents will be more capable of adapting to chronic risks, and the likelihood of poor outcomes will decrease. In contrast, children who are born into environments of chronic adversity or who experience adverse environments early in life will be more likely to have negative prenatal influences and salient disruptions in the normative development of social, emotional and behavioural processes. A wealth of empirical evidence supports the view that healthy experiences in early childhood increase the likelihood of positive life trajectories (Shonkoff & Phillips 2000). However, very little empirical research addresses intrapersonal processes as specific components of resilience in early vs. later childhood. Evidence is accruing on the potential for recovery after abusive, neglectful or violent conditions in early childhood (Rutter *et al.* 1998a; Shonkoff & Phillips 2000), but considerably more research is needed on the reasons why this is the case.

Extent of risk

The second important issue is the degree of comprehensiveness of negative environmental dimensions. While we do not dismiss the theory of cumulative risk, we propose that it overly emphasizes the additive nature of risk, and it does not address the processes underlying multiple vs. few risks. We believe that the chance for resilience decreases with increasing aspects of the chronic adversity that limit normative intrapersonal processes. Thus, the less extensive the proximal and distal characteristics of adversities, the more likely various intrapersonal processes will develop normatively, and the more likely the child will demonstrate resilience. Are the characteristics of chronic adversities dominating the child's experience or not? For instance, a child with an affectively ill mother will be more likely to develop secure attachments, healthy emotion regulation and positive internal representations if a responsive father, free of psychopathology, is present to model healthy interactions and provide environmental organization. This scenario can indeed be understood within the model of cumulative risk: a child will fare better with two risks (maternal psychopathology,

genetic predispositions) than with three risks (maternal psychopathology, genetic predisposition, paternal psychopathology). We reframe this to focus on whether or not the commonalities across chronic adversities are widespread and pervasive vs. intermittent and restricted.

A focus on the comprehensiveness of environmental characteristics also provides a framework for understanding how the triad of protective factors might promote resilience in situations of chronic adversity. For instance, a good relationship with an adult family member acts as a protective factor for children in difficult environments (Rutter 1979; Werner & Smith 1982; Gonzales *et al.* 1996), but little research has examined the underlying process for how or why social support promotes more effective adjustment in children. Our model proposes that social support acts as a buffer by creating a meaningful attachment relationship, modelling positive social interaction, and promoting emotional security and a sense of safety. A child with social support is more likely to develop normative internal representations, cognitive appraisals and better emotion regulation, all of which promote effective coping under stressful circumstances. The protective influence of family cohesion or organization (Roosa *et al.* 1996; Friedman 1999) can be explained similarly. A child living in poverty but within a cohesive family experiences less unpredictability, less disorganization and warmer interrelationships.

The protective influence of inherent predispositions can likewise be understood. For example, children with certain temperaments seem to fare better than children with more difficult temperaments (Sanson & Prior 1999). Within the framework of this model, the underlying processes through which this occurs are specified. Children in high-risk settings who have calmer or easier temperaments may be less likely to invoke punitive parenting styles, thus facilitating healthier intrapersonal processes than would otherwise develop. Easier temperaments might also reflect a more effective inherent capacity for emotion regulation. Children with other types of inherent predispositions, such as outgoing, engaging personalities, may also elicit more positive social relationships from the environment, perhaps with a teacher, grandparent or neighbour, which foster more positive internal representations and cognitive appraisals. Thus, children are most likely to demonstrate resilience when environmental characteristics facilitate more normative development and interaction between inherent predispositions and intrapersonal processes.

Additional considerations

We would like to conclude the discussion of our model with a few caveats. It is beyond the scope of this chapter to address every nuance of this heuristic model, but some final comments are necessary. First, we believe that the model represents a dynamic transactional process, although this has not been the focus of our discussion. The model is not meant to convey a linear or one-way process. We presume that child outcome behaviours listed in the final box influence every aspect of the model.

For example, a behaviourally aggressive or disordered child likely elicits more harshness and disengagement from their environment (Ge *et al.* 1996). Similarly, an aggressive child will often self-select into more conflictual settings, and these environments will further confirm and influence negative or biased cognitive appraisal systems. Not only is the environment acting upon the child, but the child is constantly shaping the environment (Kandel & Wu 1995; Rutter *et al.* 1997; see also Rutter, Chapter 19).

Secondly, we have not fully discussed the potential influence of inherent predispositions although we believe these interact at every point in the model. The genetic contribution to both the chronic adversity and child outcome may be considerable (Pike *et al.* 1996). Parents who pass on genetic risks are also more likely to provide distal and proximal environments with increased risk (Rutter 1999; see also McGuffin & Rutter, Chapter 12). In addition, genetic factors may affect adaptation to chronic adversity by influencing individual susceptibility (Rutter 2000a). Thus, differentiating the genetic contribution from the environmental contribution is difficult. A recent report of the US National Academy of Sciences has renamed these processes ‘nature through nurture’ (Shonkoff & Phillips 2000), arguing that the two go hand in hand and that a focus on trying to separate them is simplistic. Nevertheless, there is a range of research strategies that may be used to test for environmental mediation of risks (Rutter *et al.*, 2001) and these have shown the importance of many of the environmental risks discussed here (Rutter 2000b).

It is beyond the scope of this chapter to review the important fields informing gene–environment correlations in development. Our uneven presentation here is not meant to imply that genetic predispositions are not relevant to the model but, rather, we have chosen to focus specifically on intrapersonal processes in this chapter and to highlight the relative lack of research on the topic. Finally, we would like to acknowledge that in many instances, parents partially select into chronically adverse environments. Exposure to chronic adversity, as an adult or child, is rarely a random event (Rutter *et al.* 1995). This is important for understanding the nature of chronic adversities because the characteristics that lead to this self-selection into adversity may also influence some portion of our model. However, our model attempts to specify what happens once a family is living in a context of chronic adversity.

Moving the field of resiliency forward

We believe that the fields of resiliency and chronic adversity will be best served by focusing on the processes underlying the developmental trajectories for children and families living within adverse circumstances. This has implications for intervention and research. From the standpoint of intervention, our model and the existing literature suggest two main pathways for effecting change. The first pathway involves the policy arena. One clear way to promote healthy development is to limit children’s ex-

posure to chronic adversities. Reducing environmental chronic adversity is no easy task, but the importance of minimizing children’s exposure to chronic adversity should not be overlooked. Moreover, policymakers should recognize the difficulties inherent in trying to change developmental trajectories for children and youth. The removal of a chronic adversity after years of exposure will not produce a quick or radical behaviour change. This speaks to the importance of prevention as well as early intervention.

Secondly, our model and the empirical evidence suggest specific directions for clinicians working with children and families exposed to chronic adversities. Resilience is influenced by the child’s interpersonal relationships and thus family therapy may be critical to successful intervention (Rutter 1999). For young children, the salience of intrapersonal processes means that clinical intervention at the family level should assist parents in promoting an environment that can support healthier development. This might involve helping parents understand the importance of consistent predictable parenting, and working with parents to facilitate healthier attachments, regulation and cognitions. For older children and adolescents, intervention at the family level would be similarly important. In addition, individual clinical work focused on cognitive appraisal systems, emotion regulation and coping strategies would be a helpful supplement (Sandler *et al.*, 2000; Wyman *et al.*, 2000). Finally, clinical intervention could also facilitate alternative structured activities for children and adolescents outside of the family, where they can experience consistency and positive interactions within a demanding context (Allen *et al.* 1997).

Turning to the future of empirical work on chronic adversity, we urge investigators to focus on process-orientated research. We ask that research not stop at examining *what* factors are protective, but also to determine *why* they are protective. For example, we know that IQ and cognitive functioning lead to better outcomes, but we still do not know why (Masten *et al.* 1999). Future research should seek to test competing processes. For example, which of the intrapersonal processes we propose are most important for coping? Many additional questions remain. How do inherent predispositions pull for resilience? What key characteristics of chronic adversities are potentially the most harmful? What defines chronicity and how should it be measured? In addition, the methodological difficulties associated with this area of research must continue to be addressed. Specifically, the cross-sectional nature of many studies, the bidirectionality and transactional nature of effects, and the co-occurrence of risk factors, all pose methodological challenges that researchers must continue to tackle. Our hope is that this heuristic model provides a theoretical framework for answering some of the questions remaining in the literature and for guiding the direction of future research. This will be beneficial not only for deepening our research knowledge, but also for informing clinicians and policymakers about how to best assist families living under chronically difficult circumstances.

Culture, Ethnicity, Society and Psychopathology

Michael Rutter and Anula Nikapota

Concepts of culture and ethnicity

Many modern industrialized societies are multicultural, multi-ethnic and multireligious. Indeed, almost all countries have some degree of cultural diversity. Sometimes such variation is thought of either in terms of immigration or skin colour, but both constitute a seriously misleading oversimplification. Although immigration is likely to have been responsible for the cultural or ethnic diversity in the first instance, it may go back many generations. That is obviously the case with the French and English communities in Canada, and with African-Americans and Caucasian-Americans of European origin in the USA. The fact that ethnicity may not be the defining dimension is also obvious in the clashes between Protestants and Catholics in Northern Ireland, between Hindus and Muslims in the Indian Subcontinent and between Jews and Arabs in the Middle East. In all three examples, religion is the predominant defining feature rather than ethnicity.

It may also be the case that the problems faced by subgroups within a broader community derive from features that are independent of culture or ethnicity. The evil of racial discrimination is an obvious example of this kind. It applies to very heterogeneous 'non-white' groups, many of which would see themselves as having little in common with the others (Jones 1993; Modood *et al.* 1997). A further misconception is that most people have just one culture of which they are a part. Manifestly that is not the case for many people. For example, the recent UK survey by the Policy Studies Institute (Modood *et al.* 1997) showed the very high frequency of intermarriage for people of African-Caribbean origin, although very low rates for some other ethnic groups. The children may feel part of the cultural background of either, or both, parents, but also their community of rearing may be a prime identifier. Many young people rightly regard themselves as Glaswegians or Cockneys, while at the same time identifying with being 'black'. For first-generation immigrant parents the prime identification may be with their birthplace in Jamaica or Nigeria, but for the children (who may not even have visited the country), that may not be the most important feature. It cannot be assumed that parents and children have the same cultural affiliations or values, a consideration that has service implications (see Nikapota, Chapter 69).

Group identifications extend well beyond groups as defined in this way. It may be very important for individuals that they are miners or dockers or lawyers or psychologists, and these identifications, in some circumstances, may be as important

as those related to their ethnic, religious or geographical origins.

'Culture', 'ethnicity', and 'religion' all concern features that involve group characteristics that define values and styles of life. As early scholars expressed it, membership of such groups implies that individuals in them will think and act in certain ways; will conceptualize their lives in relation to group-defined goals, values and pictures of the world; and, to an important extent, behave as expected on the basis of their group membership (Berlin 1976; Shweder *et al.* 1998). However, population group characteristics may operate in several other, rather different, ways. For example, community or area influences may concern a *paucity* of group identification, values or shared goals (Sampson *et al.* 1997). The key feature may then concern *dis*-organization and a *lack* of cohesion. Alternatively, the crucial element may lie in living conditions (poverty, overcrowding, absence of community resources) that derive from discriminatory value systems or from a lack of educational or employment opportunities, or from housing (or other) policies. In these cases, the subgroup is characterized by how they are treated by society, rather than by their own values. This may be important either in terms of group-based stigma or personal social circumstances that stem from societal actions. Another possibility is that the relevant group feature concerns genetic risk or protective factors that vary across ethnic groups (see below).

What we consider in this chapter is why any of these identifications or memberships of population subgroups might be important. In discussing this issue, it is essential to be aware of the multiple meanings and diverse implications of variations that are labelled 'cultural' or 'ethnic' (Rack 1982; Greenfield & Cocking 1994; Nettles & Pleck 1994; Bhugra & Bahl 1999; Masten 1999; García Coll *et al.* 2000).

Implications of group differences

Their possible importance comes in part from the evidence of marked differences among subgroups in rates of particular disorders. Within the UK, the higher rate of schizophreniform disorders in people of African-Caribbean origin has been the subject of much enquiry (Rutter *et al.*, 2001; Hollis, Chapter 37); the much higher proportion of African-Americans in prison in the USA constitutes another example (Rutter *et al.* 1998; see also Earls & Mezzacappa, Chapter 26); the lower rates of suicide among African-Americans compared with Caucasian-Americans constitutes a third example (Nettles & Pleck 1994;

see also Shaffer & Gutstein, Chapter 33). In each case, it is necessary to ask whether the differences in rates of disorder are real or whether they are a function either of biases in processing (by health services or the courts), referral patterns, or responses to psychopathology. It should be appreciated that the issue is one that is pervasive across the whole field of disorder in relation to any kind of subgroup differences. Comparable questions arise with respect to age or sex differences in disorder (see Taylor & Rutter, Chapter 1); to rates of psychopathology in seriously visually impaired or hearing-impaired children (see Hindley & van Gent, Chapter 50); or to the social class differences in some forms of behavioural disturbance (see Fombonne, Chapter 4; Verhulst & Van der Ende, Chapter 5).

Arising out of that first issue is the second question of whether population groups differ in their frequency of exposure to risk and protective factors. Such factors may be genetic or experiential. The best documented example of the former concerns the genetically determined flushing response to alcohol seen in some Asiatics (which is protective against alcoholism) and the range of single gene disorders (such as thalassaemia or the cerebral lipidoses) that vary by ethnic group. Differences in experiential risk are obvious in the disproportionate involvement of some ethnic groups in social disadvantage. The key question is whether the associations with psychosocial functioning or disorder stem from ethnicity, from racial discrimination, from the associated social risks (e.g. unemployment, poor housing, educational disadvantage; Wilson 1987), or some complex interaction between these variables.

Cultural differences may also be important in the variations across groups in which factors provide risk or protection. An early study by Christensen (1960) showed, for example, the marked differences among cultural groups in the effects of a premarital pregnancy on subsequent marriage. More recently, the research by Stevenson *et al.* (1990) has shown the differences among countries in their response to variations in educational attainment. Studies of physical punishment suggest that both their meaning and their effects may vary by ethnicity, presumably because of different attitudes to the use of corporal punishment (Deater-Deckard & Dodge 1997). Similar issues arise with respect to people's responses to obesity and the accompanying effects in relation to eating disorders (Richards *et al.* 1990; Russell 2000).

Cultural influences may be important in people's attitudes to different indications of possible psychopathology. There has been much discussion of the diversity among cultures in the ways in which they express depression or other forms of emotional distress (Kleinman & Good 1986). In some groups, there may be a straightforward reporting of sadness, misery or hopelessness, whereas in others much the same feelings may be expressed in terms of either the somatic accompaniments or inferences or interpretations about what the negative feelings might mean. There are similar variations among groups in their attitudes to taking recreational drugs, to deliberate self-harm and suicide, and to confrontational behaviour. In many Asian cultures, confrontational behaviour in children and adolescents will be so-

cially disapproved rather than viewed as an expression of distress or frustration. Clinicians need to be aware of the variations in the ways in which different people may express what are basically the same phenomena and, similarly, they need to be aware of the variations in the values attached to such phenomena.

A related issue concerns so-called culture-bound syndromes. Despite the fact that they have been recognized for many years, there has been surprisingly little systematic research into such syndromes. At least three different possibilities need to be considered.

1 Culture-bound syndromes could arise because the main risk factors for particular disorders are largely confined to particular population subgroups.

2 Diseases or disorders that are primarily biologically based may be expressed in somewhat different ways in different groups because of variations in attitudes to the phenomena or symptomatology.

3 There may be disorders that arise primarily as a result of a particular set of beliefs within a particular subculture.

Systematic research is obviously needed to differentiate among these possibilities. In each of these instances, there are important methodological issues to be dealt with and particular research strategies needed in order to understand the mechanisms that may be involved. There are also service implications that derive out of the findings, the specific implications varying with the nature of the differences found and the nature of the mechanisms involved.

Cultural vs. cross-cultural studies

One of the major paradigm shifts in recent years has been from cross-cultural comparisons, in which a measure established and tested in one culture is used to compare two or more cultures, to cultural studies in which measures for each culture derive from the lifestyles and modes of communication in that culture (Shweder *et al.* 1998). The aim of the first approach is to study the effects of context on the universals of psychological functioning; by contrast, the second rejects the notion of universals and presupposes that there is a more intimate (and non-separable) connection between culture and psyche such that the focus needs to be on that which is unique to each culture as expressed in its own terms.

The main rationale for the shift is that the concepts and measures as derived in any one culture cannot be assumed to cover the universe of features relevant in all cultures. For example, if the starting point was a non-literate society, the investigative tools would not include tests that could pick up the variations in reading skills in a literate society (or their consequences and correlates). Less obviously, tests of problem-solving skills are much influenced by cultural context (Ceci & Roazzi 1994; Ceci *et al.* 1994). On the whole, schooled individuals solve abstract problems better than unschooled individuals when the problems are couched in the language of schooling, whereas the reverse is the case when the same cognitive tasks are couched in the language of the workplace if the work conditions do not apply to the

schooling group. The consequence is that the conclusions would be opposite according to which culture provided the starting point for the development of tests—as shown, for example, by studies involving Brazilian street vendors (Schliemann & Carraher 1994). The clear implication is that it is essential to use the context of each culture in order to conceptualize the issues and to develop appropriate measures.

However, these findings also serve to bring out the complementary points that there *are* some universals in psychological functioning and that both the differences and similarities between cultures can be assessed and understood if the comparisons are rooted in *both* the cultures to be assessed. This is evident in relation to age and gender effects on emotional disturbance and disruptive behaviour, as shown in a variety of epidemiological studies both cross-cultural comparisons and within nationalities (Bird 1996). Exactly the same point comes from comparisons among spoken languages (Maratsos 1983). Not only is the human capacity for language universal, but also there are many fundamental features that are shared across languages, as well as some that are different. The differences concern both the course of acquisition of syntax and semantics, and also some of the ways in which language is used in social discourse (Shweder *et al.* 1998). The same issues apply to psychopathology. The point that both within-group studies and between-group comparisons are needed is far from restricted to cultures. Very similar considerations arose with respect to the possibility that depression might be expressed differently in childhood from its mode of manifestation in adult life (Rutter 1986). In the event, it has turned out that the similarities outweighed the differences, although both are present (see Harrington, Chapter 29). Equally, it has been proposed that antisocial behaviour in females is expressed differently from that in males; the findings giving rise to the same conclusion (Rutter *et al.* 1998; Moffitt *et al.*, 2001). In short, the need for both within- and between-group studies applies to any situation in which either the biology or the environmental context are sufficiently different to affect the rate or expression of psychological features, irrespective of the operation of culture. The aim throughout is to use such studies to understand the range of causal factors (cultural and other) that influence the rate, form, expression and recognition of psychopathology in different groups. That requires an appreciation of how culture operates but it also requires culturally sensitive comparisons across groups (Verhulst & Achenbach 1995; Bird 1996).

Generalities vs. specificities

The extent to which psychological and psychopathological characteristics are universal across cultures is a matter to be determined by empirical enquiry. Nevertheless, some expectations may be expressed. It is very likely that all human beings experience sadness, misery, anxiety and fear because they reflect the basic biology (Izard & Shwartz 1986). It is equally probable that there will be some variations across cultures in the focus of such emotions, in their cognitive correlations, and in the ways they

are conceptualized and expressed. Equally, there is every reason to suppose that the development of selective social attachments is culture-universal (Bowlby 1969, 1980; Rajecki *et al.* 1978; see also O'Connor, Chapter 46), as a biological phenomenon that stems from humans being social animals. Moreover, the evidence suggests a substantial commonality in its correlates (van Ijzendoorn & Sagi 1999), but it would be surprising if the patterns were identical, irrespective of household composition and style of rearing.

Concepts of mental disorder

The same considerations apply to psychopathology. There are a few conditions, such as Mendelian disorders (e.g. tuberous sclerosis or Williams syndrome) that are wholly a result of some mutant gene (see McGuffin & Rutter, Chapter 12; Skuse & Kuntsi, Chapter 13), that are likely to be culture-universal provided that the genetic mutations occur in all ethnic/cultural groups. The same applies to disorders caused by chromosomal anomalies—such as Down syndrome or the fragile X anomaly. That is probably also the case with disorders that are based on neural pathology, even though they are multifactorial in origin: autism (see Lord & Bailey, Chapter 38) and schizophrenia (see Hollis, Chapter 37) possibly fit such a category. The social context may influence how these disorders are expressed and interpreted, but it may be expected that they occur in all societies; the empirical evidence (in so far as it is available) supports that expectation.

However, that cannot be expected for the broad run of common disorders involving emotional disturbance or disrupted behaviour. Of course, they reflect psychological universals and they, too, will have a biological substrate. Nevertheless, psychosocial factors are more influential and the form of the disorder is quite likely to be shaped in part by social context and cultural mores. On the other hand, the extent to which such disorders actually vary across societies will depend on the degree to which the societies differ in the sociocultural features that play the greatest part in pathogenesis and in individual response. In a later section of this chapter, we consider the empirical evidence on this matter.

Implications of cultural normality

It is sometimes assumed that if either some form of psychopathology or some psychosocial (or physical) experience is accepted as normal within a culture, it cannot be of clinical significance. A moment's thought makes it clear that that is an unsafe assumption. For many years slavery was accepted as normal and acceptable in many parts of the world but that does not mean that it had no adverse psychological consequences. Within our own lifetimes, racial segregation and discrimination (even lynching) was seen as acceptable within subcultures of the USA. Beating children was seen as normal, even beneficial, in the UK until quite recently and, even today, the law allows English parents to give permission for other caregivers to administer physical punishment to their children. Similarly, before

Bowlby's (1951) World Health Organization report, it was thought to be beneficial severely to restrict parents' visiting of their children in hospital, and residential group care was viewed quite positively. Children's emotional detachment when left in institutions used to be seen as evidence of 'contentment', whereas now we view it as psychopathology. The former may still be the view in some developing or non-industrialized countries. In addition, child labour is still a socially accepted solution to family poverty in some societies and it constitutes a large-scale problem in many developing countries, despite the emerging evidence of the damage that may result.

The reverse assumption is equally unsafe: the mere fact that some pattern of behaviour, or some type of child-rearing, is perceived as abnormal in one culture, does not automatically mean that is so in all cultures. The need in all cases is to determine the correlates and consequences within each culture. Nevertheless, there is one implication of cultural acceptability that is reasonably safe and which is clinically important. If a pattern of parental care is highly unusual and socially disapproved within a culture, it is reasonable to suppose that its occurrence may reflect personal psychopathology in the parents (although an exception to this would be those rebelling against a rigid or restrictive value system). By contrast, if the same pattern is both common and accepted as normal within a culture, it is much less likely that its occurrence will reflect psychopathology (although it may do so). In other words, the fact of cultural acceptability has fairly strong implications for the *origins* of a child-rearing practice, but much weaker implications for the *consequences* of that practice.

Measurement of disorder across societies

Tackling questions on possible differences among cultural or ethnic geographically defined groups in rates of psychopathology (either generally or confined to specific disorders) requires attention to a range of methodological issues (Hackett & Hackett 1999; López & Guarnaccia 2000). These include comparability in sampling, as well as in the assessment of disorder, paying particular attention to the need to ensure sensitivity to concepts and features that may be much more applicable in one group than others. In addition, it is essential to evaluate the possibly relevant features of each societal group in order to determine the causes of any differences found, using strategies that can pit one possible explanation (or hypothesis) against competing ones. The needs may be explicated most easily by taking several different examples from the research literature.

Rutter *et al.* (Berger *et al.* 1975; Rutter *et al.* 1975a,b; Rutter & Quinton 1977) sought to compare rates of disorder in 10-year-olds in inner London and on the Isle of Wight (an area of small towns). Rates of both emotional/behavioural disturbance and reading difficulties were found to be twice as high in London—whether measured by screening instruments or detailed individual assessments. In this case, major differences in culture were neither expected nor found and ethnic differences were

bypassed by confining attention to Caucasian children. However, it was crucial to check that there was complete coverage of the population in both areas, that the differences were not an artefact of selective in- or out-migration, and that the disorders had the same meaning in the two populations. In addition, it was crucial to use the same measuring instruments in the same way. The findings showed that the differences were indeed valid. The higher rate of disorder in inner London was found to apply to earlier onset conditions more than to those beginning in adolescence, and the area difference was found to be accounted for by the higher rate of psychosocial adversity in London, together with a higher rate of school adversity. In short, in this study, the group difference seemed to reflect some aspect of the ways in which inner-city life made the good functioning of families and schools more difficult; these family and school difficulties then, in turn, had adverse effects on the children.

A rather similar study by the same research group involved a comparison, within inner London, of children of West Indian immigrants and children from non-immigrant Caucasian families (Rutter *et al.* 1974, 1975c; Yule *et al.* 1975). In this case, the findings showed important differences between the groups in the patterns of disturbance found. Teachers rated the children of West Indian immigrants as showing more disruptive behaviour but this was not found in the detailed reports of parents when interviewed personally. Also, the two groups did not differ with respect to peer relationship problems as reported by teachers, an important negative finding in view of the fact that in most studies disruptive behaviour is associated with difficulties in peer relationships. It was concluded that, although the children of West Indian immigrants showed more disruptive behaviour at school, this did not necessarily have the clinical implications of a conduct disorder that extended to other situations. There were also differences between the groups in the patterns of family functioning, which also indicated the need for caution in making cross-ethnic comparisons.

Since the early 1970s, the situation has changed markedly in several key respects. To begin with, most children today whose families derived from the West Indies were themselves born and raised in the UK. Their parents, too, face a rather different situation: their unemployment rate now is far higher; and the proportion of single-parent households has risen greatly (Modood *et al.* 1997). In the large Policy Studies Institute survey, one-third of the children in Caribbean families had single never-married mothers compared with scarcely any in South Asian families and about 5% in white families (Modood *et al.* 1997). The unemployment rate (especially the rate of long-term unemployment) was twice as high for Caribbeans as for whites. The recent Office of Statistics health survey showed that the rate of mental disorder in 'black' children was only slightly above that in 'whites', with the rate in 'Asian' children rather lower (Meltzer *et al.* 2000). However, this picture altered as the children got older, with a significantly higher rate of conduct disorder among black teenagers. The implication overall is that the psychosocial features (such as single parenthood) may not have quite the same meaning in all ethnic groups.

The third example had as its starting point an explicit focus on one particular disorder, hyperkinetic disorder, for which there were contradictory reports on whether the rate was higher or lower in Chinese children. A research team that spanned Hong Kong and the UK examined the question in a pilot study that involved observational and psychometric measures as well as questionnaire and interview data (Luk *et al.*, in press). The findings were illuminating in showing that although teachers in Hong Kong tended to rate slightly more children as hyperactive than was the case in the UK, observational data suggested that, if anything, the true difference ran in the opposite direction. The results underline the fact that most ratings of psychopathology are inherently comparative and hence are very dependent on people's views on what is 'normal'. Many diagnoses are not open to independent validation through psychometric and observational measures but hyperactivity syndromes differ in that connection. The findings serve as a warning to be careful in drawing conclusions on the basis of group differences on ratings of dimensions such as overactivity, depression or anxiety.

The fourth set of studies, by Weisz *et al.* (1997), compared childhood rates of emotional disturbance and of disruptive behaviour in Thailand and the USA using a mixture of parent and teacher questionnaires, together with observations in the classroom. Clinical vignettes were used to tap perceptions of psychopathology and clinical records were studied to examine referral practices. Despite very marked cultural differences between the two countries, the overall rates of child psychopathology were broadly similar. However, the pattern was somewhat different, with reported emotional difficulties more frequent in Thailand and disruptive behaviour more prevalent in the USA. Interestingly, this was associated in Thailand with a *lesser* tendency to make clinic referral for pure emotional problems, together with a marked tendency to regard children's problems as less serious, less worrisome and more likely to improve. It was also striking that the national differences in rates of problem behaviour on observer ratings were in the opposite direction to those on teacher ratings (the former showing higher rates in Thailand and the latter higher in the USA). The findings from this important set of studies emphasize that differences in perception and expectation have major effects on rates of reported disturbance and that the service implications of these differences may be greater than those of the (usually minor) differences in overall prevalence of psychopathology.

Somewhat similarly, Rothbaum *et al.* (2000) combined a range of quantitative and qualitative studies of parent-child and adult male relationships to investigate the development of close relationships in Japan and the USA. They concluded that the importance and strength of relationships were similar in the two countries, but their meaning and dynamics were different. Provocatively, they argued that in Japan the developmental path mainly involves symbiotic harmony, whereas in the USA it particularly comprises generative tension. They speculate about possible psychopathological implications but acknowledge the limited data on these. The report well illustrates the complementarity of different research approaches, the need to use empirical

findings to derive overarching concepts, and the difficulty of drawing unambiguous answers from such endeavours.

The next example, that of ethnic variations in crime rates, concerns a set of data from numerous investigations, rather than those from one study or research programme. The starting point here is the official crime statistics that show, both in the UK and the USA, a vastly higher rate of imprisonment (for both teenagers and young adults) in blacks than in whites or South Asians (Sampson & Lauritsen 1994, 1997; Smith 1997). The differences are greatest for violent crime and for driving offences. The key questions are: whether the differences are real or reflect some sort of artefact in official records; whether, if real, they reflect ethnic variations in antisocial behaviour or in police practice or judicial processing; whether the antisocial behaviour has the same psychopathological meaning in all ethnic groups; and what causal factors might be operating (Rutter *et al.* 1998). The US data show dramatically that, at least in that country, the differences are all too real. Not only are homicide and violent crime rates higher in African-Americans than in whites, but so too are killings and the experience of physical assault. A young black male in the early 1990s was *eight* times more likely to be killed than a young white male. McCord & Freeman (1990) estimated that a male resident of rural Bangladesh had a greater chance of surviving to age 40 than a black male in Harlem. Self-report data in the UK and the USA tell a somewhat different story. In the USA, self-report findings have shown a substantially higher rate of serious offending among African-American teenagers than among whites (Robins *et al.* 1991; Farrington *et al.* 1996). By contrast, self-report data in the UK and in other European countries have shown ethnic variations that are quite minor compared with the official crime statistics (Junger-Tas *et al.* 1994; Graham & Bowling 1995).

Findings from both sides of the Atlantic have shown some differences in the ways in which offenders from different ethnic groups are dealt with by the police and the courts (these differences being rather greater in the USA). Rutter *et al.* (1998) concluded that the cumulative effects of biases in processing were probably greater than recognized by most reviewers but, nevertheless, it was implausible that they could account for the huge differences in imprisonment for serious violent crime. The evidence on possible ethnic variations in the psychopathological significance of antisocial behaviour is decidedly thin. However, it is noteworthy that the American Epidemiological Catchment Area (ECA) study found no increase among African-Americans in antisocial personality disorder, despite their substantially higher crime rate (Robins *et al.* 1991). The possibility that the meaning of crime may vary across different ethnic groups warrants more serious study than it has received so far.

The evidence on causal influences is also less conclusive than one would like. Sampson & Lauritsen (1997), in relation to the US situation, argued that it was the combination of adverse under-the-roof family circumstances and living in a ghetto neighbourhood without social cohesion or informal controls that provided the main risks. Undoubtedly, that constitutes an important part of the story. Certainly, within the USA, there are

major area differences in crime rates, with socially disadvantaged blacks being much more likely than similarly disadvantaged whites to live in a ghetto, and the ethnic differences may well be much less for those not living in underclass areas (Peeples & Loeber 1994). Nevertheless, there are some puzzling anomalies. Ghettos are much less marked in the UK and therefore less likely to be a major factor. Also, there seem to be important ethnic variations in the ways in which risk factors operate. Several studies have shown that a single-parent home is less of a risk factor for African-American young people than for whites (Peeples & Loeber 1994; Smith & Krohn 1995) and physical punishment too seems to be less of a risk factor (Deater-Deckard & Dodge 1997). There is also some suggestive evidence emerging in the UK that there may be an increase in antisocial behaviour among Asian second- and third-generation adolescents living in socially disadvantaged situations, as compared with that in their parents. We conclude that there are ethnic variations in antisocial behaviour that require explanation but the causal processes involved remain only very partially understood.

The last example is provided by schizophrenia. Numerous reports (McKenzie & Murray 1999; Bhugra 2000) have noted unusually high rates of schizophrenia in people from the Caribbean area now living in the UK (or in the Netherlands; Selten & Sijben 1994). A series of systematic studies have been undertaken both to check the validity of the observation and to test alternative hypotheses regarding the possible causes of the raised rate of schizophrenia (Rutter *et al.*, 2001). Population studies have confirmed that the rate of schizophrenia is indeed at least double that in whites; that the rate is similarly raised in relation to the rate among those of similar ethnicity living in the Caribbean (Hickling & Rodgers-Johnson 1995; Bhugra *et al.* 1996); that the high rate is not found in South Asians; that it mainly applies to schizophrenia but also includes atypical affective psychoses to some extent; and that it is not associated with an increased familial loading (and hence is unlikely to be caused by a difference in genetic risk). Rediagnosis of psychotic cases by a Caribbean psychiatrist provided no indication of diagnostic bias (Hickling *et al.* 1999) and other evidence has indicated that the explanation is unlikely to lie in an increased use of drugs or increased exposure to obstetric complications. Prenatal viral exposure remains a possibility as a contributory factor, although it seems unlikely to account for the high rate. Social adversities seem likely to have been influential, although it remains unclear why these should have had this effect in African-Caribbeans but not in South Asians. Whether or not the excess rate of schizophrenia represents 'ordinary' schizophrenia is uncertain. A 4-year follow-up study of one sample by McKenzie *et al.* (1995) showed a somewhat better clinical course than in whites but a less good social course. Thus, the African-Caribbeans were less likely to engage in suicidal behaviour but more likely to experience involuntary hospital admission and more likely to have spent some time in jail. A secondary analysis of a large sample of patients with research diagnoses, however, did not confirm the increased involuntary hospital care or prison, although it did confirm that African-Caribbeans were less likely to have a

continuous illness and to receive treatment with antidepressants or psychotherapy (McKenzie *et al.* 2001). Kirov & Murray (1999) suggested that, overall, the findings suggest a socially reactive psychosis, but just what those social causal factors are remains quite unclear.

Culture-bound syndromes

The term 'culture-bound' syndromes has been applied to clusters of signs and symptoms that are largely restricted to a particular culture or group of cultures (Prince 1985). Western psychiatrists tend to think of these in terms of apparently exotic clinical pictures found in other countries — with diagnoses such as 'brain fag syndrome' or 'koro' coming to mind. However, it is important to recognize that there are culture-based syndromes much closer to home. Thus, anorexia nervosa is largely limited to Westernized or industrialized nations and is closely associated with the cultural pressures on women to be thin (Russell 2000). Similarly, dissociative identity (multiple personality) disorder is largely restricted to North America, and rates of hysterical ('conversion') disorders have varied greatly over time in keeping with cultural mores (Merskey 2000). Chronic fatigue syndrome probably has features in common with culture-based syndromes (Sharpe & Wessely 2000). The implication is not to memorize exotic clinical pictures, but rather to recognize the extent to which cultural influences and attitudes can shape the manifestations of psychopathology within our own cultures, as well as in those of other people. In each case, it is necessary to appreciate the range of mechanisms that may be involved in the cultural influences, but also to remember that their operation does not mean that individual biological factors will be unimportant.

Conclusions on differential rates of disorder

For the most part, the evidence suggest that, despite wide variations in culture, ethnicity, religion and living conditions, societies differ surprisingly little in overall rates of child and adolescent psychopathology (Bird 1996; Hackett & Hackett 1999). Moreover, there is substantial commonality in the general patterning of mental disorder (Crijnen *et al.* 1999). To some extent, this may reflect constraints imposed by the use of instruments reflecting the concepts of Western societies. Nevertheless, as illustrated by the examples given, studies that have attempted to deal sensitively with cultural variations in concept and perception have also tended to show more similarities than differences among societies.

However, that rather anodyne conclusion requires the addition of several important qualifiers and modifiers. First, there are several major exceptions to the general finding of a lack of variation. The best documented concern the relatively high rate of schizophrenia and schizoaffective psychoses in African-Caribbeans living in the UK or the Netherlands (but not in those living in the West Indies), and the relatively high rate of violent and drug-related antisocial behaviour in African-Caribbeans in

the UK and USA. In both cases, the explanations are likely to involve some aspects of social adversity but quite what these are and how they operate is unknown. A possible third exception concerns the apparently higher rate of autism spectrum disorders in African-Caribbeans in the UK (Wing 1979; Akinsola & Fryers 1986; Goodman & Richards 1995), a difference usually attributed to prenatal viral infections. Although there are few systematic comparisons, the findings also suggest a slightly lower rate of overall psychopathology among South Asians in the UK despite their relatively high exposure to both social adversity and racial discrimination. Family and community cohesion may be protective but this hypothesis has yet to be put to rigorous test.

The second qualifier is that there are major group differences in rates of psychopathology within societies. These have been shown to be systematically associated with variations in exposure to social adversity. In the UK and USA, the high risks have mainly been associated with inner-city life but that has not always been the case in other societies (Quinton 1994). It is not city living as such that creates the risk but rather the accumulation of social adversities that involve social disorganization, poor job opportunities, disadvantageous housing, poor schooling, a lack of community resources, racial discrimination and social exclusion (Rutter *et al.* 1998). The specifics will vary according to whether the location is an inner city in an industrialized society or within a rural setting in a developing country. The extent to which this leads to a situation of learned helplessness and the impact on child and family needs further study. The importance of societal influences (including schooling and peer group effects) is well documented, although uncertainties remain on the precise risk and protective mechanisms involved.

Third, although there are important cultural influences on perceptions and attitudes to child psychopathology, it would be seriously misleading to conceptualize cultures as generally risky or protective in relation to mental disorder. These variations in perception are clinically important for two rather different reasons (see Nikapota, Chapter 69). Obviously, clinicians need to be aware that the ways in which families view their difficulties may not coincide with their own concepts. In addition, people's attitudes to their circumstances and to the problems they face are likely to influence their impact. The environment cannot be thought of as something objective that impinges mechanically on a passive organism. People actively *process* their experiences and *how* they do so will affect the impact of those experiences. In many instances, the *relative* nature of *experiences* may be more influential than their absolute characteristics. Thus, Hackett *et al.* (1999) in their South Indian study found that, as in Western societies, social disadvantage was associated with a higher risk for disorders involving disruptive behaviour (but not for those with emotional disturbance). However, most of the socially advantaged children would be among the poorest groups in the West; yet they did not have a high rate of disorder.

We have already drawn attention to the clinically important findings that, although many psychosocial features operate sim-

ilarly across societies, some do not. The apparently lower psychopathological risks associated with a single-parent household and with physical punishment in the African-American group were given as examples. These may reflect differences in the origins of these features or in their meaning. Thus, if single parenthood is more likely to reflect social mores rather than personal psychopathology, it may involve less risk. In their study of London secondary schools, Rutter *et al.* (1979) found, for example, that although unofficial (unauthorized) physical sanctions, such as cuffing children, were associated with worse pupil outcomes, this did not apply to corporal punishment when administered to a predetermined set of rules and procedures.

Two crucially important points need to be added to the role of culture. First, although culture tends to be conceptualized as all-encompassing, there are marked individual variations within cultures. Many people feel part of several different cultures. Secondly, cultures are far from static. They represent dynamic social processes that reflect a complex changing mix of ethnic, class, gender, religious and societal influences. For example, over the last half century, there has been a huge increase in most Western societies in the proportion of young people living together while unmarried, and having children in that situation (Rutter & Smith 1995). As a consequence, the meaning of illegitimacy has changed out of all recognition, from being an index of social alienation to one of social acceptability. So far there have been few attempts to study the extent to which these changes have altered the associated psychopathological risks (but see Maughan & Lindelow 1997 for an exception dealing with teenage parenthood), and investigations of this kind are much needed. Another example of apparent attitude change within cultures concerns the current trend for women from South Asia, from relatively traditional poor backgrounds, to travel abroad for employment, particularly to the Middle East. Until relatively recently, this would have been the subject of social disapproval but now it seems to be socially sanctioned. So far, there has been a lack of study of the associated risks and benefits for either the women or the children left behind.

Both parental and professional concepts of psychopathology have varied over time, as well as across societies. For example, during the 1960s and 1970s, there were huge differences between the USA and the UK in the diagnoses of both schizophrenia (Cooper *et al.* 1972) and hyperactivity disorders (Prendergast *et al.* 1988); neither of these apply now to anything like the same extent. Similarly, childhood depressive disorders were regarded as quite rare during the same period (Rutter *et al.* 1986), whereas now they are accepted as relatively common (see Harrington, Chapter 29). Cultural studies have attempted to chart possible similar differences between societies in lay concepts of mental disorder. The studies by Weisz *et al.* (1997) were given as a high quality exemplar. There are equally telling examples in the field of scholastic attainment, as shown by the rigorous research undertaken by Stevenson *et al.* (Chen & Stevenson 1989, 1995; Stevenson *et al.* 1990, 1993; Crystal *et al.* 1994; Randel *et al.* 2000). East Asian Americans have been shown to outperform both other Americans and Europeans in

mathematics and that this is associated with a higher set of expectations and different attitudes to homework.

Cultural and ethnic groups vary both in the extent to which they retain the attitudes and lifestyles of their backgrounds and the extent to which they adopt those of another culture. Some become assimilated within the host culture and others adopt cultural dualism. Mass media, consumerism and education may all be influential. On the whole, it seems that non-Western families living in the UK and USA tend to adopt Western attitudes to body size and shape. Accordingly, the apparent variations across industrialized and developing nations in rates of anorexia nervosa are not reflected within ethnic/cultural groups living in the West (see Steinhausen, Chapter 34). On the other hand, educational values of East Asian groups have tended to be maintained. Nikapota *et al.*'s (1998) study of four cultural groups in London found no differences in parents' ability to identify problems (as compared with professionals) but South Asian parents were least likely to ascribe emotional reasons for a problem and more likely than white or African-Caribbean parents to access help for educational difficulties. They were also less forthcoming in their answers to questions on problems—a reporting style that could have implications for their response to screening questionnaires.

The main messages that come out of the findings on cultural influences are that:

- 1 these apply as much within Western societies as in developing countries;
- 2 they are likely to influence both psychopathology and service utilization (see Nikapota, Chapter 69);
- 3 they vary greatly within societal groups and over time; and
- 4 the perceptions and attitudes of parents and children in the same family may not be the same—especially when the older generation was raised in a quite different culture to that in the host society.

The implication is that clinicians should not try to learn stereotypes about different cultural groups because they will not apply to all members of those groups and because the values are likely to change over the generations and as a result of changing social circumstances. Rather, the implication is that clinicians should be sensitive to the operation of cultural influences on all families that they see, not just those of ethnic minorities, and that they should be sensitive to the need to pick up cues on those cultural factors as they operate on individual families and children.

Conclusions

In this chapter we have emphasized the multiple facets of cultural, ethnic and societal variations and their implications for psychopathology. The main focus throughout has been on the conceptual and methodological issues that need to be taken into account in any study of possible social group or population differences. It cannot be assumed that measures of psychopathology or of family functioning have the same meaning in

all groups; within-group studies are necessary to explore the matter. Equally, however, systematic standardized comparisons across groups are possible, and informative, provided they are undertaken with appropriate cultural sensitivity. There are many similarities among societies but attention has been drawn to some clinically relevant differences (see also Nikapota, Chapter 69). These may operate in several contrasting ways. Rutter (1999) summarized these in terms of five broad concepts.

- 1 The effects of social *connotation* or meaning in changing the impact of risk or protective features or the implication of particular psychological patterns.
- 2 Social *comparative* effects by which the influence of a factor derives from its reflection of a person's social standing or value in relation to others.
- 3 A *compositional* effect in which an aggregative group characterization is used to infer some characteristic of an individual.
- 4 A social *contextual* effect deriving from the ethos or qualities of the broader social environment, such as a school or geographical area.
- 5 A social *group characteristic* effect, whereby the influence derives from the behaviour and values of a person's peer group or sociocultural group with which they identify.

Introduction

Over the years, many clinical and epidemiological studies have shown associations between life events of a severely negative kind and psychiatric disorder in children and adolescents (Goodyer *et al.* 1985, 1987, 1993; Berden *et al.* 1990; Goodyer 1990; Jensen *et al.* 1991; Sandberg *et al.* 1993, 1998, 2001; Höök *et al.* 1995; Beautrais *et al.* 1997).

In this chapter we consider four broad questions.

- 1 What do these findings mean?
- 2 What mechanisms might they represent?
- 3 What are their implications for our understanding of the causes and course of psychiatric disorder in children and young people?
- 4 How should the findings affect clinical practice?

First, however, we present a brief historical background of the concept of stress in relation to illness, mental disorder, and on the measurement of stressful life events.

Historical background

It has long been generally recognized that stressful life experiences may have an adverse effect on well-being and predispose to physical and mental disorder (Riese 1969; Garmezy & Rutter 1985; Harris *et al.* 1986; Haavet & Grünfeld 1997). Physiologists focused on the relationship between bodily changes and life experiences containing an emotional component. Through experimental and clinical studies, Cannon (1914, 1929) laid the groundwork for psychophysiological research by demonstrating that external stimuli associated with emotional arousal caused changes in basic physiological processes.

Some three decades later, a bridge to psychiatry was firmly laid out. Meyer (1957), a physician and psychiatrist, argued that life events need not be catastrophic or particularly unusual to be pathogenic. He advocated the value of life charts to bring out temporal links between such happenings as change of habitat, school entrance, graduation, marriage, divorce and bereavement, and the onset of psychiatric disorder.

This proposition was further developed in the 1960s by Holmes & Rahe (1967) through their production of questionnaires to provide overall scores of degree of life change—the assumption being that it was the extent of life change that was stressful and not necessarily the unpleasant nature of the life experiences. The first generation life event measures in childhood

(Coddington 1972; Johnson & McCutcheon 1980; Johnson 1982) were based on similar questionnaire format. In parallel with these overall approaches to life events, there were numerous studies of specific life events such as family break-up or bereavement, and disasters such as floods or hijacking.

The 1970s saw a major reappraisal of psychosocial stress research through the work of Paykel (1974, 1978), who noted the importance of differentiating between desirable and undesirable life changes; of Lazarus (Lazarus & Launier 1978), who emphasized the role of cognitive appraisal of the events; and especially of Brown & Harris (1978, 1989a), who emphasized the need to differentiate between *independent* and *dependent* events (those that could and could not have been brought about by the person's own behaviour) and who developed the notion of the psychological *threat* to the individual as viewed in the light of that person's personal *social context*. The work of Goodyer *et al.* (1985, 1987, 1990a,b), of Monck & Dobbs (1985) and, subsequently, of Sandberg *et al.* (Glen *et al.* 1993; Sandberg *et al.* 1993, 1994), building on these principles, has been instrumental in extending the use of interview assessments with children and adolescents.

At first, the distinction between *independent* and *dependent* life events was mainly based on the possibility that early symptoms of the acute psychiatric disorder might have brought about the life event (Brown & Harris 1978). Thus, someone who was becoming depressed might, through their irritability and agitation, have precipitated quarrels with other people or fallen out with friends. However, it soon became apparent that it was necessary to take a broader view of this possibility (Lazarus *et al.* 1985). Acute disorders often arise against a background of personality difficulties (see Moore & Farmer, Chapter 42; J. Hill, Chapter 43) and may be associated with comorbidity that also needs to be taken into account. It came to be accepted that it was necessary to evaluate independence in relation to any aspects of a person's behaviour and not just the early symptoms of a particular mental disorder (Brown & Harris 1986; Sandberg *et al.* 1993). In keeping with this conceptual distinction Kendler *et al.* (1999), in an adult twin study, found a genetic liability underlying the reporting of dependent, but not independent, negative life events. The results of a comparable study of children and adolescents (Thapar & McGuffin 1996), however, were less conclusive.

Although the original concept of a stressful life event was based on the degree of life change, it was evident that this was not the most important dimension. The degree of unpleasant-

ness seemed more relevant, but it became apparent that the psychological threat involved was most influential with respect to the overall psychopathological risk. Thus, although being bitten by a dog is an exceedingly frightening experience and may induce a fear of dogs, it would be quite unusual for it to precipitate a psychiatric disorder. On the other hand, being rejected by a close friend or humiliated in a public situation, although involving little objective environmental change, may be felt as very threatening because of the damage to self-esteem. Similarly, it became clear that normative life transitions that involve huge change, such as the ‘internal’ event of puberty or the ‘external’ event of moving to secondary school, may or may not carry risk, the key feature being how the person views the event in the light of their own particular life circumstance. Thus, an unwanted pregnancy in a teenager following a casual encounter may carry major threat, whereas a planned wanted pregnancy in the context of a stable harmonious committed relationship is much less likely to do so.

Investigators were sensitive to the certainty of bias if threat was judged on the basis of asking people what they thought about an event. If a person has become depressed following some negative life experience, he or she is much more likely to view the experience as having been stressful. Accordingly, it became standard practice for researchers to rate threat on the basis of an account of social context as they would judge its significance for an average person in that circumstance. Studies with both children and adults that used the degree of contextual threat to assess stressfulness of life experiences have generally found that it is only (or mainly) events carrying high long-term threat that are associated with psychiatric disorder to any substantial degree (Brown & Harris 1978; Goodyer *et al.* 1985; Sandberg *et al.* 1993). However, in practice, many such events are associated with chronic psychosocial adversities, raising the issue of the relative importance of the acute event and of the long-standing adversity (Sandberg *et al.* 1993).

Measurement of life events

Broadly speaking, two main approaches have been used for the assessment of life events. First, questionnaires have asked about the occurrence of specified life events during a particular time period. Good design can ensure that there is coverage of the major common events likely to carry long-term psychological threat, and it is reasonably straightforward to differentiate between probably independent and possibly dependent events on the basis of their nature. Thus, bereavement would fall in the former category and rejection by a close friend in the latter. However, with children there is the further complication that events brought about by parents, although independent of the child, could reflect genetic mediation. This would apply to events such as parental divorce, abuse or neglect (Jockin *et al.* 1996; O’Connor *et al.* 2000). The major advantage of questionnaires lies in their low cost and ease of administration to large samples, making them readily applicable for large-scale epi-

demiological enquiries (Silberg *et al.* 1999). However, they have the considerable disadvantage that they cannot readily deal with the personal meaning or social context of events and they are limited in their power to obtain accurate timing.

Secondly, interviews have been used to obtain detailed descriptions of events, and of their surrounding circumstances, during a defined time period. Accurate timing is facilitated by using personalized time points such as birthdays, family holidays, school terms and the like. Contextual threat, both short-term and more enduring, can be assessed according to a range of components (Goodyer *et al.* 1985, 1997; Sandberg *et al.* 1993). In the Psychosocial Assessment of Childhood Experiences (PACE; Glen *et al.* 1993; Sandberg *et al.* 1993, 1994) these include the following:

- loss of an attachment figure (such as a parent or close friend);
- loss of a valued idea (major disappointment/humiliation);
- physical jeopardy (being in physical danger because of accident, etc.);
- trauma as witness (being witness to a frightening incident involving someone else); and
- psychological challenge (taking on a new role or new responsibilities).

Origins of life events

The early literature on life events seemed to carry the implicit assumption that most arose by chance. The introduction of the concept of dependent events provided a recognition that this was often not the case, because people’s own behaviour shaped their experiences to a considerable extent. That recognition highlighted the need for systematic study of the causal factors involved in individual differences in exposure to acute and chronic negative experiences as well as the psychological mechanisms reflecting psychopathology and risk (Adams & Adams 1993, 1996; Rutter *et al.* 1995; Williamson *et al.* 1995, 1998).

Longitudinal studies have shown the huge importance of a person’s own behaviour. Thus, Robins’ (1966) follow-up of child guidance clinic attenders into mid-adult life found that antisocial behaviour in childhood was associated with a massive increase in negative experiences many years later. These included multiple divorce, unemployment, frequent job changes, lack of friends and lack of social support. Similarly, Champion *et al.*’s (1995) 20-year follow-up of London school children showed that psychopathology at age 10 years (especially conduct problems but, to a lesser extent, emotional disturbance) was associated with a more than doubling in the risk of both acute and chronic life experiences in adult life that caused long-term psychological threat. Many of the events and experiences carrying psychopathological risk involve social interactions (Rutter 2000a) and it is to be expected that these will be influenced by a person’s own behaviour. Shorter term longitudinal studies have given rise to the same conclusion. Thus, Daley *et al.* (1997), in a 2-year longitudinal study of late adolescent women, showed that those with depression that was comorbid with other prob-

lems at the outset had more stress experiences later, and that this held even after controlling for chronic adversity. They concluded that stress generation is not just a product of individual behaviour but, rather, it arises out of a person's social world, a world that has been constructed as a result of both interpersonal and intrapersonal factors.

Other studies have shown the role of parental psychopathology in generating stress experiences for children (Rutter & Quinton 1984; Compas 1987; Rutter 1989a; Jensen *et al.* 1991; Adrian & Hammen 1993; Murray & Cooper 1997; Rutter *et al.* 1997). One study showed that parental personality disorder was associated with a major increase in the rate of marital discord and of hostility to the children, as compared with community controls (Rutter & Quinton 1984). The findings raise two different issues. First, as also shown by other research (Brown & Harris 1986; Sandberg *et al.* 1993), acutely negative experiences are more common in individuals who also suffer from chronic psychosocial adversities. That finding underlines the need to determine the relative psychopathological risk associated with the acute stresses, as distinct from the associated chronic adversities. Secondly, because the parents who are providing their children with negative experiences are also passing on genes, there is the possibility that the risks from life events are, at least partially, genetically mediated. It is relevant that twin studies with both children (Thapar *et al.* 1998; Silberg *et al.* 1999) and adults (Kendler *et al.* 1993) have shown a significant genetic effect on individual differences in the experience of negative life events.

Adoption studies have similarly shown that psychopathology in the biological parents (who did not provide rearing) is associated with more negative parenting by the adoptive parents who did not transmit genes (Ge *et al.* 1996; O'Connor *et al.* 1998). This effect derives from the effects on the parents of the children's (genetically influenced) disruptive behaviour. The same research has also shown effects on the children of the parents' behaviour: the reality is a two-way interactive process. It is evident that any rigorous study of environmental risk mediation must consider the possible role of genetic mediation.

In addition to the influences on life experiences deriving from a person's own behaviour, differences in exposure to negative life events may also stem from societal influences and broad living conditions. This has been shown for family risk factors, such as family discord and disruption, through evidence that these are more common in socially disadvantaged inner-city areas than in less disadvantaged areas of small towns (Rutter & Quinton 1977). Although not focused on acute life events as such, recent area comparisons examining the effects of community social disintegration on antisocial behaviour (Brooks-Gunn *et al.* 1997; Sampson *et al.* 1997) and of the effects of housing policies on such disintegration (Power 1997) suggests that some city areas function (or, rather, dysfunction) in ways that predispose to negative life experiences. Racial discrimination and harassment, which unfortunately remain as features of most industrialized societies (Brown 1984; Madood *et al.* 1997), will do the same. In adults, life events carrying long-term threat have been found to be more common in socially disadvantaged groups

(Brown & Harris 1978); in children the same applies, probably mediated by the effects of disadvantage on chronic psychosocial adversity (Sandberg *et al.* 1993, 1998, 2000). Again, the implication is that research into the risks associated with acute life events will have to take account of these broader environmental adversities.

Testing for a causal effect

The early studies of life events simply showed that individuals with psychiatric disorder tended to experience more negative life events than did general population controls. Brown & Harris (1978) recognized that, in itself, this association did not prove causation. Accordingly, they focused on independent events (to rule out reverse causation) and tested the causal hypothesis by comparing the occurrence of events in the period immediately preceding the onset of psychiatric disorder in cases with the parallel occurrence in a similar time period preceding interview in controls. The design has become the standard life events method, and findings have been consistent in showing that life events frequently precede the onset of a psychiatric disorder. That has been so in both adults (Bebbington *et al.* 1993; Brown *et al.* 1994; Frank *et al.* 1994; Kendler *et al.* 1995) and children (Goodyer *et al.* 1985, 1987, 1990a,b; Jensen *et al.* 1991; Beautrais *et al.* 1997). The findings with adults showing a depressive disorder are the most clear-cut. Thus, Brown & Harris (1978) found that the great majority of episodes was preceded by a high threat event in the preceding 9 weeks. Surtees & Wainwright (1999) found the same, with the provoking effect on onset mainly evident in the first 6 or 7 weeks. There are far fewer findings with respect to the role of stressors in provoking the onset of child psychiatric disorders, but the available data do not show the same strong timing effect (Goodyer *et al.* 1985, 1987, 1990a, 1993; Berden *et al.* 1990; Beautrais *et al.* 1997; Sandberg *et al.* 2001). Rather, it seems that the increase in negative life events applies over an extended period of time, and not just in the weeks leading up to the onset of disorder (Rowlison & Felner 1988; Allgood-Merten *et al.* 1990; Goodyer *et al.* 1990b; Garrison *et al.* 1991; Jensen *et al.* 1991; duBois *et al.* 1992; Esser *et al.* 1993; Sandberg *et al.* 1993; Olsson *et al.* 1999).

Although the standard life events method, it involves several important methodological limitations with respect to the causal inference (Rutter, 2000a,c; Sandberg *et al.* 2001). First, the case-control comparison for a specific time period will be affected by any general (non-time-specific) difference in life events as brought about by either genetic liability or other environmental factors (such as chronic adversity). A more rigorous test is provided by within-individual comparisons of the pre-onset time period with other time periods. The only study so far to use this method gave rise to weak inconclusive time effects, although showing the usual case-control difference (Sandberg *et al.* 2001). Secondly, with very few exceptions, studies with both adults and children have used the same informant for data on life events and data on the onset of disorder. The possibility of

reporting bias is clear, and recent research has moved to using different informants for the two features (Silberg *et al.* 1999, 2001; Sandberg *et al.* 2001). Thirdly, the timing method presupposes that each episode of disorder has a simple unambiguous time point when it began. The available findings suggest that this is the exception rather than the rule. Some onsets are gradual, some symptoms begin before others, and often there is a different point when symptoms lead to social impairment (Rutter & Sandberg 1992; Sandberg *et al.* 2001). Moreover, interinformant and retest reliability on the timing of onsets is weak (Angold *et al.* 1996). Fourthly, most psychiatric disorders are recurrent or chronic; this is so in both childhood and adult life. Accordingly, a more basic question with respect to the causal role of life events is whether they affect liability to psychopathology over time, rather than just having a provoking role with respect to the timing of onset.

Twin studies in both childhood (Silberg *et al.* 1999, 2001) and adult life (Kendler *et al.* 1999) have tackled this question using two complementary research strategies. The first examines the effects of life events on psychopathology within monozygotic (MZ) twin pairs. As these are genetically identical, any within-pair association between life events and disorder must represent some form of environmental mediation. The second uses bivariate analysis in which life events are treated as a phenotype. Cross-twin cross-trait analyses (using both MZ and DZ pairs) enables the association to be partitioned into genetic and environmental components. Both strategies have shown clear (although not strong) environmentally mediated effects. However, it has to be recognized that, if only life events are measured, the findings could be a consequence of life events indexing a broader range of psychosocial risk factors. In short, life events have been shown to be part of those psychosocial features that involve environmentally mediated risk for psychopathology. The extent to which acute life events carry risk that is independent of chronic adversities is not known, but we consider below the limited evidence on this point.

Although the distinction between independent and dependent life events constituted an important methodological step, the fact that a person brought about a particular experience through their own behaviour does not mean that the experience cannot then influence the person's later behaviour or predispose to disorder (Rutter 1986; Rutter *et al.* 1993). Cigarette smoking constitutes an obvious example. People choose to smoke but that does not account for the environmentally mediated effect of smoking on lung cancer, heart disease and osteoporosis. In comparable fashion, appropriately analysed longitudinal data have shown that a harmonious marriage makes it less likely that antisocial behaviour will persist from childhood to adult life (Zoccolillo *et al.* 1992; Rutter *et al.* 1997; Laub *et al.* 1998). In the same way, the fact that a person behaves in a way that leads to rebuffs or rejections from peers, or predisposes to scapegoating in the family, does not mean that the rejection or scapegoating will not constitute a significant stress event for them. It is essential to use research designs and analyses that can provide a rigorous test of the postulated stress effect but it is important to

appreciate that the implication is for research strategy and not for an automatic ruling out of a stress effect. That is pertinent to the finding that children and adolescents with psychiatric disorder differ from community controls in their exposure to both independent and dependent life events, as well as chronic psychosocial adversities (Sandberg *et al.* 1993; Williamson *et al.* 1995; Olsson *et al.* 1999).

Some life events rate high on contextual threat because they cause a major alteration in the child's life circumstances (e.g. death of a parent). In other cases, the threat is primarily cognitive. Thus, there may be little actual change in the external environment but, nevertheless, a drastic alteration in the child's self-perception or self-esteem (as through a severe humiliation) or sense of security (such as stemming from a threat to abandon the child). Many events involve a combination of real life change and cognitively mediated threat (this would be so with a parental divorce or separation).

Some events carry both a negative and a positive affective valence. The contextually positive features usually refer to hedonic qualities, enhancement of self-esteem, or favourable effect on life circumstances. Thus, a father's loss of his job may mean that the child has more pleasurable interactions with him. However, there has been limited study of positive aspects, and the findings have been inconclusive (Jensen *et al.* 1991; Brown *et al.* 1992; Sandberg *et al.* 1993; Leenstra *et al.* 1995).

Many studies have shown that negative life events are frequently associated with, and may arise from, chronic psychosocial adversities ranging from poor housing and neighbourhood problems to illness and discordant relationships within the family (Brown & Harris 1978, 1989b; Goodyer *et al.* 1988, 1997; Jensen *et al.* 1991; Sandberg *et al.* 1993, 1998; Tiet *et al.* 1998). A key issue concerns the extent to which the psychopathological risk derives from some acute event or, rather, from these more long-standing adversities that precede and succeed the event. Thus, it is necessary to ask whether, for example, the main risk derives from the event of a parental divorce or separation or from the discordant conflict that brought about marital disruption (Fergusson *et al.* 1992). In that connection, it is necessary to distinguish between the possible effects on the timing of onset of disorder and the effects on an overall liability to psychopathology. We discuss that issue below, but the point to be made here is that it has been realized that the measurement of life events must be accompanied by assessment of more long-standing difficulties and adversities (Glen *et al.* 1993; Sandberg *et al.* 1993, 2000).

Effect of negative experiences

In so far as negative experiences have enduring effects, it is necessary to consider the mediating mechanisms by which the sequelae are carried forward in time (Rutter 2000a,c). In short, what do the experiences do to the organism? There are many possibilities (Rutter 1989b). Thus, persistence may come about because the initial adverse experiences led to altered patterns of

interpersonal interaction that, in turn, brought about further negative experiences (Rutter *et al.* 1995, 1998). Alternatively, as suggested by the findings on experiences of physical abuse, there may be altered cognitive sets or styles of emotional and cognitive processing (Dodge *et al.* 1990, 1995). A third possibility is that the stress affects neuroendocrine structure and function, as suggested by findings in both animals (Hennessey & Levine 1979; Levine 1982; Sapolsky 1993, 1998; Liu *et al.* 1997) and humans (Hart *et al.* 1996). Interestingly, there is some indication that this may even happen with prenatal stressors (Barbazanges *et al.* 1986; Kraemer 1992; Kraemer & Clarke 1996; Schneider *et al.* 1998).

The mechanism with respect to severe and lasting early adversities, but probably not acute stressors, could also lie in the developmental programming of the brain. It has been well demonstrated through animal studies that sensory input is necessary for the normal development of the visual cortex (Blakemore 1991), and it is likely that there are parallel experience-dependent neural development effects with respect to other experiences (Greenough *et al.* 1987; Thoenen 1995; Pollak *et al.* 1997).

Animal studies of severe stress have shown that this can result in hippocampal damage (O'Brien 1997). There is also limited evidence that the neural effects of social privation may differ from those of separation stresses (Matthews *et al.* 1996; Robbins *et al.* 1996). It remains uncertain whether similar effects apply in humans but it is reasonable to suppose that they may (Bremner *et al.* 1997).

Finally, it has been shown that stress experiences have adverse effects on the body's immunological responses (Drummond & Hewson-Bower 1997; Cohen *et al.* 1999), this possibly providing the mediating factor in relation to the demonstrated effects of adverse life events in increasing people's susceptibility to infections (Turner Cobb & Steptoe 1996, 1998; Cohen *et al.* 1993, 1998). Stress has also been implicated as a provoking factor in a wide range of somatic conditions such as asthma and rheumatoid arthritis (Heisel *et al.* 1973; Jacobs & Charles 1980; Walker & Green 1987; Mrazek *et al.* 1999; Sandberg *et al.* 2000), although whether this derives from immunological effects remains unclear.

Acute life events and chronic adversities

There is abundant evidence that chronic adversities carry a substantial psychopathological risk (see Friedman & Chase-Lansdale, Chapter 15) and, as these overlap greatly with acute negative life events (Jensen *et al.* 1991; Sandberg *et al.* 1993), it is necessary to assess their relative importance. However, in spite of the obvious relevance of the issue, few studies have specifically examined this question and their results are inconsistent (Brown & Harris 1978; Goodyer *et al.* 1988, 1990b; Jensen *et al.* 1991; Tiet *et al.* 1998). Instead, most studies have reported the effects of composite measures of cumulative life stress (Johnson 1986; Berden *et al.* 1990). Such composites often com-

bine acute stressors and chronic adversity (Coddington 1972; Johnson & McCutcheon 1980), so precluding examination of the relative importance of acute and chronic experiences.

Of the studies that have examined the differential and joint effects of acute negative life events and chronic psychosocial stressors in children, one found that the risk of psychiatric disorder was largely caused by chronic adversity, with acute events adding little to that (Jensen *et al.* 1991). Another study reported almost equal risks from acute and chronic stressors which, when they co-occurred, had a multiplicative effect (Goodyer *et al.* 1990a); and two further studies found acute events and chronic adversities exerting independent effects (Goodyer *et al.* 1990b; Tiet *et al.* 1998). Thus, Jensen *et al.* (1991), in a study of clinic referred children, found that most of the case-control differences disappeared after controlling for life events connected with chronic parent-related adversity (such as parental psychopathology or divorce). Goodyer *et al.* (1988) reported independent effects of almost equal magnitude stemming from recent negative life events, and two forms of chronic adversity (maternal distress and poor maternal confiding) but, when occurring together, they had a multiplicative effect on risk of disorder. Another study by the same team (Goodyer *et al.* 1990) showed that acute events and child's friendship difficulties (as a form of chronic adversity) each exerted an independent effect; Tiet *et al.*'s (1998) findings were rather similar. Our own study (Sandberg *et al.* 1993, 1998) showed that psychiatric clinic attenders and community controls differed with respect to both acute stresses and chronic adversities. The two tended to co-occur, with the risks being greatest when this was the case. In that inner-city sample, it was uncommon for psychiatric disorder to be associated with acute events that had no connection with chronic adversity. However, the findings could be different in the case of acute onset depressive disorders, of which there were scarcely any in the sample studied.

There is a great need for research to examine the relative risks for psychopathology associated with chronic adversity and with acute events when each occurs without the other. Such risks will need to be examined separately, with respect to overall liability and in relation to the provocation of onset. It is possible that chronic adversities may prove to be more important for the former and acute events for the latter. The findings on suicide (see Shaffer & Gutstein, Chapter 33) are consistent with that possibility, but the matter has not been systematically investigated as yet.

Specificity/generality of effects

Both in children and in adults, not only have negative life events been associated with a wide range of psychopathology (Goodyer 1990; Sandberg *et al.* 1993; Gowers *et al.* 1996) but they have also been shown to precede the onset of many somatic illnesses (Heisel *et al.* 1973; Jacobs & Charles 1980; Turner Cobb & Steptoe 1998) and to relate to recurrence or chronicity (Bedell *et al.* 1977; Randolph & Fraser 1999; Sandberg *et al.*

2000). Inevitably, the generality of these effects raises questions about mechanisms. If the effects are so non-specific, can they be conceptualized as at all central to the causal processes? Perhaps it is just that negative experiences give rise to a general lowering of resistance to other factors that are more directly implicated in causation.

In adults, some findings have suggested a degree of specificity, with 'loss' events more important in the provocation of depression, and 'danger' events in the onset of anxiety disorders (Finlay-Jones & Brown 1981; Miller & Ingham 1985; Finlay-Jones 1989; Brown *et al.* 1996). Goodyer *et al.* (1990a,b) did not find this was so with children; Eley & Stevenson (2000) did. There has been so little investigation of the possibility that the question must be regarded as still open.

There may also be some specificity with respect to the occurrence of post-traumatic stress disorder (PTSD) following quite exceptional events such as floods, earthquakes, shipping disasters and being taken hostage (see Yule, Chapter 32). PTSD involves a variety of specific psychopathological features but there is considerable comorbidity with a broader range of emotional disorders (Goenjian *et al.* 1995; Hubbard *et al.* 1995; Tyano *et al.* 1996; Bolton *et al.* 2000). It may be concluded that such very severe stressors can precipitate disorders other than PTSD. On the other hand, such events constitute only a tiny minority of the life events that provoke disorder (Giaconia *et al.* 1995).

Bereavement may be associated with a characteristic immediate grief reaction (see Black, Chapter 18). It may also predispose to a wider range of later psychopathology, although the risks are less than those associated with parental separation or divorce (Rutter 1971). It seems that the key risk feature concerns the conflict, discord and hostility associated with break-up rather more than the event of break-up itself (Fergusson *et al.* 1992). Similarly, with respect to the risks for depression arising in adult life stemming from childhood loss, the evidence suggests that the key risk feature concerns poor parenting, rather than loss *per se* (Harris *et al.* 1986).

All the findings point to the need to consider individual differences in susceptibility to stress; we consider that issue next.

Individual differences in susceptibility to life events

A universal finding of research into all manner of environmental stresses and adversities has been the huge heterogeneity in response (Rutter 2000a,b,c). Even after experiencing the most severe of psychosocial hazards, some succumb to disorder but others escape. There are numerous methodological problems to be overcome before a confident inference on variations in susceptibility can be made. It could be that the heterogeneity of response lies simply in individual differences in the severity of the stressor experienced, in the presence of other risk factors, or in outcomes not measured. Nevertheless, even when experiences can be experimentally controlled, as through regulated exposure to disease-inducing bacteria or viruses (Petitto & Evans

1999), or through studies of unusual events such as parachute jumping (Cox 1978; Rose 1980), or enemy attack during warfare (Bourne *et al.* 1968), marked individual differences in susceptibility have been found.

Some of this variation in susceptibility is a function of genetic influences, as shown by molecular genetic research in relation to features as diverse as infections (Hill 1998a,b), head injuries (Teasdale *et al.* 1997), cardiovascular accidents (McCarron *et al.* 1998), allergens (Cookson 1999) and smoking (Talmud *et al.* 2000). Less is known about specific genetic factors in relation to psychosocial stressors but twin data have pointed to genetic moderation of psychopathological responses to life stressors (Kendler *et al.* 1995; Rutter 2000b; Silberg *et al.*, 2001), probably through the mediation of effects on neuroticism (Kendler 1996), although that has still to be demonstrated.

Past experiences may either have a sensitizing or steeling effect (Rutter 1981). Early animal experiments showed that stress experiences, through their effects on the neuroendocrine systems, could affect resistance to later stressors (Hennessy & Levine 1979). A parallel may be drawn with protection against infections (Tyrell 1977). Protection and immunity lies not in the avoidance of infection, but rather in exposure to small doses, with the body having learned to cope successfully with the pathogen (either through immunization or natural exposure). It is likely that there is a similar sort of adaptation in relation to psychosocial stresses and adversity. There are several studies in which findings suggest that children have been strengthened by having coped successfully with life's difficulties (Stacey *et al.* 1970; Elder 1974). Conversely, previous stresses or adversity may make children more vulnerable if they did not cope well (Quinton & Rutter 1976). The findings on what leads to experiences having a sensitizing or steeling effect are sparse and inconclusive but probably the crucial factor is whether or not the experience resulted in successful coping and adaptation.

Early experiences may also render children unusually susceptible to later stresses if they left the individuals with impaired feelings of self-efficacy (Bandura 1997) or lacking in social problem-solving skills (see Compas *et al.*, Chapter 55). Brown & Harris (1978), in their studies of depression in women, found that this vulnerability was particularly associated with a lack of adequate parental care in childhood (Harris *et al.* 1986; Brown 1993; Brown *et al.* 1993; Bifulco *et al.* 1998). The empirical findings on the role of coping in children's response to life stresses are few. However, there is some evidence that an active (rather than avoidance) style using emotion-focused (rather than action-focused) strategies may reduce the risks associated with stress experiences (Armistead *et al.* 1990; Eisenberg *et al.* 1993; Sandler *et al.* 1994; Lengua *et al.* 1999; Mazur *et al.* 1999). An anxious temperament, negative affectivity, low self-esteem or poor cognitive ability may do the opposite (Davies & Cummings 1995; Sheets *et al.* 1996).

Concurrent social support may also moderate children's responses to stress. Goodyer *et al.* (1988, 1989; Goodyer 1994) found that peer relationship difficulties predicted emotional disorders in childhood, and Sandberg *et al.* (1993) found that a lack

of a confiding relationship with parents or some other close adult relative increased the psychopathological risk associated with negative life events. Silberg *et al.* (2001) found that parental anxiety or depressive disorder increased children's vulnerability to negative life events. Better family functioning and close parental monitoring have also been shown to predict resilience in young people subjected to stressful life events (Tiet *et al.* 1998).

The effects of risk experiences are also influenced by the ways in which people think and feel about what has happened to them. The same event (such as becoming team captain or school prefect) may be seen as either very positive, because it serves as a mark of prestige and accomplishment, or very negative, because it brings new challenges, new uncertainties and new people to deal with. This has been little studied in children but research with adults (Teasdale & Barnard 1993) suggests its possible importance.

In relation to long-term sequelae, how children respond to the initial negative experience may set off either negative or positive chain reactions that will bring psychological sequelae. Thus, reliance on drugs or alcohol to relieve stress, or dropping out of education, or leaping into a teenage pregnancy or impulsive marriage as a way of escaping family conflict, are all likely to increase the chances that adverse sequelae will persist. Conversely, some sorts of response may serve to elicit supportive reactions from other people and, by so doing, may predispose to positive chain reactions that foster resilience (Rutter 1999).

The topic of resilience/vulnerability in relation to stress and adversity is important, both theoretically and practically, because of the well-demonstrated individual variations in response. However, as briefly summarized here, although there are reasonable leads on some of the underlying risk and protective factors, much remains to be learned (Rutter 1999, 2000b,c; Luthar *et al.* 2000).

Clinical implications

The issues considered above give some indications for life events enquiries to be adopted as part of routine clinical practice. This applies particularly to disorders that appear to have had a sudden onset. In practice, these are most likely to involve conditions characterized by anxiety, depression or phobias. In such acute presentations, a stressful life event, even if not the main cause of the disorder, may well have triggered it off. An example may be a very unpleasant and frightening incident of a child being bullied and refusing to go to school thereafter. However, given the general run of referrals to child and adolescent mental health services, such *de novo* sudden onset cases are likely to constitute a minority. Most referrals concern youngsters with a mixture of emotional and behavioural problems that often also have evidenced a fairly lengthy existence. The psychosocial experiences usually detected in the background of these tend to consist of a mixture of chronic and acute stress exposures. Therefore, both of these should be included in the initial enquiry. Occasionally, it may still turn out that some recent stressful life event to the child

or to the parents has brought the situation to a head, and the need for professional help has become urgent. The main issue in such situations may be support to the parents in order to enable them to regain control of their lives, and to effectively cope with the child's challenging behaviour.

The questions considered above also raise issues relevant for treatment and prevention. The overrepresentation of behaviour-related negative life events among psychiatrically disturbed children and adolescents points to an important therapeutic need for interventions directed at the children themselves, to help to modify their behaviour. Moreover, the interpersonal family conflicts, commonly involving active participation of the young person, also indicate a need for therapeutic interventions for the child and the whole family. Although unlikely to cause the disorder in the first place in most cases, such behaviour-dependent negative events may well exacerbate it.

Conversely, the preventive measures should explicitly involve the parents in order to reduce the risk of the child's enduring stressful life events stemming from parental actions, often reflecting either their personal psychopathology or marital conflicts. Likewise, the need for socioeconomic interventions by the society at large is implicated by the excess of chronic psychosocial adversities, such as poverty and unemployment, as well as those stemming from parental psychopathology and criminality, all of which are more common in the socially disadvantaged. This observation therefore introduces a further significant issue; the likelihood of familial transmission, with regard to the origins of stressful life events commonly found in excess in psychiatric samples.

Looking into the future

At this stage of the chapter it is appropriate to consider what we have learned from research about the importance of stressful life events on the mental health of children and adolescents, and what are the gaps to be filled and the challenges that should be met in the future. It seems appropriate to begin such a 'forecast' with a brief statement about where the field is now. This means acknowledging that the available evidence strongly suggests that severely negative life events play a significant part in increasing the overall risk of psychiatric disorder in children and adolescents. This is especially so with regard to acutely stressful life events occurring in conjunction with high levels of chronic psychosocial adversity. Furthermore, this combination of acute and chronic life stress increasing the risk is not unique to psychiatric disorder, but appears to exert much the same influence on physical illness, such as asthma (Sandberg *et al.* 2000). The topic is therefore of undoubted importance.

Although substantial progress has been made in the development of research strategies capable of testing environmental mediation hypotheses, their utilization so far has been almost rudimentary. Compared with our knowledge about psychosocial risk indicators, relatively little is known about the actual environmental mechanisms and processes that underlie the risk

mediation. Also, the knowledge concerning diagnostic specificities in relation to risk processes remains very limited. Most research has been concerned with antisocial behaviour; and therefore much more needs to be learned about the role of environmental factors in the genesis of depression and anxiety disorders in this age group.

Future research also needs to pay attention to factors determining individual differences in exposure to stressful life events. Likewise, better research is needed to differentiate environmental effects on the person, and person-effects on the environment. More detailed knowledge about individual differences in responses to psychosocial stress and adversity is also of crucial importance. Likewise, in so far as these differences relate to mechanisms of resilience, that too remains a topic requiring research (Rutter 2000b). A shift in research focus is also needed, from the precipitants of the onset of disorder to an understanding of processes operating over time—both in the initiation and course of psychiatric disorders as they remit and relapse. In addition, the need to understand indirect chain reactions and to learn about how they operate is crucial. In that connection, perhaps the least well understood of all issues is what psychosocial risks do to the organism. More than anything else, this last question requires that psychosocial research be part of biological psychiatry.

In this spirit, it is also hoped that in the future the identification of all the genes in the human genome will open up opportunities for a more thorough analysis of neurotransmitter-related and other genes involved in personality dimensions and behaviour. Given this, a fuller understanding of how individual genetic variation influences susceptibilities to environmental hazards would be possible (see also McGuffin & Rutter, Chapter 12). This should offer new insights enabling better treatments for the mental health consequences of stress in children and young people.

Introduction

The loss of a parent by death is one of the most significant developmental challenges a dependent child can face, one which has been implicated as a major risk factor for psychiatric disorder in childhood and later. This chapter reviews the known effects of parental bereavement on children of different ages and varying levels of cognitive development, drawing on research on humans and higher primates, sets out the principles for clinical assessment of the impact of bereavement on child and family, and discusses the selection of appropriate preventive and therapeutic interventions. The effects of bereavements other than parental are less well researched but will be touched upon. The effects of traumatic bereavement (the loss by death which is sudden, unexpected and horrific as occurs in war, civil conflict, accidents, suicide and homicide) will be considered separately. The effects of witnessing or being caught up in traumatic events which do not necessarily result in bereavement are considered in Chapter 17.

In Western countries between 1.5 and 4% of children are orphaned of at least one parent in childhood (Haskey 1993). In developing countries, and those affected by natural disasters, war and civil conflict, the figures are much higher. In Britain in 1995, 1 in 5 of all dependent children was living in a one-parent family, but only 1 in 25 lone parents is widowed (compared with 1 in 4 in 1971) (Haskey 1998). As the proportion of children reared in single-parent households increases, the death of a sole parent figure is likely to be associated with an increased incidence of morbidity in the children. As premature deaths from other infectious diseases decline, deaths of parents from AIDS presents a new scourge, leaving large numbers of doubly orphaned children in many parts of the world.

The biology of loss

The poignant description by Goodall (1996) of the suffering of the infant chimpanzee in the wild, when bereft of her mother, is echoed by the experimental laboratory work of Hinde (Hinde & McGinnis 1977), Harlow (Seay & Harlow 1965) and Suomi (1983) with monkeys, and Hofer (1996) with rats, indicating that primates, at least, react in ways similar to humans when deprived of their caregiver.

In an attempt to understand the biological aspects of loss that are central to its role as a risk factor for disease, Hofer carried

out a study looking at physiological and behavioural responses of infant rats to separation from their mothers before the normal weaning time. The rats in Hofer's study displayed an initial 'distress' calling, followed more slowly by profound behavioural inhibition, said to be very similar to the sequence of 'protest' and 'despair' phases described by Bowlby in human infants (Bowlby 1969). Hofer explores the effect of the loss of 'hidden maternal regulators', such as touch and smell, on infant and later behaviour in rats. Early separation induced a susceptibility to a complex and widespread regulatory disturbance which was still manifest later in life and increased susceptibility to stress-induced pathology. However, the response was dependent to some extent on the quality of the pre-separation mother-infant relationship. He suggests that this may give a clue to understanding how regulatory interactions, such as feeding or warming, become linked in the memory with the same pattern of maternal olfactory, auditory and visual cues giving an 'internal working model' of the mother as an attachment figure. Her loss is then experienced at a deep visceral level as well as at the psychological level of sadness. He elaborates this theory to hypothesize about the way that older human children develop the ability to predict future events as a result of this internal working model and how early loss of the mother interferes with this information processing and thus shapes adult behavioural traits and future vulnerability to stress.

Recent studies on the effect of trauma on the developing brain suggest that a traumatic experience, such as the sudden and permanent loss of the main caregiver, can alter the way the brain of the infant organizes and internalizes new information, which can influence the subsequent regulation of affect and may permanently alter neurophysiological function and emotional development. The right orbito-frontal cortex, which is responsible for regulating and mediating affect, social relations and emotional balance, among other functions, may develop differentially, depending on early infantile experiences and the responsiveness or even availability of the primary caregiver in allaying fear (Schoore 1994; Perry *et al.* 1995). Schoore suggested that the experiences 'that fine-tune brain circuitries in critical periods of infancy are embedded in socio-emotional interchanges between an adult brain and a developing brain'. Although a good deal of caution is needed at this stage, if these findings are confirmed, they help to understand why the loss of the adult who has made such an accommodation is likely to affect the infant profoundly. Perry *et al.* (1995) found that, in the infants they studied, there were various adaptive mental and

physical responses to trauma, including physiological hyperarousal and dissociation. These acute adaptive states can become maladaptive traits. Their findings have implications for clinical assessment, intervention and prevention and can help to explain the increase in anxiety and depressive disorders in bereaved children both in childhood and adult life. Some of the findings may not be specific to loss but might be the effect of chronic or severe adversity.

Why should bereavement concern psychiatrists?

Grief is a normal response to bereavement, but it causes at least as much suffering as, say, fever, the normal response to an infection and may be as dangerous to the organism. Grief has many of the components of what would otherwise be regarded as a major depressive episode (e.g. feelings of sadness, insomnia, poor appetite, weight loss) and this is recognized by the DSM-IV definition of bereavement (V62.82). However, the normal processes of grief usually lead eventually to recovery, even though a new identity has to be assumed: widow, orphan, etc. (Parkes 1972). Symptoms such as guilt, thoughts of death, morbid preoccupation with worthlessness, marked psychomotor retardation, prolonged and marked functional impairment, and hallucinatory experiences are usually considered to be more typical of a pathological grief reaction. This definition is an adult-orientated one, but older children and adolescents may also fit this picture. It has been argued that the DSM-IV definition does not satisfy the observations made about childhood bereavement (Vida & Grizenko 1989) but it does at least acknowledge the need for recognition of the trigger to the development of symptoms. On the other hand, the ICD-10 does not recognize bereavement as having the possibility of generating *specific* psychopathology. What evidence there is favours the development of specific depressive disorders in adult life associated with bereavement, particularly when it occurs in childhood (Brown & Harris 1978) although chronic adversity following the loss of a parent may be the intervening variable (Harris *et al.* 1986). This is developed in more detail below.

The loss of a parent by death has interested theoreticians and clinicians for many years. Freud (1917) noted the effect of the death of a loved one on his adult patients and Bowlby (1969, 1972, 1980) developed the theory of attachment as a biological organizer of human behaviour, with the inevitable converse phenomenon of loss. Parkes (1972) was one of the first researchers to study widows systematically and to identify the high morbidity that occurs after the loss of a spouse, both immediately and in the longer term. Studies on the origins of depressive illness in adults have found life-events involving some kind of loss occur significantly more often in individuals suffering from these disorders than in controls (Paykel *et al.* 1969; Birtchnell 1970; Brown & Harris 1978; Berlinsky & Biller 1982; Paykel & Dowlatshahi 1988).

Rutter was one of the first researchers to establish that be-

reaved children were at enhanced risk of developing psychiatric problems compared with non-bereaved controls, finding that children attending the child psychiatric department of the Maudsley Hospital were significantly more likely to have lost a parent by death, than controls attending a dental clinic (Rutter 1966). Many early studies of the effects of bereavement on children used parental reports (Black 1978; Black & Urbanowicz 1985, 1987; Elizur & Kaffman 1983; Van Eerdewegh *et al.* 1985) but more recently the children have been studied directly (Raphael 1982; Kranzler *et al.* 1990; Weller *et al.* 1991; Silverman & Worden 1992; Thompson *et al.* 1998). All these studies found that children bereaved of a parent, when compared with controls, had higher levels of psychiatric symptoms in the immediate aftermath and on follow-up 1 or 2 years later. When children are studied directly, higher levels of morbidity are found. For example, a controlled study of 38 bereaved children aged 5–12 years (from 26 families out of a potential 101 families) found that 37% of the bereaved children met DSM-III-R criteria for major depressive episode 3–12 weeks after the loss (Weller *et al.* 1991).

A prospective study of 26 recently bereaved 3–6-year-olds, using matched non-bereaved controls, showed that there were significantly more symptoms, particularly symptoms of anxiety and depression in the bereaved children than in controls. Bereaved children, especially girls, reported significantly more sadness when thinking of their parents than did controls. Depression in the surviving parent was the most powerful predictor of child disturbance (Kranzler *et al.* 1990). Multiple bereavements are likely to enhance the risk of later psychopathology (Goodyer & Altham 1991).

Young children are more likely than adults to have difficulties with the comprehension of death and the processes of grief and mourning. They are more likely to develop pathological mourning reactions because of limitations in their understanding, lack of information and changes in their lives (Bowlby & Parkes 1970; Goodyer 1990b). Symptoms in bereaved children may be delayed in onset, so that studies of recently bereaved children may underestimate the distress. This may be a response, not to the bereavement itself, but to the consequences of the death. Children who lose their mothers suffer a reduction in the quantity as well as quality of care (Weller *et al.* 1991) and the finding that adult psychopathology following childhood loss of a parent is correlated with the adequacy of care following the death (Harris *et al.* 1986) has implications for preventive intervention.

Goodyer *et al.* (1990a), on the basis of a series of population studies on school-aged children, concluded that recent undesirable life events exert a significant (about five times) adverse effect on the probability of being anxious or depressed which was independent of maternal adversities (poor confiding relations in mothers' own lives and the presence of maternal distress). Emotional disorders in the children were best predicted by the presence of all three adversities. The Christchurch longitudinal study had a similar finding (Fergusson & Lynskey 1996).

Disruption of attachment because of the death of a caregiver—usually a mother—during early childhood increases

the risk to the child of developing an attachment disorder, a separation anxiety disorder, anxiety, depression or other emotional disorder during childhood and adolescence.

A literature review of the effects on children of bereavement concluded that findings were inconsistent and that there was a lack of appropriate measurement tools (Berlinsky & Biller 1982). The Harvard Bereavement Study (Silverman & Worden 1993) attempted to remedy this using multiple measures, some of which they devised. They noted that preadolescent children often did not express grief directly but there was a high incidence of somatic symptoms. They suggest that bereavement outcomes need to be conceptualized in terms that emphasize change and adaptation rather than the presence or absence of diagnostic categories.

Mental health professionals may be asked to help in the immediate aftermath of a bereavement because of dysfunction. They may also find themselves treating long-term psychopathology which is associated with an earlier bereavement. They may also be called upon to advise on or set up preventative services after a bereavement, especially a sudden, unexpected and traumatic one.

Resilience

Although bereavement enhances the risk of developing psychopathology, the majority of bereaved children do not develop psychiatric disorders either in childhood or adult life and epidemiological studies indicate that childhood bereavement in itself is not a major risk factor for later psychopathology (Harrington & Harrison 1999). Studies on the resilience of children (Rutter 1985) note that resistance to stress is relative, not absolute; the bases of the resistance are both environmental and constitutional and the degree of resistance is not a fixed entity, but varies over time and according to circumstance. For example, genetic factors (such as temperament or cognitive level) have their impact through their role in influencing individual differences in susceptibility to environmental risk, as do children's prior experiences (Rutter 1999). Later experiences are not independent of what has occurred before and vicious cycles can build up unless prevented by therapeutic intervention. Rutter makes the point that the reduction of the negative impact of an event or adversity becomes a critical issue in prevention and this forms the basis for the rationale of intervening with bereaved children and those about to be bereaved.

Children's grief reactions

Children who have reached school age are as capable as adults of comprehending death, of expressing grief and taking part in community mourning rituals. The reactions may appear different because they often take an immature form. The influences on the expression of grief and the ability to mourn by children are

related to their cognitive, emotional and physical developmental levels.

Cognitive development

The child's ability to comprehend the various components of the concept of death has been well-studied and the consensus is that by 5 years most children of normal intelligence can understand that death is irreversible, universal, has a cause, involves permanent separation and that dead people differ from live people in a number of respects: they are immobile, unfeeling, cannot hear, see, smell, taste, speak and all their bodily functions cease. The concept of corporeal deterioration is more difficult for young children to comprehend and this concept is not fully formed until nearer puberty (Kane 1979; Reilly *et al.* 1983; Lansdown & Benjamin 1985). In a review of children's reactions to death (Cuddy-Casey & Orvaschel 1997) the concepts of irreversibility and universality were found to be understood before causality, and external events, such as moving and speaking, were believed by children to cease before internal ones, such as thinking and feeling. Children younger than 5 years generally appear unable to give a narrative account of the sequence of events around bereavement.

Other cognitive difficulties involve immaturity in searching for the dead parent, an important component of the process of mourning, and anticipating both the death and the prospect of missing the dead parent. There is a developmental progression in the ability to envisage how one might feel on future occasions. For example, it would be difficult for young children to imagine that they might miss their mother all over again when they next go on holiday. Anticipatory mourning for all the small and large events and situations at which the mother will no longer be present is therefore more difficult and, when the event comes, the child is unprepared for the emotional experience of renewed loss.

Cognition plays a part in reunion fantasies, which are concrete in early childhood:

Harry, aged 3 when his father died in hospital, said when he visited his grandmother in the same hospital, one year later: 'Good, now we can see daddy again.' His mother thought he had understood that his father's death was permanent and was surprised that he had held on to the hope of reunion for so long. It clearly was revived by the visit to the last place he had seen his father alive.

Children are rarely prepared for the death of a parent or a sibling. In adults mourning is aided by anticipation of the inevitability and proximity of death (Parkes 1972). The evidence for children is contradictory. While several studies have found that if children are prepared, the morbidity is subsequently lower (Rosenheim & Reicher 1985; Siegel *et al.* 1997), Saldinger *et al.* (1999) found, in a community study of parentally bereaved young children, that forewarning of death does not lead to better mental health outcomes than when there is a sudden death. Other studies have noted similar findings (Kranzler *et al.* 1990; Freeman *et al.* 1991; Fristad *et al.* 1993). It may be a

function of developmental stage. Younger children cannot perform the cognitive task of anticipating and most studies do not analyse their findings according to age.

Cognitive limitations also affect the child's ability to recall memories, especially in the absence of contextual cues (Johnson & Foley 1984). These are often denied to them by protective adults who do not wish to remind them of their loss. The places they visited with their parent are avoided, so mourning for the lost parent is inhibited. Whereas adults can take themselves to the places in reality and in fantasy, it is more difficult for children to do so.

At least one study (Van Eerdewegh *et al.* 1982) found that the loss of a parent is associated with difficulties in learning and failure to maintain progress in school in the presence of a normal intelligence.

Learning disability

Children with moderate or severe learning disability have not been studied in relation to bereavement. Studies of adults with learning disability have found that they are often not told about significant deaths in the family, and are not given the support that both adults and children of normal intelligence receive. Their reactions to the death may be misunderstood, they may not be allowed to participate in family or community rituals (Cathcart 1995). Even when they experience a bereavement, their understanding of death may not have improved, although their reactions indicate that they are aware of a change in their lives and they can be helped to grieve and to relinquish their attachment to the dead person (Hollins & Esterhuyzen 1997; Bonell-Pascual *et al.* 1999).

Emotional development

Children's capacity to sustain sad affects increases gradually with age and maturity. Not only may they avoid the experience of the pain of grief but young children do not sustain affects for long periods and their apparent lack of sadness may deceive their caregivers into believing that they are unaffected by the loss.

One way in which children obtain understanding of events is through repetitive play, which may be distressing to adults because it lacks appropriate affective expression. Children need to be able to understand the reality of death in order to mourn and yet they are given less opportunity to see for themselves the physical deterioration and then the immobility and unresponsiveness of the dead parent. They may be prevented from going to the funeral and protected from the grief of the adults. Yet the evidence is that, properly supported, children who view the (unmutilated) body after death and attend the funeral, even of a parent, have lower morbidity levels than those who do not.

Weller *et al.* (1988) looked at an unselected parentally bereaved group of 6–12-year-olds. Twenty-six of 56 children of families approached entered the study which used structured and semistructured interviews with children and surviving parents. Ninety-two per cent attended the funeral—more of the

older than the younger ones. Their psychiatric state was assessed 2 months after the bereavement. Neither the type of death, nor the sex of child and parent, influenced the child's participation or reaction to funeral activities and there was no association between psychiatric state and attendance or transient 'atypical' reactions. Although the contrast group was too small to draw conclusions, it seemed that attending the funeral only had adverse consequences if the child was forced to go. There is little research on the advantages or disadvantages of children viewing the dead body; most of what we know comes from adult studies (Cathcart 1988). My clinical experience is that it helps children to a greater cognitive understanding of the differences between life and death. They need to be properly supported, by someone who is familiar with the appearance of a corpse (the GP is the ideal person), and it is not advisable to allow children to view a body which is mutilated, especially if the face is unrecognizable.

Children may be protected from reminders of the dead parent and this handicaps them in the normal process of grieving and resolving grief. Their concrete thinking and egocentric view of the world make it more likely that young children will feel guilty and responsible for the parent's disappearance. Longings for death and even suicidal ideas are common as part of reunion fantasies but are rarely acted upon (Weller *et al.* 1991) and although in adolescents, suicide can commonly be precipitated by loss of peers, it is rarely triggered by loss of a parent (Brent *et al.* 1988; Prosser & McArdle 1996).

Children can be taught to recognize and name emotions. Kranzler *et al.* (1990) found that children as young as 3 years were able to recognize sad affects in themselves, and that recognizing these grieving emotions correlated with a better outcome. This has important implications for preventive intervention and therapy.

Children may not understand the source of the emotions of grief and suffer alone without seeking elucidation from carers or other adults. The misconstruing of emotions may lead to hypochondriasis or other psychosomatic symptoms and these in turn may bind the surviving parent to the child, thus reinforcing the symptoms.

Carla was 4 when her mother died after a short illness. At 6 she was seen by a child psychiatrist because of disturbed sleep and hypochondriasis. Assessment revealed that she interpreted every delay in her father's return from work as evidence that he too had died. Her various symptoms served to keep him at home where she could keep an eye on him.

The ability to attribute anxiety, depression and other dysphoric emotions accurately develops with maturation. Bereaved children may feel ashamed of their reactions, believing themselves to be experiencing unique emotions. Education about emotional reactions can usefully be part of the school curriculum and a handbook for teachers has been published (Ward 1993).

Another aspect of emotional development is the continuing need for caregivers. Children who have lost one parent feel anxious lest the other one will also die or disappear. This leads

them to monitor their surviving parent, and parental expressions of grief may be misinterpreted as illness. Children may hide their own grief in order to protect their parent and avoid upsetting them. Adolescents in the process of separating from parents may either take a step back in the process and become more involved with the family, particularly if they are the eldest or the same sex as the deceased parent (Birtchnell 1971), or they may react by rejecting the family and developing new and possibly premature procreative partnerships.

Physical development

Pre-verbal children react to loss with bodily responses. They may lose their recently acquired control over urination or defecation, lose their appetites, fail to settle to sleep or become restless. Motility or speech may be temporarily lost. The immune system may be affected so that infections and other illnesses are more common in young children following the loss of a parent (Raphael *et al.* 1980; Schleifer *et al.* 1983).

Effect of parental grief on children

Parents who lose a partner, a child or a parent will undergo a grief reaction. A normal grief reaction in adults is characterized by an acute phase which lasts for a few weeks or months, during which their normal functioning may be disrupted (Parkes 1996). It is important that relatives, friends and neighbours who may be less affected by the death rally round and, by offering respite care, relieve the children of exposure to the continuing and possibly overwhelming sorrow of the parent.

Parents who lose a child experience a fundamental change in their beliefs about their family's future security. Their grief reaction is more likely to take a pathological course. Grief may be absent, delayed, prolonged or distorted and may affect their sensitivity and ability to parent their remaining children. A review of the studies of the effect on parents of the death of a child, points out that there is surprisingly little methodologically sound research in this area but that what seems to be emerging from a very limited body of sound research is that the effect of loss of a child extends beyond psychological distress for a limited duration, to, in some studies, long-term effects on mental and physical health and even to disruption of marriages (Dijkstra & Stroebe 1998).

Other bereavements

Siblings

The death of a sibling has been less well studied than that of a parent (Newman *et al.* 1997). One study of 28 children found that 2 or 3 years after the death, a high proportion of the children were emotionally or behaviourally disturbed and had a low self-esteem. The dead sibling was idealized and school work was

suffering. If the child had been prepared for the death, had participated in the patient's care and had been able to take leave of him or her and joined in the community rituals, the outcome appeared to be better. Interestingly, there was no correlation between parental and child adaptation (Pettle Michael & Lansdown 1986).

A study of 25 unselected suicide-bereaved adolescent siblings and their parents, compared them with a demographic-matched sample of adolescents unexposed to suicide, and found that the siblings were at a sevenfold risk of developing major depression within 6 months subsequent to their sibling's death. Those who developed depression had a personal and/or family history of depression or other psychiatric disorder. Their mothers were much more likely to become depressed also (Brent *et al.* 1993). A longitudinal follow-up over the ensuing 3 years of this group (20 subjects out of the original 25 participated) found no significantly increased risk for the development of depression, post-traumatic stress disorder (PTSD) or other disorders in siblings, although they did discover prolonged high levels of grief symptomatology. This was particularly marked in younger siblings. The mothers were also more likely to show more marked and long-lasting effects, those with prebereavement histories of depression faring the worst (Brent *et al.* 1997). Although there was a correlation between mother and sibling depression at 6 months, this did not persist.

Peers

Brent *et al.* (1994) compared the friends and acquaintances of the adolescent who committed suicide with the siblings and found that their rates of depression were also high and that, in contrast to the siblings, this persisted on follow-up. The authors suggest that the siblings were more likely to have been given support and encouragement to mourn than were friends and acquaintances and that this may have aided the resolution of the depressive symptoms.

Relatives

Grandparents and other close relatives are often involved as carers for bereaved children and supports for the widowed parent. They may even take over the care completely of orphaned children. There are no studies which look at the effect on the children of the grief of grandparents or how they help their charges with their own bereavement. The death of a grandparent, particularly one who has had a major caring role, has been little studied although the effect on grandparents of the death of a grandchild has (Ponzetti & Johnson 1991).

Traumatic bereavement

While all bereavements can be traumatic to children, there are types of deaths which tend to produce more frequent, severe and longer lasting morbidity. Sudden, unexpected, violent and

mutilating deaths, particularly if witnessed by the child, and which affect their lives—deaths of family members, for example—have consistently been shown to produce more serious psychological problems. Children can get caught up in war and civil conflict, and community violence, and may witness the murder of parents, siblings and other familiar people (Richman 1993; Kuterovac *et al.* 1994; Osofsky 1997; Saigh *et al.* 1998). Domestic violence can lead to the death of a parent, and in at least 50% of cases of such homicides, the children may witness it (Harris Hendriks *et al.* 1993). Other homicides, suicide by a parent or sibling, and accidents, may all be witnessed by the child. The effects on children of traumatic events is discussed by Sandberg & Rutter (Chapter 17). There is still uncertainty about the factors that make some children more vulnerable to developing psychiatric morbidity after traumatic events. The degree of exposure to the event is probably important, and witnessing death or injury in others, being separated from family and friends, a subjective fear of a threat to life, feelings of helplessness and guilt, and academic ability, may all affect outcome (Terr 1991; Harris Hendriks *et al.* 1993).

A comparative study of 10 siblings who had lost a brother or sister by accidental death with 10 who had been bereaved of a sibling by homicide (Applebaum & Burns 1991) found that all the siblings reported symptoms of PTSD with 45% meeting full criteria for the disorder. Parents were not necessarily aware of their child's distress, perhaps because they were struggling with their own symptoms. There was a correlation between the severity of PTSD symptoms in child and parent.

Of the children who experience the death of a loved one, those who witness a sudden, horrific and unexpected one and those who perceive a threat to their own life are more likely to develop PTSD (Pynoos *et al.* 1987a; Harris Hendriks *et al.* 1993). Post-traumatic stress disorder can inhibit the normal response to bereavement (Pynoos *et al.* 1987b) and it is sound clinical practice to treat PTSD before attempting to deal with the grief reaction (Raphael 1997).

Yolande was 4 when her brother died from maltreatment by her parents. She had witnessed the chronic abuse of her sibling but had not been physically abused herself. She developed troubling nightmares in which a monster kept coming for her, and other symptoms of PTSD. She was not able to accept the reality of her brother's death until her PTSD symptoms had been successfully treated. She then started to grieve for her brother, and her mourning was aided by bereavement counselling, seeing the dead body and going to the funeral. Yolande had to adjust not only to her brother's death, but to the loss of her parents who were found guilty of manslaughter and given custodial sentences. She has been successfully adopted and is doing well, although at 13 she still has to negotiate adolescence.

Family survivors of homicide are among the most likely to develop dysfunctional symptoms. One large survey found that over 25% developed PTSD at some stage following the homicide (Amick-McMullan *et al.* 1991), and the pain, rage, guilt and revenge fantasies are likely to persist far longer than in other

bereavements, both for children and adults (Masters *et al.* 1988).

Clinical assessment of bereaved children

Children and adolescents may reach the clinician as a result of referral from health practitioners because of psychiatric symptoms, but they may also be referred for consideration for preventive intervention and therapy, or for advice to schools, social services or the courts from sources such as social workers, teachers, lawyers, voluntary organizations working with victims of crime and the bereaved, and self-referrals. The usual clinical examination may be aided by some recently developed reliable and valid questionnaires for use in assessing PTSD: Children's PTSD Inventory (Saigh *et al.* 2000); Child Post-Traumatic Stress Reaction Index (Pynoos *et al.* 1987b; Pynoos *et al.* 1993), Revised Child Impact of Events Scale (Joseph *et al.* 1993); and Psychosocial Assessment of Childhood Experiences (PACE) (Sandberg *et al.* 1993). These may be particularly useful as screening instruments when there is a mass disaster and individual assessment interviews cannot be conducted with every individual (Nader 1997). Questionnaires to aid in the assessment of depression, anxiety and other symptoms are also available and the clinician may wish to develop a package of relevant and useful aids to his or her clinical examination.

Assessing children who have been bereaved, especially by a traumatic bereavement, must involve not only evaluation for the presence of psychiatric disorders, but also their attachment needs, where they should live, if it is not possible or desirable to live with the parent(s), and what contact they should have with a perpetrator parent. The children's parents and/or caregivers must be part of the assessment, which has to include an evaluation of the effect of the bereavement on their parenting functions.

While it may be helpful to spend some time with the family together, it is essential to interview each child (and adult) individually. This is of particular importance when the experience of a child may be idiosyncratic and horrific so that secondary traumatization of other children in the family is avoided where possible. Children often strive to protect their surviving carer when they have been bereft of one, and will not easily describe or play out distressing events in their presence for fear of upsetting the adult.

With young children, exploration of their understanding of the components of the concept of death, particularly concepts of permanence and irreversibility, the degree of responsibility they have assumed for the death, and their perception of changes in a surviving parent or caregiver, will aid in devising appropriate interventions. The specific assessment of post-traumatic reactions is necessary in traumatic bereavements and should probably be a feature of the assessment of all bereaved children. When there has been loss of a parent(s), assessment for attachment disorders is indicated. Feelings of responsibility for the death, guilt for sins of omission or commission, fears that others

in the family might die, rage at others (including the dead parent or sibling) and fantasies of revenge should be specifically enquired for in both child and adult.

When exploring the impact of a death on a child's functioning, taking note of possible anniversary reactions in child or parent may help to answer the question, 'Why are they presenting now?' Exploring previous losses both for the child and the family, and any other vulnerabilities (traumatic separations, familial mental illness, loss of home or country, etc.) will enable the clinician to evaluate the meaning for the child and family of this loss. For example, a child reacting to the neonatal death of a sibling he or she barely knew, is probably responding to the parents' grief and his or her relative neglect by them. Support for the parent in their grieving may be more appropriate than therapy for the child in such a case (Hindmarch 1995).

If the family come from a different ethnic or religious background from the prevailing one, exploration of the way that culture views and deals with death is an essential preliminary to intervention (Parkes *et al.* 1997).

After the sudden death from heart failure of their lone parent, the three daughters, aged 6, 8 and 11 years, were cared for by a fellow member of the Jehovah's Witness church. She brought them to a family counselling service because of their profound grief at their mother's death. The carer had little time for this grief. She told them that their mother might be resurrected at any time and therefore they should be full of joy, not sorrow.

Intervention and treatment

The majority of children who are bereaved will not require psychiatric treatment, although most will benefit from contact with a concerned adult outside the family who will provide a listening ear and an opportunity to understand and come to terms with their loss. This may be provided by a school counsellor, a health visitor or counsellor attached to a GP's surgery, or volunteer bereavement counselling services. Child and adolescent mental health services can provide useful support, training and consultation to such services. Bereavement counselling is one of the few preventive interventions where sound evidence exists for it having a significant effect on community mental health (Parkes 1980; Kreitman 1989). However, this evidence is based on adult studies and the evidence of the benefits of bereavement counselling for children is nowhere near so clear-cut.

Who are the high risk groups where resources should be concentrated in an effort to prevent morbidity? Assessment of the following groups as a routine is recommended.

- Children under 10 years.
- Those with learning difficulties.
- Those who have suffered previous losses.
- Where there is a family or personal history of psychiatric disorder.
- Where the death is sudden or otherwise traumatic.

- Children caught up in witnessing violent deaths of those known to them (homicide, accident, suicide).
- Where there is a perceived threat to their own life.
- Those where there are multiple adversities.
- Those where the surviving parent(s) are failing in their care of the child.

Good quality controlled trials of interventions for bereaved children are few. Black & Urbanowicz (1985) randomly allocated unselected recently bereaved children into a family intervention group who were offered six family therapy sessions and a group who had no intervention. Follow-up at 1 year of both groups (45 families, 83 children) showed that the post-bereavement morbidity had been reduced from 40 to 20% in the intervention group. The sessions concentrated on helping the surviving parent to help the children to understand what had happened to their dead parent, supporting the parent and sharing mourning. By the second year follow-up there were no statistical differences between the groups, possibly because of the loss to follow-up of the most disturbed families (Black & Urbanowicz 1987). This study did not interview the children directly at follow-up but had almost no attrition in the intervention group.

The Family Bereavement Program of Sandler *et al.* (1992) in Arizona is a well-researched intervention programme, designed to improve the variables in the family environment which have been found to affect child mental health. The evaluation used a random assignment of families to either an intervention or control group ($N=46$); there was a manual for the intervention and the outcome was measured with several instruments and self-evaluation. They found that use of the programme increased parental perceptions of the warmth of their relationship with their children; increased satisfaction with social support; and reduced parental reports of depression and conduct disorders in their older children. There were fewer positive reports from the children and younger children did not seem to benefit significantly.

Preventive intervention groups for bereaved children have been described (Fleming & Balmer 1991; Lohnes & Kalter 1994; Morrison Tonkins & Lambert 1996) but few have been adequately evaluated. Most did not have control groups, had small selected numbers, and relied on adult reports of the children's progress. Stokes *et al.* (1997), who run a bereavement service for children which includes children's camps, have pointed out the difficulties of providing control groups, but are attempting to develop measures to evaluate outcome.

Individual psychodynamically orientated therapy is well described by Furman (1974) but there has not been specific evaluation of such work in relation to bereavement. Various techniques are described for working with bereaved children but there are no controlled trials described (Smith & Pennells 1995).

When specific pathology has set in, treatment must be that of the condition diagnosed. There are specific issues in relation to children who have developed a psychiatric disorder resulting from bereavement which need to be addressed. Clinicians can help the carers to promote mental health by being truthful about

what has happened to the parent or sibling, by involving the children in community rituals (funeral, cremation, memorial services; Weller *et al.* 1988), visiting the grave and by monitoring explanations given to the children to ensure that they do not violate the child's logic. If the child is told that 'Mummy is in heaven', he will expect her to return, as she did when she went to visit grandma in Brighton the other week. Parents may need help in distinguishing for the child what it is that went to heaven—was it the body of mother, or only the spirit? Building an inner representation of the dead parent appears to aid coping in bereaved children and can be a focus for therapeutic work (Nickman *et al.* 1998).

With traumatic bereavements, the attention must be to treating the effects of the trauma, before turning to grief work. There were hopes that PTSD might be prevented by 'de-briefing' techniques of crisis intervention. Recent evidence has not supported this hope. A follow-up of the children where one parent killed the other showed that brief intervention was not sufficient to protect the children from developing psychiatric problems (Harris-Hendriks *et al.*, 2nd edn. 2000). A controlled trial in children and adolescents of cognitive behavioural therapy for PTSD showed that in a population sample with a single traumatic incident it was effective (March *et al.* 1998). A meta-analysis of treatments for PTSD looked at 61 outcome trials and found that behaviour therapy and eye movement desensitization and reprocessing (EMDR) were the most effective (Van Etten & Taylor 1998).

Brom *et al.* (1989) conducted a controlled trial of psychodynamic psychotherapy with traumatized adults, comparing it with systematic desensitization and hypnotherapy with waiting list controls. All treatment groups had better symptoms than the controls, with psychotherapy having more effect on avoidance symptoms, while the other two achieved greater reduction in intrusive symptoms. As yet there has been no controlled comparison of treatments in children.

Children who are traumatically bereaved by the homicide of a parent or sibling require many interventions. Those responsible for their care (relatives, social services, the courts) may seek advice in regard to placement, contact with a perpetrator parent, as well as therapeutic needs. The clinician may find it helpful to see the perpetrator parent him- or herself and perhaps to conduct an initial therapeutic session with him or her and the child/children if appropriate, before making recommendations (Harris Hendriks *et al.* 1993; Black 1995).

Conclusions

Although over the last decade there has been considerable increase in interest in bereaved children, we still lack definitive large-scale studies of the effect of the death of a parent or sibling on children, both immediately and in the longer term. Common sense as well as clinical experience leads one to the conclusion that children, even more than adults, are likely to be profoundly affected by such deaths, although longitudinal studies indicate

that divorce and separation of parents pose greater risks for the mental health of children than death of a parent. Such intervention and treatment studies as we have point to a modest but significant decrease in morbidity with many modes of treatment, and much client satisfaction. In the area of traumatic bereavement we are on firmer ground and some well-conducted studies have shown us the extent of suffering endured by even very young children and given us the means to mitigate it. In our present state of knowledge and given finite resources, psychiatric resources should be restricted to treating high-risk children, such as those experiencing traumatic bereavements, and those with defined psychiatric disorders or dysfunctional symptoms, and supporting other counselling services for bereaved children by offering consultation, training and encouragement.

Introduction

One of the major changes that has taken place in psychiatry over recent decades has been the growing appreciation of the need to take into account developmental considerations. This has led to the concept of developmental psychopathology (Sroufe & Rutter 1984; Cicchetti 1989; Cicchetti & Toth 1995; Rutter 1996a; Cummings *et al.* 2000; Rutter *et al.* 2000). At one time, many people would have assumed that a developmental perspective meant a focus on the role of very early life experiences in creating a risk for later mental disorders. It is now appreciated that this constitutes much too narrow a view of development. It has to include the biology of brain development as well as the psychology of the development of the mind and the various ways in which developmental level influences people's response to their experiences. This chapter reviews some of the key findings on these three facets of development and considers the clinical implications that flow from them.

Biology of development

The biology of development is genetically programmed to follow a particular course. The genes that regulate development are non-segregating genes that have come to be present in all humans as a result of evolution (Bock *et al.* 2000). Genes determine the fact that everyone is born with a potential to develop communicative language, to walk in an upright position and to develop selective social attachments. These non-segregating genes, present in everyone, differ in their effects from the segregating genes considered in the chapters by McGuffin & Rutter (Chapter 12), Skuse & Kuntsi (Chapter 13) and Simonoff (Chapter 66). Of course, at a basic level, both sorts of genes are directly comparable, and there is no sharp demarcation between the two. Thus, for example, although there are non-segregating genes that determine the universal capacity for language, there are also segregating genes that underlie individual differences in people's language skills.

A key feature of the genetically programmed biology of development is that it is probabilistic in the way that it works (Finch & Kirkwood 2000); there are inbuilt self-correcting mechanisms to ensure that development proceeds appropriately. For example, in brain development there is an initial overproduction of neurones, accompanied by their migration from one part of the brain to another, followed by selective pruning

(Greenough *et al.* 1987; Greenough & Black 1992; Nelson & Bloom 1997; Bateson & Martin 1999; Bruer 1999; see also Goodman, Chapter 14). Genes determine that this always happens, but genes do not determine precisely what happens with each individual neurone. The process of neuronal migration and functional differentiation, as well as the selective pruning, is influenced by cell–cell interactions that are, in turn, influenced in part by experiential input. This has given rise to simplified aphorisms such as, 'Cells that fire together wire together' and 'Use it or lose it'. The general notion is that, just as brain structure influences brain function, so function shapes brain development.

This general style of development applies just as much to other parts of the body as it does to the brain. Parallel considerations apply to the development of the neuroendocrine system. The general plan and course of neuroendocrine development is the same in all humans but development is also shaped by experiences—as shown, for example, by the effects on structure and function of the neuroendocrine system of severe stressful experiences in early life (Hennessey & Levine 1979; Levine 1982). Segregating genes and experiences both influence the timing of puberty, as do exercise and body weight (Pickles *et al.* 1994; Graber *et al.* 1995).

There has been a tendency in the writings of some behaviour geneticists to assume that everything is determined by either genetic or environmental factors or some form of interplay between the two. There is a recognition that there is need to break down each into further components, such as the differentiation between additive genetic effects and epistatic or synergistic genetic effects and that between shared and non-shared environmental effects (see McGuffin & Rutter, Chapter 12). However, on its own, this view constitutes an oversimplification, for two rather different reasons. First, it ignores the need to consider the universals of biological development with respect to the interplay between genes and environment. Secondly, the partitioning of population variance into genetic and environmental effects ignores the fact that chance variation also plays a part (Goodman 1991; Jensen 1997; Finch & Kirkwood 2000). Thus, all females are born with two X chromosomes, and it is invariable that one of the X chromosomes is inactivated. On the other hand, it seems to be largely a chance matter which of the X chromosomes is inactivated.

Role of chance in determining individual differences

Molenaar *et al.* (1993) have written about chance as something that constitutes a ‘third force’ in the determination of individual differences. At first sight, that might seem nothing more than recourse to an unmeasurable variable to account for that which is currently beyond our understanding. However, it is rather more than that. For example, most people exhibit minor imperfections of physical development (Waldrop & Halverson 1971; Vogel & Motulsky 1997; Tarrant & Jones 2000). These may be evident in features such as an extra rudimentary nipple, extra teeth, missing muscles, and other oddities (the great majority of which are without serious functional significance). Often, people are unaware that they have these imperfections but they are readily detectable by systematic examination. It is known that such minor congenital anomalies tend to be more common in children born to older mothers, and they are also more common in monozygotic twins than dizygotic twins (monozygotic twinning itself being a variety of congenital anomaly). With respect to these general risk factors, it is clear that the occurrence of developmental anomalies is open to influences on groups of individuals that are potentially understandable and measurable, but the details of their presence in any one individual are essentially unpredictable. A higher than usual number of congenital anomalies have been found to be associated with an increased risk for various different forms of psychopathology, including autism, schizophrenia, and attention deficit hyperactivity disorder (ADHD; Marenco & Weinberger 2000). The mechanisms involved in these pleiotropic risk mechanisms are unknown. It is unlikely that the anomalies themselves mediate risk; it is more probable that they index some form of perturbation in the developmental process as it has occurred at an early intrauterine phase.

Apart from the presence of congenital anomalies, which could have arisen through a variety of mechanisms, there have been other attempts to assess whether or not individuals have been subjected to unusual developmental perturbation. Asymmetry in dermatoglyphic patterns has been one suggested way forward (Tarrant & Jones 2000). At the moment, there are few hard findings on the role of chance variation in developmental processes but the possibility of their importance needs to be taken seriously.

Developmental programming

The concept of developmental programming is that particular experiences influence the structural and functional development of the organism in a lasting way. In the context of brain development, the role of visual input shaping the structure and function of the visual cortex is much the best known and best demonstrated example. This was first demonstrated by the Nobel Prize winning research of Hubel, Wiesel and their colleagues (Hubel & Wiesel 1965) and has been amply confirmed

since (Blakemore 1991). One practical consequence is that, if a child’s strabismus is not corrected in the first few years of life, it is highly likely that binocular vision will not be possible later. There is a possible parallel in the field of language development. In the early months of life, all babies show roughly the same skills in phonological discrimination but, as they become more exposed to the language input, their phonological discriminations come to be adapted to the language to which they are exposed (Kuhl 1994; Kuhl *et al.* 1997). At a later age, individuals find very difficult phonological discriminations that are not part of the language with which they grew up. A somewhat similar pattern of development arises with grammatical constructions. Older second-language learners have no difficulty in acquiring the vocabulary of a second or third language, but both their phonology and their grammar tend to betray the origins of their first language. Functional imaging findings (Kim *et al.* 1997) also suggest that the neural basis of later second-language learning differs from that which underlies normal first-language learning. With respect to brain development, Greenough *et al.* (1987) conceptualized the process of experiential influences on brain growth in terms of experience-expectant development. In other words, biological development is programmed on the basis of an expectation that a particular range (albeit a very wide range) of expectable experiences occur.

What has proved much more controversial is the question as to how far this concept may be extrapolated to the effects on brain development of variations in experiential input within the normal range. Extrapolation has seemed to be encouraged by the findings from animal research that brain development differs between caged animals given extra experiences and ordinary laboratory caged animals. The implication has seemed to be that environmental enrichment has somatic effects that are both lasting and of functional importance. The research is of high quality but the problem is that it is doubtful whether the so-called enriched environment is in fact superior to the environment that the animals would have experienced in the wild. Rather, the researchers in this field have concluded that additional experiences have done something to counteract the severe deprivation that is ordinarily the state of affairs with caged laboratory animals. The evidence suggests that the biology of normal brain development requires experiential input but that the range of experiences providing it is very wide. Clearly, this makes evolutionary sense in that development needs to be able to occur in a wide variety of environmental conditions. Gross departures from the average expectable environment may be damaging in their developmental consequences, but the extent of environmental variation that is consistent with normal brain development is very wide. Accordingly, the notion that particularly high-quality experiences in early life will make for ‘better’ brain development does not have empirical support. It may well be advantageous for children to have particularly rich, varied and emotionally supportive experiences in early life but this does not mean that such experiences programme brain development. Of course, all learning has neural consequences (how else could learning occur?) but that is not quite the same

thing as effects on the programming of the structure of brain development.

We may conclude that it is likely that rather extreme and extensive restriction of experiences are likely to be important for this type of developmental programming to occur. The one well-documented recent human experience that provides just such a restriction is that obtained in Romanian orphanages, prior to the fall of the Ceauşescu regime, of severe institutional privation (see O'Connor, Chapter 46). The findings are provocative with respect to developmental programming notions (Rutter, in press; Rutter, O'Connor & the English and Romanian Adoptees Research Team, submitted). The implication for developmental programming is that serious effects should persist despite radical changes of a beneficial kind in the environment. In so far as that suggests that recovery cannot take place if the change of environment does not occur until after the age of 2 or 3 years, the findings clearly contradict the expectation. To the contrary, dramatic developmental gains across all domains were apparent (Rutter *et al.* 1998c; O'Connor *et al.* 2000a). On the other hand, the findings were equally striking in showing a higher frequency of substantial deficits in the children whose depriving institutional care extended after the age of 2 years, as compared with those who left the institutions under the age of 6 months. The two groups differed with respect to their general cognitive index at age 6 years by 24 points—a very large difference indeed (O'Connor *et al.* 2000a). The findings with respect to sociobehavioural deficits were of the same magnitude (Rutter *et al.*, 2000a).

Several queries need to be raised before making assumptions of developmental programming. To begin with, the children were severely malnourished as well as psychologically deprived. However, the deficit findings according to age of leaving the institution were similarly apparent in the subgroup of children who did not show significant malnourishment (Rutter, O'Connor & the English and Romanian Adoptees Research Team, submitted). Accordingly, the persistence of effects cannot be wholly attributed to malnutrition, although the deficits were greater in those who were severely malnourished. Also, it was necessary to check that the findings were not a consequence of the duration of time in the adoptive home, rather than the period in the institution (the one ordinarily leading directly to the other). Longitudinal data showed that (after a period of some 2.5 years in the adoptive home) it was the length of time in the institution that was the decisive factor (Rutter *et al.* 2000b). The gains between age 4 and age 6 were quite minor, and neither the outcome at age 6 nor the gains between 4 and 6 were systematically related to variations in the qualities of the adoptive family, although these were generally of high quality and therefore exhibited a narrow range of variation. In short, evidence suggested that there were substantial cognitive and social sequelae that persisted for some years (findings from the currently ongoing follow-up at age 11 years will be needed to determine how long), despite a radical change of environment.

The question is what basic process mediates these persistent effects and whether that process can reasonably be conceptualized as some type of developmental programming. A further question

is how far the findings on this very extremely deprived group have implications for more ordinary variations and circumstances in the industrialized world. Yet another question has to be posed about the nature of the experiential restriction that led to these effects. On the face of it, it would seem unlikely that the same type of restriction led to the cognitive impairment as that which led to the social deficits (e.g. quasi-autistic patterns, impaired selective social attachment, inattention/overactivity). There were modest intercorrelations between these different outcomes but the correlations were not high. Perhaps it was the general restriction of conversation and play that had the major role in the cognitive impairment (the children were generally confined to cribs without toys, without experiences outside the crib, and without much talk—most of the children being entirely without language at the time they left the institution). Conversely, perhaps the lack of interchanges with people, together with a lack of personalized caregiving, played a greater part with respect to the social sequelae. What is relevant is that studies of children reared in much better functioning institutions in the UK have shown somewhat comparable (albeit much milder) social sequelae that have occurred in the absence of cognitive impairment (Hodges & Tizard 1989a,b; Roy *et al.* 2000; Rutter *et al.*, in press).

The first concept of developmental programming is based on the need of the organism to have certain experiences (within a broad range) if somatic development is to proceed normally. A somewhat different programming concept has been put forward by Barker *et al.* (Barker 1991, 1997; O'Brien *et al.* 1999) to describe the ways in which early somatic development adapts to the prevailing environmental circumstances. One of the stimuli for this notion was the empirical association that was observed between low birth weight and an increased risk of cardiovascular disease. The finding was of developmental interest because, although undernutrition in early life is a risk factor for cardiovascular disease, it is overnutrition that is the risk factor later on. The hypothesis is that the organism is programmed to deal with subnutrition and that, as a consequence, this means that it is wrongly programmed to cope with overnutrition, if that is what happens in later life. This second concept is crucially different from the first in three crucial respects.

- 1 It is concerned with the effects of variations in experiences within (as well as outside) the normal range.
- 2 It is concerned with organismic *adaptation* to particular environmental circumstances (rather than normal growth that is dependent only on a type of environmental input that would be present in any ordinary circumstances).
- 3 The developmental effects of the early experiences do not concern either optimal functioning or even generally normal functioning. Rather, they prepare the organism to be in the best state to cope with *continuation* of the same environmental circumstances. If the environment changes, the consequence may be malfunction because the organism was adapted to be responsive to the needs provided by a different set of circumstances.

In the metabolic domain, the implication is the important, but counterintuitive, implication that compensatory feeding in middle childhood to make up for subnutrition in the womb or

infancy may actually be damaging. In the psychological arena, there are possible parallels in the effects of institutional deprivation on the development of social relationships (O'Connor *et al.* 1999, 2000b; Rutter *et al.*, 2000a). Perhaps the brain becomes adapted to coping with an extremely barren environment that is largely lacking in interpersonal play or communication, and is thereby maladapted to dealing with a normal social post-adoption environment. The 'programming' notion is possibly relevant because it suggests that developmental effects become relatively fixed after a particular sensitive period of openness to environmental influences, and that the effects involve adaptation to a particular environment.

There may even be a third type of programming effects. Early experimental studies of stress on the development of the neuroendocrine system in rodents (Hennessey & Levine 1979) showed that the usual effect was enhancement of structure and function. In other words, the effects of early exposure to a noxious environment provided a degree of resistance later to similar noxious experiences—a so-called 'steeling' effect (Rutter 1981b). However, clinical experience suggests that the reverse may also occur—a 'sensitization' effect. Experimental studies are now beginning to confirm the reality of such effects in which early stresses *increase* vulnerability to later stresses (Heim *et al.* 2000; Ruda *et al.* 2000). What remains unclear is what determines which occurs (steeling or sensitization), and what biological processes mediate each type of effect.

Brain plasticity re-responses to physical injury

At one time, it used to be thought that the effects of early brain injury were much less than those of later brain injury (the so-called 'Kennard principle'). It is now known that that is a misleading oversimplification, although there are indeed major effects of age on responses to brain injury (Rutter 1993; Goodman 1994; see also Goodman, Chapter 14). The key finding is that unilateral brain lesions in infancy do not lead to either lasting language impairment or distinctive patterns of differences in verbal and visuospatial skills, regardless of which hemisphere is injured. On the other hand, early injuries do lead to general cognitive impairment. It is also striking that the degree of cognitive impairment seems to be influenced at least as much by active epileptic activity, suggesting that the impairments come from abnormal brain discharges as much as from lack of brain function (Vargha-Khadem *et al.* 1992). The implication is that, in early life, the brain has the plasticity required for either hemisphere to take up responsibility for specialized functions, such as language. The precise neural processes that provide this plasticity are as yet not well understood but their importance is clear.

It is important not to overgeneralize these findings on inter-hemispheric plasticity because it is quite clear that early brain impairments can lead to severe lasting deficits in specialized skills. The findings with respect to both developmental language

disorders (see Bishop, Chapter 39) and autism (see Lord & Bailey, Chapter 38) clearly make that point. The implication, however, is that such specialized deficits are likely to stem from systems failures or bilateral lesions, rather than from any focal lesion, however severe, on just one side of the brain.

Implications of cognitive processing and memory

It has long been known that there are major developmental changes in the ways in which children process their experiences. Even very young babies think about what happens to them and, moreover, they conceptualize and draw conclusions about their experiences. This is evident, for example, in the ways in which young children understand and respond to what is said to them, conceptualizing the meaning of what they have heard and so initially both undergeneralizing and overgeneralizing as they 'play with' the language concepts and their meaning (Rutter 1987). It is evident too, in the ways in which babies' initial somewhat indiscriminate response to other people's social overtures changes in the middle of the first year of life to a high degree of specificity (see O'Connor, Chapter 46; Rutter 1981a). It has also been found that it is only towards the end of the second year of life that toddlers develop a well-articulated set of standards that they apply both to themselves and to the world around them (Kagan 1982).

The concept of so-called 'infantile amnesia' is also well-established (Rutter *et al.* 1998a). It is not that children forget all that they have learned during the first two years of life or that their experiences during that age period do not register; it is obvious that language learning in those early years persists into adult life, as does all sorts of other learning. The key distinction is between implicit and explicit memories (Tulving 1983; Baddeley 1990). Children maintain the skills and knowledge that they have learned in early life but what is largely lost is recall of particular events and experiences during that early period. Few people have much in the way of memories of discrete happenings during their first 2 or 3 years. Although the precise reasons for this amnesia are not well understood, it does seem related to the process of recall rather than registration of the original learning. Perhaps this is a consequence of the fact that the concepts and ways of thinking, at the time of attempted recall in later life, are so different from those operating in the infancy period. The implication is that, although early experiences may well have enduring effects, they are unlikely to operate through the triggering of particular discrete memories of events or happenings.

Once more, questions have to be asked about the neural substrate for these different forms of learning, memory and recall. The Zero to Three movement has sought to extrapolate from neuroscientific findings, to argue that major experiences have to operate in the first three years if they are to have enduring effects. That is a misleading assumption, for at least three rather different reasons. First, as already noted, explicit memories of an

enduring kind are not usually present until after the age of 2 or 3 years. Children's ability to conceptualize about their experiences also increases greatly with age. It was on these grounds that Kagan (1980) argued that, completely contrary to the views of the Zero to Three group, it is only *after* infancy that experiences are likely to have enduring effects. That is because it is only after the infancy years that children develop more complex conceptualizations of what has happened to them.

The second reason that the extrapolation is unwarranted is that neuroscientific findings have shown that brain development is far from complete by the end of the second or third year. Many important developments take place during childhood and adolescence, even extending into adult life (Krasnegor *et al.* 1997). It is true that brain growth is at its most rapid and extensive during early life but it goes on much longer. Furthermore, although the new growth of neurones is predominantly a feature of early brain development, recent research has shown that, at least in some parts of the brain and in some circumstances, there can be neuronal proliferation even in adult life (Eriksson *et al.* 1998; Gould *et al.* 1999; Scharff *et al.* 2000).

Thirdly, although it may be that new learning is supported by the acquisition of new synapses (Greenough & Black 1992), the initial proliferation of synapses does not seem to be environmentally driven. Learning probably results in a loss of some connections and a strengthening of others as a result of competitive interactions among populations of neurones (Goldman-Rakic *et al.* 1997). In so far as that is the case, that suggests that brain plasticity is likely to extend through the period of synaptic loss extending into early adult life (Huttenlocher 1979, 1994).

Much remains to be learned about the interconnections between brain functioning and the workings of the mind, and between both of these and the input of experiences. Tentatively, it may be concluded that, although developmental programming effects (by which brain growth is sculpted by experiences) are most evident in the first few years of life, even then the effects are not necessarily permanent and irreversible. Also, the sculpting effects of experiences on brain development probably mainly applies to rather gross variations in pervasive experiences, rather than to variations in experiences within the normal range. However, later experiences may also have effects on brain structure. Because cognitive and affective processing is so important in response to experiences, it is also the case that in some ways later experiences may make more of an impact. They, too, will bring about changes in the neural structure, albeit ones that differ from developmental programming effects.

It should be added that it is highly unlikely that the concept of developmental programming reflects a single process. The notion of brain sculpting as a result of universally expectable experiences suggests that variations within the normal range of experiences will not have structural effects. By contrast, the rather different programming concept as applied to the effects of nutrition on metabolic functioning or of infections on immunity is thought to apply to experiences within the normal range. It is not known whether, or how, that concept might operate in relation to brain development.

'Switching on' of genes

Although all genes are present at birth, they may not exert their effects until much later in life. Most obviously, that is the case with genetic influences on the timing of the menarche or menopause. It is also apparent in the case of Mendelian disorders of late onset, such as Huntington disease. It is necessary to consider whether similar 'switching on' effects apply with respect to genetically influenced psychiatric disorders that do not usually begin until late adolescence or early adult life—such as schizophrenia or bipolar affective disorder. The processes may well differ among these various later onset disorders. For example, although the psychotic features of schizophrenia are not usually present until the late teens, non-psychotic cognitive, social and behavioural abnormalities are frequently present from the early childhood years onwards (Weinberger 1987; McGrath & Murray 1995; Marenco & Weinberger 2000; McDonald *et al.* 2000; see also Hollis, Chapter 37). In other words, it has become increasingly apparent that it is necessary to conceptualize many cases of schizophrenia as neurodevelopmental in origin, rather than as adult-onset psychoses. That leaves open the question as to what are the factors that underlie the transition from the behavioural precursors of childhood to the overt psychotic features of adult life. Do they rely, for example, on the changes in brain development that take place in the adolescent period? To what extent does the schizophrenia that involves childhood precursors differ from schizophrenia where these are apparently absent? It has become very apparent that a more developmental approach to the understanding of schizophrenia is going to be required.

The situation with respect to bipolar affective disorder may not be quite the same (see Harrington, Chapter 29). Although there is some association between early neurodevelopmental delays and bipolar disorder, the effects are very much weaker than they are with schizophrenia (McDonald *et al.* 2000). Although Biederman *et al.* (Biederman *et al.* 1996; Faraone *et al.* 1997) have argued that it is relatively common for ADHD to lead on to mania in adult life, this has not been evident in other follow-up studies of children with ADHD (see Schachar & Tannock, Chapter 25). It seems more likely that the apparent connection derives from a surface similarity between particular behaviours, rather than progression from one form of psychopathology to another. Large-scale systematic follow-up studies of children and adolescents with major depressive disorders (Weissman *et al.* 1999a,b; Fombonne *et al.*, 2001a,b) have also shown the infrequency with which early depressive conditions develop into bipolar disorders in early adult life. Although bipolar disorders can, and sometimes do, begin in childhood, it is much more frequent for them to begin in later adolescence or early adult life. It is possible, although not as yet demonstrated, that this is a function of genes whose effects usually 'switch on' during this age period.

The situation with respect to unipolar depression may be different again. To begin with, it is striking that the sex ratio changes during adolescence (Rutter *et al.* 1986; Weissman *et al.*

1999a,b; Fombonne *et al.*, 2001a,b). In childhood, depression is more common in boys whereas, from adolescence onwards, it is substantially more common in girls. Genetic liability for depression increases substantially from childhood to adolescence/adult life but this increase is mainly evident in the case of females (Thapar & McGuffin 1994; Silberg *et al.* 1999). This rise in genetic effect is accompanied by substantial gene-environment correlations and, also, interactions (Silberg *et al.*, in press); and it is possible that, to an important extent, the genetic effect is operating as a result of its influence on the interplay with the environment. It is not clear at the moment why that should mainly apply to females rather than males.

Age-related variations in responses to psychosocial experiences

To an important extent, people's responses to psychosocial experiences vary according to their age at the time. However, it is necessary to exercise caution in drawing conclusions about the reasons for these age-related variations. That is because, in a real sense, age is an ambiguous variable because it indexes biological maturity, because different elements of biological maturation do not proceed together; and because age also reflects past experiences and current social situations (Rutter 1989a). Before drawing conclusions about the underlying causal mechanisms, it is important to determine which of these various aspects of age are responsible for the association.

Hospital admission, and other forms of stressful separation, may be taken as an example (Rutter 1979). The evidence suggests that adverse psychological effects are infrequent in the case of separations during the early infancy period; are maximal during the toddler period; and less evident, again, in the case of separations during the school-age years. It is probable that these changes reflect the role of selective social attachments. The effects are less likely in infancy because infants have yet to develop such attachments and therefore do not have well-developed selective relationships that can be disrupted by separation. Conversely, older children have developed such relationships but, with increasing cognitive capacity, have learned that it is possible to maintain relationships during the course of a separation. Accordingly, although they may be upset at the time, the sequelae are less marked and less prolonged. In short, in this case the age-related effects seem to be a function of both what is taking place developmentally in relation to the establishment of selective social relationships and also what is occurring in the parallel development of cognitive understanding.

Somewhat similarly, it seems that the relative failure to develop intense selective social relationships, the so-called disinhibited attachment disorder, is a consequence of institutional rearing in the first few years of life; whereas (although not well documented) apparently it is not found with respect to the occurrence of institutional care in older children (see O'Connor, Chapter 46). The effects on a function that has still to develop and on one that is already well established are likely to be different.

A possibly rather different age trend is apparent in the case of marked grief reactions (Dowdney 2000; see also Black, Chapter 18). Although young children may well be greatly distressed by a bereavement, they are less likely to exhibit the severe grief reaction at the time that is characteristic in adults. This may be because they think about the loss in ways that involve less preoccupation with its meaning and less projections forwards and backwards in time. Of course, that does not mean that the effect of early loss are less than those of later loss. Indeed, the converse may be the case, because, although the loss itself may not have direct long-lasting stress effects, if it leads to impaired patterns of parental care (as is sometimes the case), that will carry with it important vulnerabilities (Harris *et al.* 1986). Poor parental care in the absence of parental loss is a major risk factor for psychopathology, whereas loss that is accompanied by good parenting is not. As is the case with brain injury, the issue is not the age at which effects are most marked but, rather, that the effects differ in type according to children's age at the time.

Hormonal effects

The effects of hormones need to be considered in relation to two main age periods: just before birth and puberty. It is well established from animal studies that androgens have a programming effect on early brain development such that there are subtle, but important, differences between males and females (Greenough *et al.* 1987; Gorski 1996; Goy 1996). These effects have some implications for later sex-typical behaviours of various kinds. It seems likely that something comparable takes place with respect to human development (Collaer & Hines 1995; Ruble & Martin 1998). There is some supporting evidence deriving from studies of individuals with physical anomalies of one kind or another but it is not at all clear whether or not these play any significant part in relation to sexual disorders (see Zucker, Chapter 44).

The massive hormonal changes, and the extent to which they differ between males and females, during adolescence are well known and have physical effects that are obvious and striking. What is much less clear are their psychopathological implications. These need to be considered in relation to four types of disturbance: antisocial behaviour, depression, eating disorders, and drug and alcohol use and abuse.

Antisocial behaviour

It is well established that androgens have a major effect in both sexes in relation to sex drive and patterns of dominance (Rubinow & Schmidt 1996). There is a rise in the production of androgens in both males and females, although it is much greater in the former (where the testes have a major role), the rise in females deriving from the adrenals. At first sight, it might seem obvious that the much greater rise in androgens that occurs in males is likely to account for the male preponderance in antisocial behaviour, and especially in violence and sex crimes. However, the empirical research findings raise doubts

about this explanation. To begin with, contrary to what one might expect, the sex difference in antisocial behaviour is least evident in adolescence, rather than most evident as the hormonal explanation would lead one to suppose (Rutter *et al.* 1998b; Moffitt *et al.*, 2001). The male preponderance is more marked, both before puberty and in adult life. Also, variations in androgen levels within males are not particularly strongly associated with variations in aggression, although they are more strongly linked with variations in dominance (Tremblay *et al.* 1997). It would be foolish to suppose that hormones have no role in relation to the sex differences in antisocial behaviour but, equally, it would be quite wrong to suppose that they provide the main explanation (Rutter *et al.* 1998b; Moffitt *et al.*, 2001). The main difference between males and females lies in early onset antisocial behaviour that is associated with hyperactivity, and that continues into adult life. Some sort of mechanism that involves neurodevelopmental function seems more likely than one that resides in hormonal effects.

A distinction needs to be drawn, however, between the effects of puberty as such, and the effects of reaching puberty at a much earlier (or later) age than usual. Stattin & Magnusson (1990), in Sweden, found that girls who had an unusually early menarche were more likely than other girls to become involved in socially disapproved behaviour. Caspi *et al.* (1993), in New Zealand, found the same. Both studies, however, found that although the stimulus was biological, the mediating mechanism was social. The effect was found only in early maturing girls who became part of an older peer group that provided antisocial models. Risk mechanisms need to be considered in terms of causal claims in which the influences on the origin of a risk factor may not be the same as the mode of risk mediation with respect to the pathological outcome (Rutter *et al.* 1993).

Depression

Note has already been made of the marked rise in depression in females during adolescence, and similar questions need to be asked about the possible role of hormones. An early study of a clinical sample suggested that the main association was with chronological age rather than puberty as such (Angold & Rutter 1992) but a more recent general population study suggested the reverse (Angold *et al.* 1999). The latter found evidence of stronger associations with hormonal levels than with the physical manifestations of puberty. It seems rather unlikely that there is direct effect of hormones on depressive disorder because of the lack of consistent associations with either hormonal changes associated with the menstrual cycle or with the menopause. On the other hand, the female preponderance in depression does seem less marked in old age than it is in mid-adult life (Bebbington 1996, 1998). The causal processes involved have yet to be established, but two possibilities seem most likely. First, although the hormonal changes do not directly cause depression, it may be that the changes associated with puberty in females in some way serve as a longer lasting predisposing vulnerability factor that makes women more susceptible to depression. Alternative-

ly, it may be that the hormonal changes are not themselves the most important feature; instead, it may be that they index other features of biological development that are more directly responsible for the risk of depression.

Eating disorders

Eating disorders constitute the third group showing a dramatic rise in frequency that occurs roughly around puberty (see Steinhausen, Chapter 34). The question is what it means, and what causes it. One possibility is that a key stimulus is provided by the marked increase in deposition of fat that is characteristic of puberty in females but less so in males. The hypothesis, then, is that it is the dissatisfaction with weight gain that leads to dieting, and that the dieting in turn leads on to anorexia nervosa. The story seems likely to be valid with respect to the very frequent dieting behaviour that is so characteristic of female adolescents in Western society (Attie & Brooks-Gunn 1989). However, although dissatisfaction with weight gain in adolescence may provoke the onset of dieting, it seems that depression and disturbed family relationships may play a greater part in the persistence of disturbed eating patterns (Attie & Brooks-Gunn 1989; Patton *et al.* 1997).

Although dissatisfaction with weight gain may be the key factor provoking the beginning of dieting, it is much more doubtful whether it accounts for the rise in anorexia nervosa in adolescence. If it was critical, it might be supposed that the severe dieting that is characteristic of both ballet dancers and some athletes should frequently lead on to anorexia nervosa; however, the evidence suggests that that is surprisingly unusual (Szmukler *et al.* 1985; Patton *et al.* 1990). It might also be supposed that the less frequent occurrence of anorexia nervosa in boys should be found particularly often in those with an unusual deposition of fat. The evidence on this point is fragmentary but that does not seem to be the case. Although it seems likely that the changes associated with puberty do indeed play a part in the genesis of anorexia nervosa, queries remain on the mechanisms involved. The mere association between eating disorders and puberty does not, in itself, provide a causal explanation. The same applies to the sex difference. It is important to appreciate that age-related differences in rates of psychopathology provide crucially important leads for questions to be tackled but they do not, in themselves, provide an answer.

Substance use/abuse

The fourth type of psychopathology showing a marked rise during adolescence concerns use and abuse of alcohol and other drugs (see Weinberg *et al.*, Chapter 27). The cause of the rise in drug use in the teenage years is not obvious. It is possible that part of the explanation may lie in age-related psychological responses to the physical substance. For example, it seems that most children do not experience the euphoric response to stimulants that is characteristic in adults (see Heyman & Santosh, Chapter 59). However, whether this applies more generally to

other drugs is doubtful. It could be that drug use stems in part from the rise in risk-taking behaviour that is evident during adolescence. That might explain why drug-taking is more likely, and tends to begin earlier, in individuals showing antisocial behaviour that includes risk-taking features (Robins & McEvoy 1990). In some cases it may be that there is recourse to drugs as a way of dealing with negative mood (see Weinberg *et al.*, Chapter 27). Longitudinal studies of depressed youths, however, provide little support for this possibility; the effects of depression seem much weaker than those of antisocial behaviour with respect to the predisposition to drug-taking (see Rutter, Chapter 28). Alternatively, it may be that part of the explanation lies in the role of social groups. Much consumption of alcohol and taking of drugs takes place in social settings, and these come to occupy a much greater part of young people's social lives during adolescence. Still, that leaves the question as to why the taking of drugs and alcohol should be such prominent features of these social groups. Does that derive from cultural features, biological features, or some interplay between the two?

An unusually early menarche is associated with an increase in smoking and drinking of alcohol in girls (Stattin & Magnusson 1990), as well as the already mentioned increase in socially disapproved behaviour. A Finnish twin study (Dick *et al.* 2000) showed that the effect was confined to girls in urban (rather than rural) settings. It also found that the effect was not caused by any shared genetic liability between early puberty and drinking/smoking. The effect of early puberty on drinking does not persist into adult life to any marked extent. As the social context alters, so the meaning and impact of early puberty changes. The initial effect did not bring about lasting personality change. Rather, the early puberty made a difference because it altered the peer group and extent of parental supervision, but (as with other influences) if the person's social circumstances change, the environmental effects may well prove to be evanescent (Clarke & Clarke 1976, 2000).

Response to physical substances

Over the last few decades, there has been a growing awareness of the ways in which substances ingested by the mother during pregnancy may have adverse effects on the fetus. The thalidomide tragedy, with its devastating effects in causing limb deformities, is the most dramatic example of this kind. However, from a psychopathological perspective, infection, alcohol and recreational drugs occupy a greater importance. The evidence on the role of maternal infections is greatest in the case of influenza as a contributory predisposing factor to schizophrenia (McGrath & Murray 1995; see also Hollis, Chapter 37). There is circumstantial evidence that influenza, when it occurs during the second trimester, is associated with an approximate doubling of the risk of schizophrenia (but see Westergaard *et al.* 1999 for contrary evidence). Maternal rubella has well-established devastating effects on fetal development, leading to mental retardation, blindness and deafness. This is associated with an increase in

autistic-like patterns, although they differ in course from those seen with 'ordinary' autism (Chess *et al.* 1971; Chess 1977).

Heavy consumption of alcohol in the first trimester is known to be associated with physical consequences to fetal development (the so-called 'fetal alcohol' syndrome) and indeed has important psychological consequences, particularly in relation to patterns of inattention/overactivity (Streissguth & Kanter 1997). It also seems that there are likely to be adverse effects at levels of alcohol consumption that are very high but yet do not lead to the identifiable physical anomalies. The evidence is inconclusive as to whether even moderate levels of alcohol consumption carry psychological risks, but the available evidence suggests that with modest levels of consumption the risks are minimal, even though it may be prudent to avoid taking alcohol at all during the early months of pregnancy (Stratton *et al.* 1996; Streissguth & Kanter 1997). The animal evidence (Schneider *et al.* 1997, 1999) is provocative in its suggestion that stress experiences in pregnancy increase the fetus' vulnerability to maternal alcohol and that these effects are most marked in early gestation.

Although there is abundant evidence that the occurrence of depression in young people is associated with a much increased rate of recurrence of major disorder in adult life (see Harrington, Chapter 29), it appears that the response to tricyclic medication is not the same. All the major well-controlled trials of tricyclic medication in young people have failed to show substantial benefits (Hazell *et al.* 1995), whereas almost all such trials in adults have shown significant effects. Even in adults, there are marked individual differences in response, and in childhood too there are occasional individuals who seem to show beneficial responses. Nevertheless, considered as a whole, there seem to be marked age differences in the likelihood of a person having a beneficial response to tricyclic medication. The reasons for this age difference remain unknown. It is not, apparently, that there is a general insensitivity to antidepressant medication because response to selective serotonin re-uptake inhibitors (SSRIs) has been more positive (Emslie *et al.* 1997, 1999).

Neural substrate of continuities and discontinuities in psychopathology

The need to consider a possible neural substrate for changes in psychopathology as people grow older arises with respect to several different mental disorders. Mention has already been made of the transition in schizophrenia from the neurodevelopmental delays, attention difficulties, social deficits and behavioural problems that are characteristic of childhood manifestations, to the more florid negative symptoms in adult life, together with thought disorder, delusions and hallucinations. It is necessary to ask whether this change is a function of progression in the disease process itself or, rather, whether it reflects the effects on psychopathological manifestations that derive from normal changes in brain development that, as it were, 'unmask' a psychotic vulnerability (McDonald *et al.* 2000). Attempts are being made to tackle this question by determining whether imaging

studies can show progressive changes in the period leading up to the onset of psychotic manifestations. The same basic strategy has also been applied with respect to the cognitive impairment that is associated with schizophrenia (Cosway *et al.* 2000). As discussed by Marenco and Weinberger (2000), there is some preliminary evidence of brain changes during this prodromal period, although uncertainty remains on the neural processes that they reflect.

Somewhat similar questions arise with respect to the frequent development of epileptic attacks during late adolescence and early adult life in individuals with autism (Rutter 1970; Howlin, S. Goode & M. Rutter, in preparation). In this case, the issue is not a change in psychopathology as such but rather the development of epileptic activity. Although it has been claimed that this is often associated with psychopathological deterioration (Gillberg & Steffenburg 1987), that has not been found in other studies (Hutton, S. Goode & M. Rutter, in preparation). Although epileptic attacks can begin at any age in autistic individuals, onset in late adolescence/early adult life is peculiarly characteristic, and it is rather different from the predominance of onset in early childhood that is usually found in both mentally retarded individuals and in general population samples (Cooper 1965; Richardson & Koller 1996). Once more, the question is whether this reflects changes in the disease process of autism, or whether normal brain development during this age period is unmasking an epileptic liability.

A further phenomenon of neural substrate concerns the feature that has come to be called 'kindling' (Post 1992). It has been observed that the experience of a major depressive disorder has effects that seem to create a self-perpetuating tendency to an increased liability to recurrence, despite a decreased susceptibility to the effects of negative life events (Brown *et al.* 1994; Frank *et al.* 1994). Kendler *et al.* have used a twin design to test for the reality of this effect, with confirmatory findings (Kendler *et al.* 2000, in press). Curiously, however, the data also seemed to show that the kindling effect was greatest in individuals inferred to be at low genetic risk (Kendler *et al.*, 2001). Much has still to be learned about this phenomenon but its existence seems to be confirmed, and it serves as a reminder that the experience of a major mental disorder may have effects on the organism that carry implications for the likelihood of a recurrence.

Personality development

Over the years, there have been major changes in concepts of what is involved in personality development (Rutter & Rutter 1993; Caspi 1998; Rutter *et al.* 1998b). Four features warrant particular emphasis. First, although it is the case that, as with other psychological attributes, consistency in temperamental features increases over the years of childhood, measures at ages as early as 3 years do predict later psychopathological functioning to a significant (but only moderate) degree.

Secondly, temperamental characteristics should not be conceptualized as representing the genetic basis of personality. They

are subject to genetic influences but not to any greater extent than other behaviours. Temperament evolves over the course of development through the combined effect of genetic and environmental influences.

Thirdly, nature and nurture are not independent of one another (see also McGuffin & Rutter, Chapter 12). Genetic effects operate in part through their role in bringing about differences in environmental risk exposure—as a result of influences on behaviours that serve to shape and select environments—and in susceptibility to risk environments.

Finally, from infancy onwards, personality involves not only biologically influenced behavioural propensities, such as activity level or autonomic reactivity, but also thinking and feeling patterns (Rutter 1987). Children develop ideas about standards and values (Kagan 1982), and they gain a self-concept of what sort of person they are (Harter 1998). This includes a view of their value (self-esteem) and their ability to cope with different life challenges and situations (self-efficacy; Bandura 1995, 1997). It also involves an internal model of their past experiences and their expectations of how other people are likely to respond to them. Their concept of the world being a loving or hostile environment will, in turn, influence how they behave in their interactions and relationships with other people (Dodge *et al.* 1990, 1995; Thompson 1998).

Psychological substrate of continuities and discontinuities

These personality features, together with other characteristics, contribute to psychological mechanisms in continuities and discontinuities in psychopathology. It is not that these mechanisms do not have a neural substrate; they do (all learning and thinking has to involve brain processes), but the brain changes are of a type that can adapt to, and incorporate, new learning and new concepts.

At least three rather different features need to be considered with respect to continuities and discontinuities. First, there is the most fundamental question of what it is that environmental experiences do to the organism that leads to the carrying forward of effects that persist beyond the time span of the negative experience itself (Rutter 2000a). Numerous possibilities exist (Rutter 1989a). Mention has already been made of developmental programming effects, although it is likely that these apply to only a minority of rather severe experiences. There are also effects on neuroendocrine function. Animal studies have, on the whole, suggested that negative experiences lead to an enhancement of neuroendocrine structure and function that is protective against later stresses (Hennessey & Levine 1979; Levine 1982), whereas human evidence suggests rather the reverse (see Sandberg & Rutter, Chapter 17). The reasons for this disparity remain ill-understood at the moment. In addition, there are the effects on thought processes. Attachment theorists have placed great weight on the likelihood that the experience of negative relationships in early childhood leads children to develop negative

internal working models of both themselves and of the relationships that they may expect with others. The supposition is that it is these negative cognitive sets that provide the mechanisms that are the carrying forward of psychological sequelae. There is no doubt that children do, indeed, think about their experiences and do develop concepts and ideas about their meaning with respect to themselves and to the world about them. It is plausible that such cognitive and affective models influence the persistence, or non-persistence, of adverse effects of negative experiences, but the empirical research to test this proposition is largely a task for the future. Dodge *et al.* (1990, 1995) have asked similar questions in relation to the mechanisms by which adverse experiences, such as physical abuse, become transformed into an increased liability for antisocial behaviour. They hypothesize that the process might involve effects on cognitive processing of experiences leading to an increase in the tendency to make hostile attributions. Their findings provided modest support for the hypothesis but the cognitive measures accounted for a relatively small proportion of the variance in the outcome measure. It is unclear whether this means that other mechanisms were involved or, rather, that there were measurement problems with respect to such cognitions in early childhood. The findings so far may not provide a solid answer, but there is no doubt that this is the type of question that needs to be asked.

A second, somewhat related, issue concerns the effects of psychopathology on cognitive processing. It was once thought that negative cognitive attributions constituted a key risk factor for depressive disorder. That may be the case to some extent but, at least with adults, the available evidence casts doubt on the role of negative cognitions as an independent risk factor for depression. On the other hand, the same evidence does suggest that the experience of depression leads to negative cognitions that, in turn, do play a substantial part in the continuation of the depressive features (Teasdale & Barnard 1993). It is observations of this kind that have played a major part in the development of cognitive behavioural approaches in the treatment of emotional disorders (see Brent, Chapter 54).

The third issue concerns the role of major life experiences in bringing about continuities or discontinuities in behaviour. It was once thought that the 'norm' or 'ordinary expectation' was that, once a behaviour was present, it would continue indefinitely unless something happened to change it. It is now clear that that is a wholly mistaken and misleading assumption (Rutter 1994). The expectation cannot be simply of unchanging continuity. Rather, both continuity and discontinuity have to be accounted for, and the role of life experiences needs to be part of those considerations. Caspi & Moffitt (1991) have made the important point that when there were continuities between life experiences (which is usually the case), stresses and adversities will usually operate to enhance pre-existing behavioural tendencies, rather than change them. It is only when experiences are of a kind that show discontinuity with the past that turning point effects may be found (Rutter 1996b). For individuals who have shown antisocial behaviour in childhood, a supportive harmonious marriage makes a big difference in leading to a much reduced

likelihood that antisocial behaviour will continue, and to an increased likelihood of adaptive social functioning (Zoccolillo *et al.* 1992; Sampson & Laub 1993; Rutter *et al.* 1997; Laub *et al.* 1998). Of course, it is only a minority of antisocial individuals who make such a supportive marriage, and it is important to consider the possibility that the apparent protective effect is an artefact of the pre-existing behaviour or pre-existing psychosocial risk factors associated with individuals who are fortunate enough to land up in that situation. Nevertheless, detailed and careful statistical analyses have shown that the protective effect is, indeed, a real one. The likelihood of making a marriage to a supportive partner is strongly predicted by prior behaviour and prior circumstances (Quinton *et al.* 1993) but the positive adult life experience clearly makes a difference. Amongst other things, the findings point to the fact that the experiences that people bring about themselves can, nevertheless, have important effects on their own behaviour (Rutter *et al.* 1993).

Risk and resilience

One of the central concepts in modern medicine is that of risk factors and vulnerability. Very few disorders have a single main cause; rather they arise through an interplay among risk factors, each of which involves an increase in vulnerability or susceptibility, but none of which causes disorder directly. The likelihood of developing coronary artery disease is increased by low birth weight, high cholesterol levels, smoking, an increased clotting tendency, lack of exercise, and by a high waist:hips ratio—a rather diverse range of risk features. Similarly, osteoporosis in women is more likely if the person smokes, takes little exercise, lacked an adequate calcium intake in early life, and has low sex hormone levels. Much the same applies with psychiatric disorders in childhood and adult life. The greatest psychopathological risk arises from the cumulative effect of multiple environmental and genetic risk factors (Rutter 1999, 2000a,b). From a developmental perspective, the key questions are *how* these come together and *which* mediating mechanisms are implicated. Do they concern an increased reactivity to later psychosocial hazards, a negative mental set, a lack of self-efficacy, or a propensity to behave in ways that tend to engender stress situations—to mention just a few possibilities (Rutter 1989b)?

With all kinds of environmental risks (physical and psychosocial), there is huge individual variability in response (Rutter 2000a,b). The term resilience is applied when there is relatively normal functioning despite the experience of major risk factors. The evidence suggests that multiple factors play a part in this important phenomenon (Luthar *et al.* 2000; Rutter 2000b): including temperamental and other genetically influenced features; prior experiences; the impact of the risk experience at the time; the ways in which the individual conceptualized and thought about the experience; compensatory protective features that counteract the risk; and subsequent circumstances and happenings. A consideration of how these might be operative in the

individual case will be relevant in planning therapeutic interventions (Rutter 1999; see also Rutter & Taylor, Chapter 2).

Psychopathological progressions

There are several examples in the field of mental disorders where it is necessary to account for apparent progressions in psychopathology: drug dependency; antisocial personality disorder; suicide; progression from anxiety disorders to depression; and the progression from dieting to anorexia or bulimia nervosa.

In order to become dependent upon drugs or alcohol, it is necessary to make the first transition from no use of drugs to taking the substances at all; to move on to take them regularly at a high level; to become psychologically and/or physically dependent on the substances; and ultimately, to develop physical and social damage from the substance abuse (see Weinberg *et al.*, Chapter 27). In addition, there is likely to be a progression from taking just one drug to being reliant on multiple drugs. The features that provide maximum risks are by no means necessarily the same at all stages in this progression, as shown for example by Robins's (1993) research with heroin dependence in Vietnam veterans. African-Americans from the inner cities were the group most likely to take heroin but, on the return from Vietnam, it was rural whites who were more likely to continue to be dependent on the drug.

Genetically influenced specific responses to individual substances may be important in some circumstances. The unpleasant flushing response to alcohol that is present in some orientals constitutes a good example of a pharmacological response that is protective because of its unpleasantness (Vanyukov & Tarter 2000). There are other parallels, too, with respect to physiological responses that increase or decrease the risks of heavy use of substances. In addition, there may be genetically influenced or environmentally influenced features that have a role in the use of drugs, but not necessarily in the transition to dependence (Kendler *et al.* 1999). For example, longitudinal studies as well as retrospective cross-sectional studies have made clear the high frequency with which antisocial behaviour predisposes both to drug-taking in general and, especially, to the early use of drugs (Robins & McEvoy 1990). In other circumstances, dysthymic mood may constitute a predisposing factor, albeit a weaker one, to the use of drugs to relieve negative emotional states (Rao *et al.* 1999). However, findings also show that effects are bidirectional. Alcohol intoxication, possibly through its disinhibiting effects, makes violent crime more likely; and dependence on 'hard' drugs predisposes to thefts, probably because of the money needed to support the drug habit (Rutter *et al.* 1998b).

Although there is some evidence that the causal factors operate in somewhat different ways at different points in this progression, it is also necessary to consider the possibility that the different features all represent varied manifestations of the same underlying liability. The genetic evidence suggests that, to some extent, that is probably the case although that does not represent

the whole of the story. The causal pathways for these progressions in psychopathology are not at all well worked out, and there is a considerable need to try to investigate the causal mechanisms for each of the various phases and transitions.

Somewhat similar issues arise with respect to the transitions from hyperkinetic behaviour in early childhood to oppositional/defiant disturbance during middle childhood, to conduct problems in later childhood and adolescence, and then on to antisocial personality disorder (and other forms of personality disorder) in adult life. Although, according to traditional systems of classification, these are all considered different mental disorders, the genetic findings suggest that, to a considerable extent, they reflect the same underlying genetic liability (Rutter *et al.* 1998b). Thus, oppositional/defiant problems and conduct disorders share the majority of their genetic liability (Nadder *et al.* in press; Eaves *et al.*, 2000); and the same applies to the associations between both of those and prior ADHD. What is different here, however, is that the available genetic findings so far (much more needs to be done in order to sort out the mechanisms) suggest that the co-occurrence of hyperactivity indexes a different form of antisocial behaviour that involves a stronger genetic liability (Silberg *et al.* 1996). It is nevertheless the case that by no means all children with hyperactivity go on to develop antisocial behaviour, and also the transition is largely in the direction of earlier hyperactivity to later antisocial behaviour (with the reverse pattern distinctly uncommon); and this raises the possibility that either the transition requires an interplay of environmental risk factors (for which there is some evidence; see Moffitt 1990) or that the phenotype of hyperactivity creates an increased likelihood of negative family interactions that themselves predispose to the transition. Again, a developmental perspective requires that the causal mechanisms be viewed in terms of possible indirect chain effects as well as in terms of direct causes.

Mention has already been made of the need to examine continuities and discontinuities between the severe dieting and dissatisfaction with body shape that is so common in females during adolescence and the much rarer clinical syndrome of anorexia or bulimia nervosa. Is there a transition from the one to the other, perhaps requiring a different set of risk factors, or are the apparent similarities just surface parallels without there being a common underlying liability? Clearly, dieting predicts eating disorders (at least at a partial syndrome level) but is that because dieting represents the early phase of the disorder or is it because dieting itself serves as a risk factor (Patton *et al.* 1999)?

The situation with respect to anxiety and depression is rather different in that it is clear that there is a strong association at the individual level, and that both involve the shared liability factor of neuroticism or emotional liability (see Rutter & Taylor, Chapter 2). However, there is the additional consideration that longitudinal studies suggest that the usual course is for anxiety in childhood to lead on to depression in adolescence or early adult life, with the reverse pattern being much less common. Does this mean that age-related factors influence which manifestations are most striking at different ages, or are there

mechanisms of one kind or another that are implicated in the transition from anxiety to depression?

A further example is provided by the risk factors for suicide. Longitudinal studies suggest that depressive disorder and antisocial behaviour both constitute risks but, presumably, the former does so through the effects of severe depression of mood leading to feelings of hopelessness and despondency about the future, whereas the latter operates through the role of risk-taking behaviour and use of drugs (Harrington *et al.* 1994). Again, the question that needs to be asked is whether these are two parallel risk factors that operate in additive fashion or whether the developmental findings imply that there are two different developmental chains operating differently and yet which both increase the risk of suicide.

So far, most of the research that has been undertaken has focused on statistical associations in order to identify risk and protective factors, and much less attention has been paid to the possibility that the causal processes may differ at different points in the causal chain. We need to investigate that possibility. That is perhaps one of the main features to derive from the developmental perspective.

Sex differences

Throughout this chapter, there has been frequent reference to the presence of major sex differences in psychopathology. The reasons for that remain largely unexplained; nevertheless, the patterns are somewhat consistent. There is a male preponderance in almost all of the early onset disorders that seem to involve some form of neurodevelopmental impairment: autism (see Lord & Bailey, Chapter 38); developmental language disorders (see Bishop, Chapter 39); and hyperactivity (see Schachar & Tannock, Chapter 25). At first sight, antisocial behaviour might seem an exception to this trend but careful analysis of the evidence indicates that the main male preponderance applies to early onset antisocial behaviour that is associated with hyperactivity (Moffit *et al.*, 2001) and, hence, even that may be attributable to some form of neurodevelopmental feature. Of course, that leaves entirely open the question why these neurodevelopmental impairments are more common in males, but it narrows the question in so far as it focuses on the neurodevelopmental features rather than on a diverse range of psychopathology.

The other pattern is exemplified by the female preponderance that arises in adolescence, especially with respect to eating disorders and depression. It seems most unlikely that that sex difference is related to neurodevelopmental impairment; a rather different set of mechanisms need to be implicated. Genetic factors seem likely to play a part but such evidence as is available in the case of depression suggests that they may operate through their impact on nature–nurture interplay, rather than directly on disorder as such (Silberg *et al.* 1999, in press).

There are other disorders where the situation is more complex. For example, with schizophrenia it is not so much that there is an overall sex difference but that in males onset tends to

be earlier than it is in females (Castle *et al.* 1998; Tarrant & Jones 2000). It is not yet known why that is so. Similarly, with respect to the use and abuse of substances, it is not so much that there is an overall sex difference but that the particular pattern of sex difference varies with each substance. Again, we lack a good explanation.

Much of the research into sex differences up to now has been based on the sociological feminist perspective, focusing on the role of women in society. Those considerations may well be important with respect to some sex differences, but the strong likelihood is that a range of different explanations may need to be invoked, and that some of these will be largely biologically, rather than socially, influenced. This remains a high priority for future research.

Conclusions

Developmental considerations arise at all points in chapters throughout this volume. In this chapter, we have simply sought to pull together some of the different considerations and topics that must be investigated. Developmental approaches to psychopathology have brought some important advances but, even more than that, they have raised a rather different set of research questions that have still to be addressed. The purpose of this chapter has been to indicate what some of these might be.
