Both social skills training and social problem-solving training accept that there are deficits in a child's or adolescent's ability to interact with their peers. There has been some disagreement in relation to claims that the primary deficit is in the child's abilities to analyse the nature of a social interaction and to activate successful prosocial strategies. Alternatively, it has been argued that children can understand the social situation but lack the skills to take part in a way in which they will gain the liking and respect of their peers. A third view has held that much of the difficulty experienced by children is their lack of ability to understand and process emotional cues, both internal and external.

Applications to oppositional-defiant disorder and conduct disorder

Children with behavioural difficulties seem to:

- generate fewer solutions to social problems;
- develop solutions that tend to be aggressive;
- tend to misinterpret positive and neutral cues from others as negative ones;
- attend only to immediate consequences—longer-term ones are ignored;
- are apparently relatively insensitive to interpersonal conflict; and
- fail to recognize the causes of other children's and adults' behaviour

(Spivack *et al.* 1976; Shure & Spivack 1978; Spivack & Shure 1982; Asarnow & Callan 1985; Dodge 1985). However, these children also have poor abilities to label emotions, they show labile and intense emotions and they come from families where there is also a diminished vocabulary concerning feelings. They have poor empathic skills (Ellis 1982).

Social skills group programmes, such as the Dinosaur School curriculum (Webster-Stratton & Hammond 1997) have been developed for the younger age group. These include elements to develop:

- relaxation techniques;
- recognition of emotions and empathy training;
- social problem-solving skills (as per problem-solving skills training, PSST);
- anger management;
- friendship skills;
- communication skills; and
- managing in the classroom setting.

For example, the friendship skills part of the Dinosaur programme (Webster-Stratton 1996) is delivered over three to four sessions of 2 h each. The first session concentrates on the concepts of helping with the aims of learning what friendship means and of understanding ways of helping others. The second session in this part of the programme concentrates upon sharing and learning the relationship between helping and sharing. The third session moves to 'teamwork at school' through learning about teamwork, learning to understand the benefits of sharing, helping and teamwork and practising friendship skills. The final element of this part of the whole programme concentrates on 'teamwork at home' extending the ideas from the three previous sessions.

In the communication skills section of the programme (two to three sessions) children:

- learn how to ask questions and tell something to a friend;
- learn how to listen carefully to what a friend is saying;
- learn why it is important to speak up about something that is bothering them;
- understand how and when to give an apology or compliment;
- learn how to enter into a group of children who are already playing;
- learn how to give suggestions rather than commands; and
- practise friendship skills.

The methods used throughout this programme use many ways to help the children overlearn the ideas. This is a particularly rich and child-attractive multimodal social skills programme. Other programmes aimed at children with behavioural difficulties use many of the elements seen here, combining them in slightly different ways.

Social skills approaches to helping children with behaviour problems in groups and individually have been reviewed recently by Taylor *et al.* (1999). They took three age ranges: young children up to age 7 years, studies covering the 6–13 years age range, and adolescents. In the youngest age group, the only randomized control study to date was carried out with the Dinosaur curriculum (Webster-Stratton & Hammond 1997). This showed a reduction in aggressive behaviour at home and an improvement in peer social skills, as reported by parents and observed in interaction tasks. These changes persisted until 1-year follow-up. Even greater changes were achieved when the programme was combined with a parenting group. The teachers in school did not report changes. This may reflect a lack of generalization, as noted in other social skills programmes. It may be overcome by a more detailed collaborative approach involving the teachers heavily from the outset. This finding has led to further developments in Webster-Stratton's intervention programmes.

There were more studies in middle childhood. Most concerned school samples rather than clinical referrals. The results of interpersonal skills training for primary school children when applied in groups have been disappointing. Kazdin *et al.* (1992) and Kazdin (1996) achieved moderate success using an individual problem-solving training approach (see Compas *et al.*, Chapter 55) in middle childhood, supplemented by parenting programmes delivered to the parents of each child rather than a

group approach. This study did involve children with clinical levels of disturbed behaviour. Change was produced in the school setting as well as at home, with effects persisting 1 year later. However, many of their children still scored in the clinical range for disturbed behaviour despite significant improvements.

Lochman *et al.* (1991) developed an anger-coping programme for children in middle childhood that addressed both cognitive and affective processes to remediate skills deficits in conflict situations. The programme was highly structured and was delivered in group format. Specific goals were to 'increase children's awareness of internal cognitive, affective and physiological phenomena related to anger arousal; enhance self-reflection and self-management skills; facilitate alternative, consequential and means-end thinking in approaching social problems and increase children's behavioural repertoire when facing social conflict'. The programme was broader than a pure PSST approach and used a range of social skills methods as well as some that were specific to this programme, e.g. concentration on physiological cues. Their social skills programme has been shown to have some lasting effect in school-selected populations, both in teacher ratings and in observer ratings (Lochman *et al.* 1984, 1989, 1993).

Interpersonal skills training for adolescents has been disappointing when delivered in group format for aggressive behaviour-disordered adolescents. Feindler *et al.* (1984) found some effect for mild problems (arguing, shoving and cursing) but they have found no effects upon fighting, property damage and severe verbal abuse. Others have found similar negative results (Huey & Rank 1984; Guerra & Slaby 1990). Byrnes *et al.* (1999) were more optimistic. Their data showed a substantial reduction in criminal recidivism that correlated with the hours spent in a group or individual treatment, but not in family therapy, as part of an intensive day and residential programme. However, this was not a controlled trial but a review of the population that took part in the programme over a 4-year period. The style was eclectic, using cognitive-behavioural techniques as well as a more traditional group therapy approach. The study is therefore open to selection and other biases because not all clients entered each therapy.

Application to attention deficit hyperactivity disorder

ADHD is associated with social skills deficits (Whalen & Henker 1985). School observations suggest that children with ADHD are similar to their peers in terms of positive and neutral interactions but differ in being more bossy, intrusive and aggressive (Abikoff & Hechtman 1996). In the light of these observations, various attempts have been made to develop social skills training programmes. Meichenbaum & Goodman's (1971) original individual self-instructional programme has been expanded to include social skills elements and is used by some as a group programme. One review concluded that it worked best if the therapy focuses both on academic and social tasks and involves therapy-based contingency management (Baer & Nietzel 1991).

Abikoff & Hechtman (1996) developed group social skills programmes from two programmes developed in the 1980s: *Getting Along With Others: Teaching Social Effectiveness to Children* (Jackson *et al.* 1983) and the Walker Social Skills programme (ACCEPTS) (Walker *et al.* 1983).

Nolan & Carr (2000) concluded that self-instructional training and social skills training have positive effects on pre-adolescent school children with ADHD. Social skills training over 12 sessions supplemented with therapy-based contingency management and parental psychoeducation is probably effective in reducing home- and school-based behaviour problems. However, the studies reviewed did not address the long-term effects of such interventions. The recent MTA trial did not find an additional benefit to medication to be derived from the social skills programme that was a part of that trial (MTA Group 1999). This suggests that there is further work to be done to make the social skills interventions currently in use more specific and to improve their generalization.

Application to drug abuse

One trial (Liddle & Dakof 1995) suggested that multisystemic family therapy that included group and individual approaches to social skills and social problem-solving training was better than group therapy alone.

Application to sexually abused girls

McGain & McKinzey (1995) found that group therapy was better than no treatment for girls who had suffered sexual abuse. Trowell *et al.* (2000) studied the comparative effect of individual psychodynamic psychotherapy (up to 30 sessions) with a weekly psychotherapeutic/psychoeducational group of up to 18 sessions. Girls who had been subject to sexual abuse (age 6–14 years) were randomly allocated to the two treatments. Girls treated with either form of therapy improved in mental health (as rated by reduction of psychopathology and reduction of C-GAS scores). Re-experiencing of the trauma was differentially improved by the individual psychodynamic therapy.

Application to anxiety disorders

Albano & Barlow (1996) developed a cognitive-behavioural group treatment for socially phobic adolescents. This included an important social skills component, although it was not the central thrust of the programme. Social skills approaches do not seem to have been much developed for this group of disorders.

Application to depression

Social skills components are included in group cognitive-behavioural therapy programmes such as that developed by Lewinsohn *et al.*'s (1996) Coping With Depression–Adolescent (CWD-A) course. It is based on a social learning view of depression and focuses on training the youngsters in social skills

throughout the course as well as dealing with the specific cognitions of depression on the basis of work showing that depressed people have deficits in social skills. Butler *et al.* (1980), in a school-based programme lasting 10 sessions, found that a social skills approach may be more useful in that setting compared with a cognitive-behavioural approach. However, Fine *et al.* (1991) found that supportive group therapy was better than their social skills programme for clinically presenting depressed adolescents, although the differences disappeared over a 9-month follow-up, because the youngsters who had been treated with a social skills programme continued to show improvements.

Application to separation and divorce

Several studies have shown that group support for children combined with social skills and problem-solving skills training leads to better coping and better adjustment in school than found in control conditions (Roseby & Deutsch 1985; Alpert-Gillis *et al.* 1989). Some of the programmes also specifically help children with stress management (Pedro-Carroll *et al.* 1992). There is an impact on behaviour at home and in school as well as mood state. Methods include discussion, instruction, therapist and video modelling, role-play and rehearsal, together with social skill homework assignments.

As a salutary warning, another popular programme in which the children are offered support groups which has been in widespread use in the USA has been shown to be ineffective (Skitka & Frazier 1995).

Groups for parents

In many of the programmes cited in this section, parallel parent groups are conducted to help them support their children in the work. This seems to be an important issue for generalization, as does close liaison with schools if school-related behaviours are being targeted.

Groups in schools

Groups have been run in school settings, both for specific school-related problems and for more generalized difficulties. Several of the studies cited above have sampled their populations from schools. In such cases there is always the question as to whether these children and adolescents are similar to clinically referred cases or whether they differ in type or severity. One advantage in running groups in schools is that of the captive audience. It does not rely on parents bringing the children to clinics. However, there is the risk of poor generalization of effects because typically parents are not involved very much. Group interventions have been given to youngsters withdrawn from classes or as universal interventions as a prevention measure. Such interventions include bullying programmes.

More recently, teacher training programmes that aim to improve behavioural classroom management such as the Assertive

Discipline Programme (Canter & Canter 1992) and that of Webster-Stratton (see above) have been tried. The latter is intended to articulate with her parenting programme delivered as a universal intervention and later with introducing an adaptation of her Dinosaur school to whole classroom settings for infant school children (4–8 years).

Kolvin *et al.* (1981) reviewed psychotherapeutic school intervention programmes. Of the many studies he reviewed, he found only two with positive outcome that had adequate follow-up data (Mezzano 1968; Warner 1971). More work has been carried out subsequently but the field is still quite limited (Walker *et al.* 1983; Bierman 1989; Frankel *et al.* 1996).

Kolvin *et al.* developed a non-directive group therapy (four to five children, mixed sex groups) for 7 year olds based on Rogerian principles and drawing on the work of Axline (1947) and Ginott (1961). A similar client-centred Rogerian approach was used with older children (12 year olds, single sex groups) but the groups were based on discussions rather than activities. The therapists were given a moderately intensive training in the methods that they were to use in the schools over 1 year prior to the start of the trial. Nearly 600 of the 4300 children screened were selected for presence of social, psychiatric or learning difficulties in mainstream schools at age 7–8 years and at 11–12 years. The children were randomly allocated to one of the treatment approaches or to the control group.

Group therapy for the primary school children (PG) and for those of secondary school (SG) were compared with no intervention (ARC), to individual nurture work in the younger age group only, to behaviour modification (BM) in the older group, and to parent counselling/teacher consultation (JPC and SPC) in both groups. All treatments except PG and SG were delivered individually. Interestingly, an attempt was made to involve parents in the BM approach, although apparently not as a central plank from the outset. It failed through lack of interest on the part of the parents (for alternative approaches see Scott, Chapter 56).

Of the younger children with neurotic disorders, those who received nurture work or the play group treatment showed improvement at 18 months that was maintained at the 3-year follow-up. For those with antisocial disorders the effect was similar, but the benefit was not seen until the 3-year assessment. Those who had been offered teacher/parent counselling showed less improvement, as did the no-treatment controls.

For the older children with neurotic difficulties, both behaviour modification and the group therapy brought benefits by 18 months. At the 3-year assessment both showed benefits compared with parent/teacher counselling or no treatment. For those with antisocial problems, group treatment was better than both parent/teacher counselling and behaviour modification at 18 months. At 3 years, all three treatments showed more improvement than the no-treatment controls. Treatment benefits generally were greater in the older children.

More recently, Frankel *et al.* (1996) developed a social skills programme conducted in schools for peer-rejected children aged 7–12 years. Their treatment plan aimed to:

- 1 reduce the negative effect of the child's current reputation with his or her peers;
- 2 reduce the importance of the peer-rejecting group by helping the child to expand his or her social network;
- 3 instruct parents and children how to work together to make having a friend over to play work more successfully; and
- 4 improve the child's non-aggressive responses to teasing and conflicts with children and adults to reduce the ability of peers to provoke the child.

Children were seen in groups of six to nine pupils over 12 sessions of 1 h. Their parents were seen separately in a concurrent group. The sessions were divided into four sections with feedback of homework assignments, didactic teaching of a new skill, practice in coached play and then a new social skills homework task.

Children were taught the do's and don'ts of group entry, slipping into games and rejection, learning to praise others and negotiating changes of game, being a good host, confrontations with adults, e.g. inappropriate accusations of cheating, coping with teasing (through good humour), being a good winner and avoiding physical fights.

The programme has yielded promising results including those for children with ADHD, particularly when the parent component was enhanced with some generalization to the school setting. The published results for the children who had oppositional-defiant disorder were less encouraging.

Efficacy vs. effectiveness — a challenge

Weisz *et al.* (1995) have had a particular concern with the difference between studies carried out in expert academic research settings (efficacy studies), sometimes with convenience samples, and those carried out in clinical centres (effectiveness studies). Much larger effects of treatment have been found in the efficacy studies. There were far fewer clinic-based studies—they could only find six conducted since 1960 and three before then, as opposed to more than 100 efficacy studies. Cases presenting to clinics tend to be more complex and severe and the resources available to treat them may be less. The physical conditions in which the efficacy studies were carried out were better and there was more use of behavioural approaches than in the effectiveness studies. Other factors, such as specific therapist training, the possibility of greater skill among research therapists, more specificity of treated problems in the efficacy studies and the greater structure of research therapy did not seem to play a part in explaining the results. The effect of this review and other work has been to increase pressure on investigators to conduct therapeutic research in clinical settings with more typical patients.

Conclusions

Over the past decade substantial advances have been made in the delineation of the types of individual and group interventions

that can work for children and adolescents. Some indications of the effectiveness and limitations of a psychodynamic approach to child and adolescent therapy have begun to be clarified. The research into psychodynamic groups remains rather more limited. There is an urgent need to define the modifications that have been made clinically to the methods of running adult psychotherapy groups and then to provide controlled trials of the method as a whole and of modifications to it.

In the domain of social skills training, the picture is at present mixed. Some programmes appear to work but when large-scale trials take place the results seem to be much more uncertain. This may form part of the widespread issue of efficacy vs. effectiveness. Further work is needed to define the specific elements of such programmes that are effective, how they can efficiently be combined and how generalization can be ensured. Kazdin's model of behaviour disorders as resembling chronic medical illnesses in their requirement of periodic intervention needs further investigation. If he is correct, what are the appropriate interventions and when will they have most effect? Tantalizing suggestions of sleeper effects in various social skills programmes continue to appear and are then treated with scepticism by others in the research community.

In the domain of social skills training, the relationship between behaviour patterns that can be learnt and the belief systems of the child, parents and teacher remains largely unexplored. This may be appropriate but it would gainsay experience from individual and family approaches where there seem to be creative links across the domains that might be usefully explored to increased effect in this area of treatment and research. Equally, the echoes of disturbed early parent-child relationships are largely ignored in the pragmatic 'here and now' approaches of the skills deficit models but they may need to be addressed at times to provide a context in which a belief in successful change can occur. Such pieces of work can be taken up in multimodal therapies but they are easily ignored in programmatic treatment trials. This is not an argument for a return to long-term individual non-directive therapy for parents or children, but rather a clinical request for short-term focused pieces of integrated work. As ever, much remains to be done.

Role of pharmacological treatment in child psychiatry

Drug treatment represents a powerful way of altering the behaviour and mental states of children. There are large differences in prescribing practices between countries, and current usage includes drugs that may be ineffective or even hazardous. In the USA, the use of medication tends to exceed what has been validated by objective evidence for safety and efficacy (Jensen *et al.* 1999). In the UK, the reverse situation may exist: underprescribing for children whose conditions could be effectively treated with drugs. There is an understandable worry about medication in children, particularly in terms of possible long-term side-effects, yet there are few data on whether children really are more vulnerable to side-effects. Some children are denied treatment with medication, either because of ideological opposition to this form of therapy, or lack of knowledge. Medication has an important place in child psychiatric treatment, and expertise in the theoretical and practical aspects of drug use should be available in all child mental health services.

In recent years, the emphasis on evidence-based practice has led to a more rational evaluation of the use of drugs in child psychiatry. While there remain few definitive randomized controlled trials of the use of medication in child psychiatry, for some conditions, such as obsessive-compulsive disorder and hyperactivity, child psychiatry has led the way in evidence-based practice in psychiatry (Rapoport 1998). Although a controlled trial may show that a particular treatment is, on average, more effective than a control therapy for a specific indication, the decision about whether or not to prescribe for a particular child is clearly more complex. The potential prescriber should ask the following:

- Does the child have a condition known to be responsive to medication?
- How severe is this disorder, and what is the outcome target for this child?
- Which aspects of the child's condition are likely to be improved by medication and which will be unaffected?
- What is the chance of response (from trial evidence and from case judgement)?
- What is the balance of benefits and risks, both short- and long-term?
- How will response and outcome be monitored?
- Is monitoring for hazards required?

In almost every case, pharmacological treatment for children with psychiatric disorder should be just one part of a package of psychological, social and educational intervention. Even in conditions where drug treatment plays a significant part, and there are many where it does not (see Tables 59.1 and 59.2), drug treatment will nearly always only be a component of a multimodal treatment plan. For example, the tics of Tourette syndrome may be highly responsive to treatment with dopamine antagonists, and this may be an important part of the treatment, although it carries a significant risk of side-effects. However, for the majority of children, a knowledge of the natural history of Tourette syndrome and a suitable psychoeducational intervention can obviate the need for treatment of the tics with drugs (Peterson & Leckman 1998; Leckman & Cohen, Chapter 36).

In this chapter, the evidence for rational prescribing of psychopharmacological agents in young people will be reviewed, together with brief accounts of the basic pharmacology, pharmacokinetics and toxicology. Clinical guidelines for the use of drugs in the management of individual child and adolescent psychiatric disorders is given in the chapters on individual disorders, although some brief guidance is given for specific disorders. There are several good manuals available for clinical guidance on disease management, drug doses and other clinical details, in particular Werry & Aman (1999), Kutcher (1997) and Walsh (1998). Where possible, reference is made to recent review articles on individual drugs groups or management of specific disorders (March & Vitello 2001; Riddle *et al.* 2001).

General considerations in prescribing for children

Clinical observation and clinical trials

The history of psychopharmacology is characterized by chance findings, and paediatric psychopharmacology is no exception. Use of stimulants to treat hyperactivity was based on the unexpected discovery that children treated with amphetamines for post-lumbar puncture headache were less hyperactive and irritable (Bradley 1937). Clinical observation has provided many such clues for drug treatments in child psychiatry, and usually then leads to more formal scientific study. Controlled trials, the assessment of behavioural and neurochemical effects in animal models, and an experimental analysis of effects on

Table 59.1 Summary of child psychiatric disorders in which drug treatment plays a significant role.

Disorder	First-line drugs	Second-line drugs
Psychosis	Atypical antipsychotics Risperidone Olanzapine Amisulpiride	Typical antipsychotics Haloperidol Chlorpromazine Clozapine
Hyperactivity	Stimulants Methylphenidate Dexamphetamine	Imipramine Clonidine Venlafaxine
Obsessive-compulsive disorder	SSRIs Sertraline Fluoxetine Paroxetine Fluvoxamine Citalopram	Clomipramine
Tourette syndrome/tic disorders	Clonidine Risperidone Sulpiride	Pimozide Haloperidol SSRIs
Depression	SSRIs Sertraline Fluoxetine Paroxetine Citalopram Fluvoxamine	Tricyclic antidepressants Imipramine Amitriptyline Clomipramine Atypical antidepressants

Anxiety disorders
Enuresis

psychological processes all contribute to the evaluation of drug efficacy.

Because of the inherent difficulties of experimental studies in children, much of the knowledge of drug effects has been extrapolated from adult studies. However, children differ from adults developmentally as well as pharmacologically, so caution is needed until appropriate efficacy studies are carried out in children (Tosyali & Greenhill 1998). However, the commonly held idea that drugs are more hazardous in young people is not necessarily true. For example, antipsychotic-induced akathisia seems to be less common in children and adolescents, but acute dystonias seems to be more common in adolescent males (Keepers *et al.* 1983).

Regulatory controls and procedures: medicolegal issues

Until about 30 years ago, treatments were chosen on the basis of clinical judgement rather than on objective testing. Many drugs now in use have never been subjected to controlled clinical trials, although all newly introduced drugs must be before a licence is granted. For a particular drug to be licensed for use for a specific indication and in a particular age group, regulatory authorities demand that the appropriate studies must be carried out. In the USA it has been estimated that approximately 80% of drug use in paediatrics is unlicensed or 'off-label' (Jensen *et al.* 1999). This means that it is prescribed with the clinician's judgement. In some cases there is published clinical trial evidence for efficacy, and this greatly strengthens a clinical decision to prescribe 'off-label' for a child.

A controlled clinical trial aims to compare the response of a *test group* of patients receiving a new treatment to that of a *control group* receiving an existing standard treatment. If there is no current treatment, the control group may receive no treatment or a *placebo*. To avoid bias, clinical trials should be randomized and double-blind. Jensen *et al.* (1999) classified evidence supporting the use of psychotropic medication in children into three levels. Level A denotes support by two or more randomized controlled trials, level B denotes support from at least one randomized controlled trial and level C is supported only by uncontrolled trials or clinical opinion. These

ratings for eight psychotropic drug groups were then compared with the frequency with which the drugs were prescribed. With the exception of attention deficit hyperactivity disorder (ADHD) treatment with stimulant drugs, there was little association between frequency of use and clinical trial evidence of efficacy.

Patterns of drug use in different countries and settings

There are marked differences in prescribing practices in different countries, although these differences have had little objective measurement. The management of ADHD in the USA and the UK provides a striking example of cultural differences in both diagnosis and treatment.

In the USA, one child in 20 meets the DSM-IV diagnostic criteria for ADHD. The prevalence in Europe seems to be much lower, about one in 200, mainly because European psychiatrists use the narrower ICD-10 diagnosis of hyperkinetic disorder (HD). Children with similar symptoms are more often labelled as having conduct disorder in the UK, as opposed to ADHD in the USA. The result is that clinicians in the UK tend to use psychosocial treatments without medication, unlike their counterparts in the USA who use medication as the first line of treatment. In some countries in Europe, especially in the UK and France, there has been widespread public hostility to the use of psychotropic medication for this purpose. In certain countries such as India, stimulants are not available and hence second-line medications, such as tricyclic antidepressants (TCAs) and clonidine, are used as first-line drugs. It is therefore difficult to formulate uniform guidelines for the management of even very common disorders.

Other demographic variables may show associations with variation in medical treatment. A recent retrospective analysis of prescriptions for psychotropic drugs in US youths aged 5–14 years reported that African-American youths were less likely than Caucasian youths to have been prescribed psychotropic medications, especially methylphenidate (Zito *et al.* 1998). This is an important finding and needs to be investigated further to find out whether youths with similar symptoms receive different diagnosis (conduct disorder instead of ADHD) leading to different treatment.

Differences between children and adults

Pharmacokinetics

Much less is known about the pharmacokinetics of psychotropic medications in children than in adults. Generally, drug response may vary with age, weight, sex, disease-state, absorption, distribution, metabolism and excretion; thus developmental factors that influence these are important to consider. Although the extent of drug absorption for most medication is similar in children and adults, the rate of absorption may be faster in children, and peak levels are reached earlier. Absorp-

tion is also dependent on the form in which it is administered (liquid vs. tablet) and levels peak faster for liquid preparations.

Hepatic metabolism is highest during infancy and childhood (1–6 years), approximately twice the adult rate in prepuberty (6–10 years), and equivalent to adults by the age of 15 (Bourin & Couetoux du Tertre 1992). This is clinically important, as younger children may require higher milligram/kilogram dosages of hepatically metabolized medications than older children or adults (Wilens *et al.* 1992). In addition, a transient decrease in metabolism for some medications has been reported in the few months before puberty, which is believed to be caused by the competition for hepatic enzymes with sex hormones. Protein binding and volume of distribution affect the pharmacokinetics of medications. These parameters differ in children and have practical clinical implications, such as the fraction of drug that is active (unbound). Body fat increases during the first year, then gradually falls, until puberty. Substantial fat stores slow elimination of highly liposoluble drugs from the body (e.g. fluoxetine, pimozide).

Pharmacodynamics

The pharmacodynamic properties of a drug are the mechanisms and responses that are mediated by binding to one or more target molecules, which are commonly receptors, ion channels, enzymes or carrier molecules. Little is known about differences in pharmacodynamics throughout development but, as neural development is better understood, it is becoming clearer that children may have different target molecule distributions or subtypes, and indeed that brain development continues into adult life.

A clinical puzzle is that TCAs seem relatively ineffective in depressed children (Hazell *et al.* 1995). Possible explanations have included differences in pharmacokinetics and pharmacodynamics, including the hormonal milieu of the brain or incomplete maturation of neurotransmitter systems involved in the control of affect. There may be clinical selection biases, such as inclusion of adolescents who will over time turn out to have bipolar illness.

The maturation of autonomic cardiac control may have an important influence on psychotropic related cardiotoxicity in children. Vagal modulation of heart rate increases during the first decade of life, peaks sometime during the second decade, then declines gradually with age to the sixth decade of life. Sympathetic modulation follows a similar pattern, but rates of maturation of the two branches are not the same. Furthermore, there is considerable variation between individuals of similar age in autonomic maturation. The relative loss of vagal modulation associated with TCA use may be accentuated in some younger subjects because of these maturational factors (Mezzacappa *et al.* 1998), leading to cardiotoxicity.

Main classes of drugs used in child psychiatry

Stimulants

Basic pharmacology and mechanism of action

Stimulant drugs, including methylphenidate, dexamphetamine and pemoline, are widely used and effective in the treatment of ADHD. There are many published reviews of the clinical efficacy literature; for example, Greenhill *et al.* (1999) report that by 1996 there were 161 randomized controlled trials of these drugs, constituting the largest body of treatment literature on any child psychiatric disorder. Despite this extensive clinical and pharmacological knowledge, the basis for their efficacy in

ADHD remains unclear. The recent review of stimulant medication by Santosh & Taylor (2000) gives a detailed account of the existing prescription practice of stimulants, neurological basis of stimulant action, evidence base for use of stimulants, prescription guidelines, their use in ADHD with comorbidity and other indications, and cost-effectiveness.

Stimulants act by releasing monoamines from nerve terminals in the brain. Noradrenaline and dopamine are the most important mediators, but serotonin release also occurs. They increase intrasynaptic concentrations of dopamine by blocking the dopamine transporter, and by displacement of monoamines from synaptic vesicles. Human functional imaging studies are beginning to allow us to measure these processes more directly (Volkow *et al.* 1998). The core behavioural response in hyperactive children seems to be an improved ability to ‘inhibit’, and

Table 59.3 Summary table of drugs and their indications.

Drug class (specific examples)	Main indications	Possible indications
<i>Stimulants</i>		
Methylphenidate Dexamphetamine	ADHD, narcolepsy	Resistant depression
<i>Antipsychotic and antimanic drugs</i>		
Chlorpromazine, thioridazine, trifluoperazine and other phenothiazines	Schizophrenia, Tourette syndrome/tic disorders	Psychotic features in affective disorders, acute aggression
Haloperidol, droperidol, pimozide, sulpiride	Schizophrenia, Tourette syndrome/tic disorders	Psychotic features in affective disorders, acute aggression, PDD
Atypical antipsychotics: clozapine, olanzapine, amisulpiride, risperidone	Schizophrenia, Tourette syndrome/tic disorders	Psychotic features in affective disorders, acute aggression, PDD
Lithium	Mania, bipolar disorder	
Carbamazepine	Mania, bipolar disorder	
Sodium valproate	Mania, bipolar disorder	
<i>Antidepressants</i>		
Tricyclic and related antidepressants: amitriptyline, clomipramine, imipramine, trimipramine, dothiepin	ADHD (especially those with anxiety and/or tics), OCD	Enuresis
SSRIs and related antidepressants: fluoxetine, fluvoxamine, paroxetine, sertraline, citalopram, venlafaxine	OCD, depression	Panic disorder, anorexia and bulimia, PDD
MAOIs	Resistant depression	Resistant ADHD
<i>Anxiolytics, sedatives and miscellaneous drugs</i>		
Benzodiazepines	Sedation	Acute aggression
Antihistamines	Sedation	Anxiety disorder
Anticonvulsants	Epilepsy	Sleep problems
Clonidine	ADHD, tics	Repetitive self-injury in PDD
Naltrexone		

Abbreviations: ADHD, attention deficit hyperactivity disorder; MAOI, monoamine oxidase inhibitor; PDD, pervasive developmental disorder; SSRI, selective serotonin reuptake inhibitor.

Table 59.4 Dosage range of psychotropic medication used in children and adolescents.

Drug	Dose range
Stimulants	
Methylphenidate	5–60 mg/day
Dexamphetamine	2.5–40 mg/day
Pemoline	37.5–112.5 mg/day
Antidepressants	
<i>Tricyclic antidepressants</i>	
Imipramine, desipramine	10–20 mg/day in <6 year olds 10–75 mg/day in >6 years (prepubertal) 50–150 mg/day postpubertal
Clomipramine	10–200 mg/day
<i>Selective serotonin reuptake inhibitors (SSRIs)</i>	
Fluoxetine	10–60 mg/day
Fluvoxamine	50–300 mg/day
Sertraline	25–150 mg/day
Paroxetine	10–60 mg/day
Citalopram	10–60 mg/day
<i>Serotonin noradrenaline reuptake inhibitors (SNRIs)</i>	
Venlafaxine	37.5–150 mg/day
<i>Antipsychotics</i>	
Haloperidol	0.5–8 mg/day (prepubertal) 1–16 mg/day (postpubertal)
Sulpiride	25–500 mg/day
Clozapine	50–600 mg/day
Pimozide	1–12 mg/day
Olanzapine	2.5–20 mg/day
Risperidone	0.25–6 mg/day
Amisulpiride	25–1000 mg/day
Sertindole	2–16 mg/day
Ziprasidone	40–120 mg/day
Quetiapine	25–500 mg/day
<i>Antiepileptic medication</i>	
Carbamazepine	5–10 mg/L (serum level)
Sodium valproate	50–100 mg/L (serum level)
Clonazepam	0.5–4 mg/day
<i>Others</i>	
Lithium carbonate	0.4–1.0 mEq/L (serum level)
Clonidine	0.05–0.25 mg/day
Buspirone	10–45 mg/day
Naltrexone	12.5–50 mg/day

therefore enhance persistence in motor and cognitive functions, but the pharmacological mechanisms underlying this remain obscure (Solanto 1998). Genetic, neuroimaging and neuropsychological findings all suggest that the brain abnormalities in

ADHD are neurodevelopmental in origin (Zametkin & Liotta 1998). Susceptibility to ADHD may be increased by variation in genes encoding components of the dopamine system, such as receptors and transporters (reviewed by Faraone & Biederman 1998). The catecholamine-rich frontosubcortical systems appear to be dysfunctional in some children with ADHD, perhaps suggesting a link with sites of stimulant drug action, although no consistent abnormalities in peripheral catecholamines have been found.

Pharmacokinetic issues

Stimulants are rapidly absorbed following oral administration, show low plasma protein binding and are eliminated from the body within 24 h following hepatic metabolism. One study has suggested that the behavioural response is sustained even after drug discontinuation (Gillberg *et al.* 1997) but, in general, the effects cease when the drug is stopped.

The different stimulants have slightly different half-lives, and this may be important in clinical practice (Barkley *et al.* 1999). Methylphenidate has the most rapid onset of action (1–3 h) and shortest half-life (2–3 h), so that clinical effects wear off after 4–6 h. Slow-release preparations may be useful in children who develop rebound hyperactivity, or in whom frequent dosage is impractical. There is little evidence for the development of tolerance in children taking stimulants for treatment of ADHD (Safer & Allen 1989), although clinically there are reports of decreased efficacy after prolonged administration.

Side-effects and toxicity

Although the stimulants are safe, dose-dependent side-effects may occur, and are similar for all stimulants. The most common side-effects are delay of sleep onset, reduced appetite, stomach-ache, headache, jitteriness and dysphoria (Barkley *et al.* 1990). They often wear off spontaneously, or may be reduced by lowering the dose. Persistent or severe side-effects may require changing drugs. Growth retardation may occur during acute treatment (Klein *et al.* 1988), but in longer follow-up, adolescents show no significant growth impairment (Vincent *et al.* 1990), although studies into adult life are needed. There is also a suggestion that children with ADHD may have slower growth rates independent of stimulant use, perhaps as a component of the neurodevelopmental disorder itself (Spencer *et al.* 1996a).

Sleeplessness can be a problem and it is clinically important to distinguish those children whose insomnia is an unwanted effect of the drug from those children whose insomnia may be caused by the recurrence (or worsening) of the behavioural difficulties as the medication effect subsides. There is little evidence that stimulants produce a decrease in the seizure threshold (Crumrine *et al.* 1987) or that addiction results from the prescription of stimulants for ADHD. Clinical experience suggests that the euphoriant response to stimulants that is evident in adult life, and which predisposes to recreational usage and de-

pendence, is much less usual in childhood. Similarly, the effects of amphetamine in predisposing to a paranoid psychosis (Connell 1958), so prominent in the abuse of this drug in adult life, has not been a feature in childhood. Unfortunately, systematic studies of age-related differences in response seem to be lacking.

The long-term use of pemoline has been associated with abnormalities in liver function tests and, in some cases, liver failure (Berkovitch *et al.* 1995). This has led to it being withdrawn from licence in the UK (although it may be prescribed on a named-patient basis), and being used only as a second-line treatment in the USA.

Main indications including trial data or other evidence of efficacy

There is abundant evidence for the short-term beneficial effects of stimulants for the treatment of ADHD. A review of clinical trials by Greenhill *et al.* (1999) summarized the findings from 5899 patients recruited to clinical trials; 65–75% showed improvement in response to stimulants, compared with only 4–30% in response to placebo.

A recent study of methylphenidate and dexamphetamine found that 96% improved behaviourally in response to one or other drug (Elia *et al.* 1991). Contrary to common assumptions, stimulants have a wide variety of social effects in addition to improving the core symptoms of inattention, hyperactivity and impulsivity. Stimulant effects on attentional, academic, behavioural and social domains, however, are highly variable between individuals (Rapport *et al.* 1994). Greater hyperactivity, inattention and clumsiness in the absence of emotional disorder predict greater positive response to methylphenidate (Taylor *et al.* 1987). Stimulant medication remains effective over many years as indicated by short-term measures, but it remains unclear whether, in the long term, treatment of ADHD in childhood has an impact on adult functioning.

Despite this strong clinical trial evidence for efficacy, there are many clinical issues which the trial data do not answer. The threshold level of ADHD symptoms for initiation of treatment has not been defined, so the diagnosis alone serves as the main criterion for starting treatment. There is no good association between plasma levels and behavioural response, so dosage regimes continue to be clinically judged. There are few good predictors of individual variability in response. Clinical experience suggests an important role for parent training, or school-based interventions, but controlled trials have shown little additional effect of these interventions over medication alone (MTA Cooperative Group 1999). There is extensive discussion in the literature about aspects of study design that may predispose to a differentially positive outcome for drug treatment. Pelham (1999) suggests that the measurement of outcome after the ending of behavioural treatment, but while medication treatment was still continuing, may have biased the findings. Another interesting finding from the MTA study was the improved response to methylphenidate in the research protocol group compared with those in the 'standard' community treatment

group. This may be because the research group protocol involved a very detailed initial evaluation of the optimal dose of stimulant necessary for each child (involving a 4-week period of using various doses of stimulant and placebo), and subsequent close monitoring of drug dosage. In contrast, the community group received standard dose regimens, less specifically tailored to the individual child. A commentary by Taylor (1999) concluded that services for children with ADHD should always incorporate the option of treatment with medication, as behavioural treatment alone is unlikely to be effective. He also notes that while the MTA study did not show significant additional value of behavioural treatment, its beneficial effects may emerge in longer term study, or for specific subgroups of patients.

The presence of a comorbid condition may alter the response to stimulant medication. There is disagreement as to whether response to stimulants is reduced in children and adolescents with comorbid anxiety disorders. Low doses of methylphenidate have been shown to produce an elevation of heart rate in children with ADHD with comorbid anxiety (Tannock *et al.* 1995). Pliska (1989) found fewer stimulant responders amongst subjects with ADHD and comorbid anxiety and some had a placebo response as large as the stimulant response itself. Other studies find that children with comorbid anxiety respond as well as those without anxiety to stimulants (Livingston *et al.* 1992); it is currently generally accepted that stimulants are the first-line drugs in this group, although TCAs may represent a useful alternative if anxiety is exacerbated or response is poor (Spencer *et al.* 1996b).

There are concerns about stimulants precipitating or exacerbating tics, and some studies have found worsening of tics in 25–30% of patients (Spencer *et al.* 1996b). For children who have Tourette disorder or chronic tics, low to moderate doses of methylphenidate often improve attention and behaviour without significantly worsening the tics (Gadow *et al.* 1999; Law & Schachar 1999). The current consensus is that cautious treatment with stimulants may be both tolerable and useful to many children with tics and ADHD (Castellanos 1999). Pliska *et al.* (2000) have published expert opinion-based algorithms in the management of ADHD in the presence of comorbid tics, aggression and anxiety/depression.

Stimulants should be used with caution in autism with comorbid ADHD. Quintana *et al.* (1995) report good stimulant response in a double-blind placebo controlled study in this comorbid group. However, it is not unusual in clinical practice to note a worsening in repetitive behaviours.

For drugs with such well-established therapeutic efficacy, and a high safety margin, it is remarkable that such a level of controversy exists about stimulant use in children. Greenhill *et al.* (1999) point out that no evidence of long-term harm has been revealed in nearly 30 years of evaluated use. They conclude that stimulants should not be withheld from children with ADHD, or limitations placed on the chronicity of use, but rather that practice standards should be high, including careful initial diagnosis and optimum monitoring of the response to treatment.

Antipsychotic drugs

Basic pharmacology and mechanism of action

The antipsychotic drugs are all dopamine receptor antagonists, although many of them also act on other targets, such as serotonin, noradrenaline and glutamate receptors. A robust finding from adult studies of schizophrenia is the strong association between D₂ receptor binding activity, and antipsychotic potency (Seeman *et al.* 1976). Antipsychotics may take days or weeks to be effective, suggesting that secondary effects, such as altered numbers of D₂ receptors in limbic structures, may be more important than the direct receptor blockade. There is no reason to suppose that juvenile forms of the psychoses have specific differences in the mechanisms of response to drug treatment, although general differences related to developmental immaturity in neurotransmitter systems may apply. Dopamine antagonism is also likely to be the mechanism of action of antipsychotics in Tourette syndrome, where they are effective in diminishing tics. The antipsychotic drugs are also widely used in a range of behavioural emergencies, and in some instances in child psychiatry for less acute behavioural disturbance, particularly in the context of autism and mental retardation. There is evidence for efficacy in these conditions, although it is not known whether dopamine blockade is the key mechanism of action.

The main categories of antipsychotic drugs are the *classical* or *typical* antipsychotics, and the newer drugs that are often called *atypical*. The classical group includes chlorpromazine, haloperidol and thioridazine. Relatively new drugs in this group include pimozone and sulpiride. The 'atypical' or 'newer' antipsychotics have different pharmacological profiles (serotonin–dopamine antagonism), generally have fewer extrapyramidal side-effects, and may be effective in groups of patients resistant to treatment with the classical antipsychotics. Clozapine was the first atypical antipsychotic agent introduced and remains the only one to be therapeutically superior to other antipsychotics in efficacy (in resistant schizophrenia). The other atypical antipsychotics include risperidone, olanzapine, amisulpride, quetiapine and ziprasidone. The behavioural effects of all antipsychotics are similar, but their side-effects differ.

Pharmacokinetics

In children as in adults, there is huge individual variation in plasma drug levels, with little correlation between drug dosage and blood levels (Ernst *et al.* 1999). In general, children eliminate drugs more rapidly than adults, and the antipsychotics are no exception; for example, chlorpromazine has a shorter half-life in younger children (Furlanut *et al.* 1990).

Side-effects and toxicity

Antipsychotic drugs have the potential to produce significant side-effects (for a review see Campbell *et al.* 1999), in parti-

cular extrapyramidal side-effects (including acute dystonias, akathisia, parkinsonism and dyskinesias), sedation and, rarely, neuroleptic malignant syndrome (Silva *et al.* 1999). The dyskinesias are the most serious of these, and the prevalence in children ranges from 8 to 51% (Gualtieri *et al.* 1984). This includes both tardive dyskinesia and withdrawal dyskinesia. Withdrawal dyskinesia may occur with either gradual or sudden cessation of antipsychotic agents, with one-third or more of children developing these movements when the drug is abruptly withdrawn. Withdrawal dyskinesia is usually reversible, whereas tardive dyskinesia may persist even if the antipsychotic agent is discontinued. 40 of 118 (33.9%) autistic children receiving haloperidol over a 15-year period (for hyperactivity, tantrums, aggression, withdrawal, self-injurious behaviour and stereotypies) developed drug-related dyskinesias (Campbell *et al.* 1997). They were predominantly drug withdrawal dyskinesias and the risk was increased with duration of exposure to drug, cumulative drug dose and the female gender.

The atypical antipsychotics are less likely to cause extrapyramidal side-effects, although there are case reports of risperidone-induced dyskinesias in children (Demb & Nguyen 1999). Clozapine induces little if any dyskinesia in adults, but can cause blood dyscrasias, especially in children (reviewed by Wahlbeck *et al.* 1999).

Main indications of antipsychotic drugs

Psychosis

Antipsychotic medication continues to be the only specific treatment of documented efficacy for psychosis, although most of the evidence for efficacy in children is an extrapolation from the adult literature. Differences between early onset and adult schizophrenia seem at most to be only quantitative and developmental, and it is reasonable to assume that data from adult studies should form the basis for the treatment of early onset cases. The effectiveness of antipsychotic drugs in adults with schizophrenia has been shown in more than 100 double-blind randomly assigned controlled studies, but there are few studies with adolescents and children (Realmuto *et al.* 1984; Spencer & Campbell 1994). Clinical experience, and one systematic study (Rapoport *et al.* 1980a), suggests that children with schizophrenia may respond less well to antipsychotics than do adults, although one of the few controlled studies suggests that the response is similar (Spencer *et al.* 1992). With the exception of clozapine, there is no evidence to suggest that any one antipsychotic agent is superior in the treatment of schizophrenia. The choice of medication should be based on the agent's relative antidopaminergic potency and side-effects spectrum, and the patient's history of medication response. Currently, most clinicians would recommend the use of an atypical antipsychotic for first-line maintenance therapy in psychosis, although many use the more conventional group for acute behavioural control, often in conjunction with a benzodiazepine.

Clozapine (Frazier *et al.* 1994; Kumra *et al.* 1996) is recom-

mended mainly in patients with early onset schizophrenia who are either non-responsive to typical antipsychotics or have developed tardive dyskinesia, although there are theoretical arguments for its first-line use in young patients. It has been found to be effective in at least 30% of adult patients with treatment-resistant schizophrenia (reviewed by Wahlbeck *et al.* 1999). It can only be prescribed in conjunction with a blood-monitoring programme, because of the risk of blood dyscrasias. Newer antipsychotics, such as risperidone or olanzapine, are being used in open clinical trials currently, with encouraging results (Kumra *et al.* 1998), although they do not share clozapine's property of having additional effects in resistant psychosis. The major advantage of the newer antipsychotics is their improved side-effect profile, and in particular the reduced risk of extrapyramidal side-effects, less sedation and resultant improved compliance.

Autism

Antipsychotic drugs are quite widely used in autistic spectrum disorder, in an attempt to reduce repetitive and aggressive behaviours. Campbell *et al.* (1999) reviewed the clinical trials of haloperidol in the treatment of these behaviours, and reported evidence of statistically significant therapeutic efficacy. Despite the improvement noted with haloperidol, about one-third of the children developed dyskinesia as a side-effect (either withdrawal or tardive dyskinesia) (Campbell *et al.* 1997), which suggests that typical antipsychotic agents should be used infrequently and with caution in autism. Open trials of the atypical antipsychotics, e.g. risperidone (McDougle *et al.* 1997) and olanzapine (Potenza *et al.* 1999), reported improvements in angry and labile affect, sleep, interfering repetitive behaviour, aggression, impulsivity and self-injury in children and adolescents with autism (for a review see Santosh & Baird 1999). Significant side-effects of both drugs include major weight gain, hypotension and sedation. A double-blind placebo controlled trial of risperidone reported similar improvements in older individuals with autism (McDougle *et al.* 1998).

Tourette syndrome

Antipsychotic drugs are the most effective treatment for motor and vocal tics, although side-effects of these drugs may limit their usefulness in long-term treatment. Haloperidol has proved effective in controlled trials (Shapiro *et al.* 1989) and a more recent study suggested that pimozide may be superior to haloperidol (Sallee *et al.* 1997). Atypical antipsychotics are being increasingly used in tic disorders, and preliminary studies with ziprasidone (Sallee *et al.* 2000), sulpiride and risperidone show promising results.

Aggression

Antipsychotic drugs have been used for the treatment of aggression in the context of conduct disorder or learning disability

(mental retardation). In neither case is there clear evidence for efficacy. In adults with mental retardation, a recent meta-analysis found no clinical trial evidence for efficacy of antipsychotics in the treatment of challenging behaviour (Brylewski & Duggan 1999). Nevertheless, in clinical practice these drugs are widely used, and behavioural improvement is reported by clinicians and families (for a review see Campbell *et al.* 1999).

Many other medications have been tried in the treatment of behavioural disorders including conduct disorder, aggression and delinquency, but the consensus is that psychopharmacological treatment alone is insufficient (Campbell 1992).

Attention deficit hyperactivity disorder

Antipsychotics, as well as many other psychotropic medications, have been tried in the treatment of ADHD; there are no systematic data supporting their use, or the use of fenfluramine, benzodiazepines or lithium in ADHD (Green 1995). Dopamine-blocking agents may seem an illogical combination with stimulants, but there is some trial evidence for an increased benefit for methylphenidate plus thioridazine over methylphenidate alone—especially in behaviour as seen at home rather than at school (Gittelman-Klein *et al.* 1976). This must be set against the known toxicity of antipsychotic drugs, and cautious practice will only use the combination in rare and extreme circumstances. In principle, the advent of atypical antipsychotics with fewer hazards may have altered the ratio of risk:benefit. Risperidone, for example, is coming into frequent use before trials have been completed, on the basis of a reputation for fewer extrapyramidal hazards. It is not free of adverse effects, sedation and weight gain being prominent, and it may antagonize some of the actions of methylphenidate (such as those mediated by D₂ receptors). In general, the combination of stimulants and antipsychotics—like most other forms of polypharmacy—should only be tried by a specialist service, and that in those exceptional cases where it is to be used, an atypical antipsychotic should be chosen.

Lithium

Basic pharmacology and mechanism of action

The psychotropic effects of lithium were discovered in 1949 by Cade, and this inorganic cation is still a mainstay in the prophylaxis of manic-depressive (bipolar) illness in adults. Its mechanism of action is uncertain, although it is known to interfere with two important second messenger systems, and thus to have widespread and complex effects on neurotransmitter function.

Pharmacokinetic issues

Lithium is given orally, usually as the carbonate salt, and its elimination is almost entirely dependent on renal excretion.

Children tend to have a higher glomerular filtration rate and a higher proportion of body water than adults, which may mean that higher doses of lithium, relative to body weight, are needed to achieve therapeutic levels, and steady state may be achieved more rapidly (Vitiello *et al.* 1988). Apart from this higher excretion rate, lithium pharmacokinetics is overall similar to that in adults.

Side-effects and toxicity

Lithium is generally well tolerated in children and adolescents, although younger children with neurological problems may be more vulnerable to side-effects (Campbell *et al.* 1991). Common side-effects in children are nausea, tremor, polyuria and enuresis. Other potential side-effects which are documented in adults include weight gain, acne, hypothyroidism and impaired renal function. In younger children (aged 4–6 years) more neurological side-effects have been reported, including tremor, drowsiness, ataxia and confusion, especially at the beginning of treatment (Hagino *et al.* 1995), suggesting that a strong clinical indication would be needed to justify lithium use in such young children. Lithium has a narrow therapeutic index and monitoring of the plasma concentration is an essential part of treatment (Tueth *et al.* 1998). Acute lithium toxicity can cause coma, convulsion and death, and may need treatment with plasmapheresis.

Main indications including trial data or other evidence of efficacy

The main indication for lithium use in young people, as in adults, is for the prophylaxis of bipolar disorder, and the treatment of acute mania. There have been very few good studies in children, and in general use of lithium in children is based on evidence from adult studies (Ryan *et al.* 1999). There is some evidence for efficacy in the treatment of aggression, and little evidence for efficacy in the treatment of ADHD and conduct disorder.

Mood stabilization

There are few randomized controlled trials of lithium in young people. One study in substance-dependent adolescents with comorbid bipolar illness showed significant benefit of lithium treatment, in terms of global impairment and illicit drug use (Geller *et al.* 1998). Other small cross-over and open studies have given variable results. Strober *et al.* (1990) showed greater rates of relapse in adolescents with bipolar disorder who discontinued lithium treatment.

In summary, open trials of lithium in adolescents appear to give similar response rates to adults. Its usefulness in younger children seems less clear, particularly as this group seems more prone to adverse effects. A study in children less than 12 years showed little apparent benefit of lithium (Carlson *et al.* 1992).

Aggression and conduct disorder

Several open studies have shown lithium to be useful in the treatment of extreme aggressiveness, particularly in the context of mental retardation (DeLong & Aldershof 1987). There have been small studies suggesting positive effects of lithium in conduct disorder (Campbell *et al.* 1995) and others with negative results (Rifkin *et al.* 1997).

Antidepressant drugs

Basic pharmacology and mechanisms of action

Antidepressant drugs comprise a diverse group, and new agents frequently appear on the market, reflecting the recognized shortcomings of those that are currently available. The main shortcomings (see below) are limited clinical efficacy, delayed onset of action and prevalence of side-effects.

The pharmacological rationale for these drugs rests mainly on the monoamine theory of depression, which holds that depression results from a functional deficit of monoamine transmitters—particularly noradrenaline and serotonin. Current thinking about the action of antidepressant drugs, and a look ahead, are given in reviews by Frazer (1997) and Nestler (1998).

Currently, the main types of antidepressant drugs are the following.

- TCAs (e.g. imipramine, amitriptyline, clomipramine, desipramine).
- Selective serotonin reuptake inhibitors (SSRIs, e.g. fluoxetine, fluvoxamine, paroxetine, sertraline, citalopram). These widely used drugs appear to be as efficacious as TCAs (and possibly more so in children, see below) with fewer side-effects.
- Monoamine oxidase inhibitors (MAOIs, e.g. phenelzine, tranylcypromine, moclobemide).
- ‘Atypical’ antidepressants (e.g. maprotiline, bupropion, venlafaxine, trazodone, nefazodone, mianserin, mirtazapine). This is a heterogeneous group. Maprotiline inhibits noradrenaline uptake, and resembles the TCAs, although its chemical structure and side-effects are different. Venlafaxine inhibits both serotonin and noradrenaline reuptake, and has weaker receptor blocking actions than TCAs. The mechanism of action of bupropion is unclear. The others act mainly as antagonists of various monoamine receptors, including presynaptic adrenoceptors and serotonin receptors.

Despite their pharmacological differences, the different groups appear to be indistinguishable with respect to clinical efficacy in adults. However, they differ in their side-effects, which may be the main basis for the choice of which drug to prescribe in individual cases.

Pharmacokinetics

Detailed information about these drugs has been obtained in adults, the few studies in children being confined to TCAs. In

adults, all of the drugs are well absorbed orally. Their plasma half-lives vary widely between drugs, and also between individuals. Thus, imipramine (relatively short-acting) has a half-life of 6–24 h, while fluoxetine (long-acting) has a half-life of 24–200 h. For several reasons, there is generally little correlation between plasma concentration and clinical response.

- Many antidepressants give rise to long-lived active metabolites.
- The clinical response usually takes 2–4 weeks to develop after treatment has started. The reason for this delay is not known, but it suggests that the clinical effect reflects a secondary adaptation to the primary action of the drug.

Comparison of TCA half-lives in children and adults suggests that they are generally two- to three-fold shorter in children, and equi-effective doses, on a body weight basis, are correspondingly larger in children. Despite the wide variation in half-life between different drugs and different individuals, most of these drugs are given once daily.

Side-effects and toxicity

1 TCAs and drugs classified as atypical antidepressants are active as antagonists at several different monoamine receptors, notably muscarinic cholinergic receptors, histamine (H_1) receptors and noradrenaline (α_1) receptors, as well as various different serotonin receptors, and these actions account for many of their side-effects:

- sedation (mainly amitriptyline, trazodone, clomipramine, maprotiline, uncommon with bupropion);
- anticholinergic side-effects (dry mouth, blurred vision, constipation, urinary retention—mainly TCAs, maprotiline, rare with other atypical antidepressants);
- postural hypotension (mainly TCAs, maprotiline, trazodone), paradoxically, hypertension at rest sometimes occurs, particularly with imipramine;
- weight gain (mainly TCAs);
- seizures (especially bupropion, but also reported with TCAs);
- cardiotoxicity, evident as a slowing of conduction and tachycardia, which can progress to ventricular dysrhythmias, is the most serious adverse effect of TCAs, and sudden deaths have been reported in children (Biederman 1991). Other antidepressants are much safer in this respect.

2 SSRIs. The side-effects appear to be associated with the primary mechanism of action of these drugs, and there is little evidence that individual SSRIs differ significantly from each other; venlafaxine has a similar profile:

- agitation and insomnia;
- headache;
- nausea and vomiting, mainly at the beginning of treatment.

Sexual dysfunction, a major problem associated with SSRIs in adults, is inconsequential in young children but may be important in adolescents.

3 MAOIs. The serious side-effects of first-generation MAOIs,

especially hypertensive crisis ('cheese reaction'), greatly limited their clinical utility, particularly in children. The newer MAO-A-specific and reversible compounds, such as moclobemide, overcome some of these problems, but have not yet gained wide acceptance for use in children.

Clinical uses and efficacy

Depression

A depressive disorder starting in childhood or adolescence is a serious psychiatric condition that may become a chronic illness. The prevalence of major depressive disorder and dysthymia increases dramatically in adolescents, reaching close to adult levels in late teenage years. Treatment of depression includes effective resolution of the current episode and effective prophylaxis to prevent further episodes or to reduce their morbidity if they do occur. Medication should be used in conjunction with interventions designed to improve interpersonal, social and academic functioning.

There is increasing evidence that SSRIs are effective in child and adolescent depression, and should generally be the first choice of medication (Emslie *et al.* 1999). Commonly used SSRIs include fluoxetine and paroxetine, with accumulating experience with sertraline and fluvoxamine. The evidence from a few controlled studies and numerous open trials show that around 60–70% of cases will show some improvement. A more recent randomized controlled trial of fluoxetine showed a 56% rating in improvement in the drug treatment group, compared with 33% in the placebo group (Emslie *et al.* 1997).

In contrast, TCAs are probably relatively ineffective in children. A large double-blind, placebo-controlled trial of desipramine hydrochloride showed no benefit compared to placebo, regardless of the type of outcome measure used or subtype of the major depressive disorder (Kutcher *et al.* 1994). A meta-analysis of the efficacy of TCAs in the treatment of childhood depression concluded that there was no evidence they were more effective than placebo (Hazell *et al.* 1995). The total numbers of children studied are small, and in general childhood depression has many similarities with adult depression; however, current evidence does not support the general use of TCAs in childhood depression, although they may be useful in individual cases (Geller *et al.* 1999).

There are preliminary findings with atypical antidepressants, but numbers remain very small. A small study of refractory childhood depression showed positive responses to nefazodone (Wilens *et al.* 1997) but a small controlled study of venlafaxine failed to show significant difference between drug and placebo (Mandoki *et al.* 1997), although clinical anecdote suggests that this may be a useful drug in the younger age group. There is little evidence that the typical MAOIs, such as tranylcypromine or phenelzine, are effective treatments for depressed children or adolescents. The dangers of traditional MAOIs are well known and the special dietary requirements that accompany their use make them difficult to use in children and problematic in adoles-

cents. Ryan *et al.* (1988) concluded that it was risky to use MAOIs in adolescents, although this was before the introduction of reversible MAOIs, such as moclobemide, which have yet to be evaluated in children but might prove useful in resistant depression.

In childhood depression that is non-responsive to an SSRI, a trial of another SSRI is advisable. If this is ineffective, a trial of a drug with added noradrenergic impact, such as venlafaxine, may be used. If the patient continues to remain symptomatic, re-view diagnosis—if depression remains the diagnosis, augmentation with lithium or buspirone should be tried. Continued non-response should lead to the use of atypical antidepressants such as bupropion, nefazodone, reboxetine, or the use of a reversible MAOI drug, such as moclobemide. Non-response to this strategy should lead one to contemplate the use of electroconvulsive therapy (ECT) if impairment remains significant. Psychological intervention, such as cognitive-behavioural therapy and environmental manipulation, should be attempted together with the pharmacotherapy in all resistant cases. ECT will need to be contemplated earlier if the patient is in depressive stupor, very suicidal or severely impaired. A low dose of one of the atypical antipsychotics (such as olanzapine) should be added to the antidepressant if there are psychotic symptoms. It is advisable that resistant childhood depression be managed in a specialist centre.

Obsessive-compulsive disorder

The treatment of obsessive-compulsive disorder (OCD) with clomipramine is probably the best established use of a TCA in childhood, with the serotonin reuptake properties of clomipramine being an essential part of its efficacy. Leonard *et al.* (1991) found a very high relapse rate in children and adolescents following substitution of clomipramine with desipramine in a cross-over study. In another double-blind placebo controlled multicentre study of 60 adolescent patients with OCD, treated for 8 weeks, a mean reduction of 37% in total obsessive-compulsive score was seen in the clomipramine group compared to 8% in the placebo group (DeVeugh-Geiss *et al.* 1992). However, the SSRIs have now largely superseded clomipramine as a first-line treatment for OCD in young people, because of their improved side-effect profiles. There is controlled clinical trial evidence of SSRI efficacy and safety for fluoxetine and fluvoxamine (reviewed by Grados *et al.* 1999) and more recently for sertraline (March *et al.* 1998). Although the effect sizes are relatively small, they are generally equivalent to clomipramine, and are consistent with findings from adult studies. Over 75% of the children and adolescents treated in an open trial of citalopram showed a moderate to marked improvement in OCD symptoms with only minor and transient adverse effects (Thomsen 1997). Medication treatment for childhood OCD may need to be long term; Leonard *et al.* (1993) reported that response to treatment with clomipramine in childhood or adolescence predicted a better outcome 2–7 years later. However, only

11% were totally asymptomatic, 43% still met diagnostic criteria for OCD and 70% were on psychoactive medication at follow-up, including the asymptomatic patients. As in adults, up to 80% of young people with OCD relapse on discontinuation of medication, but there is clinical suggestion that remissions may be prolonged if medication is combined with cognitive-behavioural therapy.

A double-blind placebo-controlled cross-over trial of fixed dose fluoxetine (20 mg/day) in Tourette syndrome showed that fluoxetine had no effect on tics but produced a modest decrease in obsessive-compulsive symptoms. The most common side-effect was transient behavioural activation which occurred in about half of the subjects and was more common in children (Riddle *et al.* 1990).

Attention deficit hyperactivity disorder

Although far less studied than stimulants, controlled trials of TCAs in both children and adolescents demonstrate efficacy in the treatment of ADHD (Popper 1998). Despite the narrow margin of safety, they may be used as second-line drugs for stimulant-resistant ADHD, and for those who develop significant depression or other side-effects on stimulants, and for patients with comorbid tics or Tourette disorder, anxiety disorder or depression. The long duration of action of TCAs averts the need for a dose at school and rebound is not a problem. Efficacy in improving cognitive symptoms does not appear as great as for stimulants.

Desipramine is effective in both children and adolescents (Biederman *et al.* 1989), but is more cardiotoxic than imipramine. Consequently, imipramine is probably the first choice amongst TCAs in the treatment of prepubertal children with ADHD. In two open trials of children and adolescents, many of whom had a poor response to stimulants, TCAs increased attention span and decreased impulsivity (Wilens *et al.* 1993).

There have been some studies of atypical antidepressants in the treatment of ADHD. An open study of venlafaxine suggested efficacy (Olvera *et al.* 1996). Bupropion may decrease hyperactivity and aggression and perhaps improve cognitive performance of children with ADHD and conduct disorder (Conners *et al.* 1996) and was found to be as effective as methylphenidate in a double-blind controlled trial (Barrickman *et al.* 1995). Its most serious side-effect is a decrease in seizure threshold and it may exacerbate tics.

Although used safely in some contexts, the combination of imipramine and methylphenidate has been associated with a syndrome of confusion, affective lability, marked aggression and severe agitation (Grob & Coyle 1986). A double-blind controlled cross-over study of 16 hospitalized children with ADHD, mood disorder, or both, and with either conduct disorder or oppositional-defiant disorder, treated with a combination of desipramine and methylphenidate showed that the combination was significantly better than either drug alone although clini-

cally the benefits were modest. In this carefully monitored setting there were no untoward side-effects (Carlson *et al.* 1995).

Anxiety disorders

Four placebo-controlled studies of TCAs for separation anxiety disorder, with and without school refusal, provide contrasting results. The inconsistencies may be explained by differences in dosages and comorbidity patterns and lack of control of concurrent therapies. In the original studies of Gittelman-Klein & Klein (1971, 1973), 35 children receiving imipramine were significantly more successful in returning to school than those on placebo (81% on imipramine and 47% on placebo). Although recent studies have failed to replicate these results (Berney *et al.* 1981; Bernstein *et al.* 1990; Klein *et al.* 1992), clinical experience suggests that some children and adolescents with anxiety-based school refusal improve on TCAs, and they may also be effective in treating panic disorder in children and adolescents (Ballenger *et al.* 1989; Black & Robbins 1990).

Literature is starting to emerge about the use of SSRIs for children with anxiety disorders. Open trials of fluoxetine have demonstrated significant effect in children and adolescents with social phobia, overanxious disorder or separation anxiety disorder (Birmaher *et al.* 1994). Similarly, case reports (Wright *et al.* 1995), an open trial (Dummit *et al.* 1996) and a controlled study (Black & Uhde 1995) indicate that fluoxetine (10–40 mg/day) may be beneficial in the treatment of elective mutism. A recent randomised controlled trial has shown efficacy of fluvoxamine for a range of child anxiety disorders (The Research Unit on Pediatric Psychopharmacology Anxiety Study Group 2001).

Pervasive developmental disorders

SSRIs, such as fluoxetine (Cook *et al.* 1992) and sertraline (Steingard *et al.* 1997), have been used in autistic children with encouraging improvements in aggression, repetitive and maladaptive behaviour, social relatedness and self-injurious behaviour in the short term. Fluvoxamine in a double-blind placebo-controlled study has also produced similar improvements in adults with pervasive developmental disorders (PDD) (McDougle *et al.* 1996).

Enuresis

Imipramine is well established in the treatment of enuresis. It may act by decreasing the deepest stages of sleep to lighter sleep, by stimulating secretion of antidiuretic hormone (ADH) indirectly or by peripheral mechanisms. A study that compared imipramine, desipramine, methscopolamine and placebo showed that both TCAs were superior to placebo or methscopolamine but did not differ from each other (Rapoport *et al.* 1980b). Despite a lack of comparative clinical trials, desmopressin (a synthetic analogue of ADH) is now considered a safer,

more effective and better tolerated alternative to the use of TCAs for treating enuresis.

Anxiolytics, sedatives and miscellaneous drugs

Basic pharmacology, pharmacokinetics and side-effects

A wide variety of psychoactive drugs have been tried in many different psychiatric disorders, sometimes in combination, in adults and in children. With a few exceptions, there is little systematic evidence for efficacy and safety. The main drugs which have been usefully deployed in child and adolescent psychiatry are summarized in Table 59.5, and the subsequent section reviews the evidence for clinical usefulness. A more detailed review by Riddle *et al.* (1999) considered all of the drugs mentioned in this section, including benzodiazepines, buspirone, clonidine and naltrexone.

Clonidine

An α_2 -adrenoceptor agonist has been shown in placebo controlled trials to attenuate significantly hyperactivity and disruptive behaviours in children with ADHD. A recent meta-analysis of published trials suggests that clonidine is less efficacious than stimulants, and that side-effects may be significant (Connor *et al.* 1999). Although clonidine is not effective in treating inattention *per se*, it may be used alone to treat behavioural symptoms in children with tics (Steingard *et al.* 1993) or in those where stimulants are ineffective or not tolerated. When discontinuing clonidine, the dosage should be reduced gradually to avoid a *withdrawal syndrome* consisting of increased motor restlessness, headaches, agitation, elevated blood pressure and pulse rate and possible exacerbation of tics reported in patients with symptoms of Tourette syndrome and ADHD (Leckman *et al.* 1986). Depression and impaired glucose tolerance are side-effects that can occur in susceptible patients.

Open trials suggest that clonidine may be useful in combination with a stimulant for the treatment of ADHD, when the stimulant alone is ineffective or when the dose is limited by side-effects. Recently, there has been concern about the use of clonidine in combination with stimulant medication (Swanson *et al.* 1995), based on the cases of four children who died suddenly. The evidence derived from these cases is hard to interpret because of special circumstances and inadequate detail (Wilens & Spencer 1999). Recommendations are conflicting: Swanson *et al.* (1999) believe that the use of the combination is ill-advised until controlled studies can be conducted to evaluate efficacy and side-effects. Most practitioners appear to be taking the line of cautious use rather than a complete ban, and including ECG monitoring in their evaluations.

Clonidine has also been used in Tourette syndrome in both open and double-blind trials. Positive studies suggest that about 40% of patients with Tourette syndrome benefit from its use (Leckman *et al.* 1991), but there are at least as many negative

Table 59.5 Basic pharmacology of anxiolytics, sedatives and miscellaneous drugs used in child psychiatry.

Drug	Mechanism of action	Actions	Side-effects	Pharmacokinetics
Benzodiazepines: Lorazepam Oxazepam Alprazolam Temazepam Nitrazepam Diazepam Chlordiazepoxide Flurazepam Clonazepam	Enhancement of inhibitory effect of GABA acting on GABA-A receptors	Sedative Anxiolytic Anticonvulsant Reduces muscle spasm	Confusion Amnesia Impaired co-ordination Tolerance and dependence	Most are well absorbed orally Inactivated by hepatic metabolism Half-lives vary from 6–12 h (e.g. lorazepam) to over 48 h (e.g. diazepam). Active metabolites prolong effect of many benzodiazepines
Valproate	Uncertain Weak GABA-enhancing and Na-channel blocking actions	Mainly antiepileptic Also has sedative/antimanic action	Nausea Somnolence Hepatotoxicity Weight gain	Well absorbed orally Half-life 12–15 h
Carbamazepine	Block of Na channels	Mainly antiepileptic, with weak stimulant activity. Used in trigeminal neuralgia	Nausea Dizziness May cause tics Occasionally causes emotional lability, aggressive behaviour Leucopenia and hepatotoxicity at high plasma levels	Well absorbed Plasma half-life varies from 12 to 60 h, tending to decrease because of induction of metabolizing enzymes Monitoring of plasma level is advisable to keep below 10 mg/L
Clonidine	Partial agonist at α_2 adrenoceptor Inhibits noradrenaline release in brain	Sedation Reduced sympathetic activity, causing lowering of blood pressure	Hypotension Sedation Dry mouth Dangerous in overdose (bradycardia, hypotension)	Well absorbed by mouth Can be given as skin patch to provide sustained action Plasma half-life is about 12 h, but pharmacological effect is briefer (2–4 h)
Naltrexone	Antagonist at μ -opioid receptors	Little effect in absence of opiates Inhibits opiate effects, and can precipitate withdrawal syndrome in addicts	Drowsiness Nausea Headache	Well absorbed orally Plasma half-life about 4 h Action prolonged by formation of active metabolite
Antihistamines: Promethazine Diphenhydramine	Antagonists at histamine H_1 receptors	Sedation Antiemetic	Drowsiness and confusion Anticholinergic effects	Well absorbed orally Plasma half-life approx. 12 h (6 h for diphenhydramine)

studies (reviewed by Riddle *et al.* 1999). In addition to reducing the simple motor and phonic symptoms in Tourette syndrome, clonidine seems useful in reducing hyperactivity and ameliorating complex motor and phonic symptoms. Clonidine tends to have a slower onset of action than antipsychotic drugs. Tolerance to clonidine does not appear to develop. Its major side-effect is sedation, which commonly appears

early in the course of treatment, but tends to abate after several weeks.

Clonidine has been shown in double-blind placebo-controlled trials to improve hyperactivity, irritability and oppositional behaviour in autism, a clinical group in whom stimulants may be contraindicated because of a tendency to increase rigidity or stereotypies (Fankhauser *et al.* 1992).

Guanfacine hydrochloride

Guanfacine hydrochloride is a long-acting α_2 -agonist and has a more favourable side-effect profile than clonidine. It has recently been used as monotherapy for children with ADHD and Tourette syndrome, whose tics may become worse with the use of stimulants (for a review see Scahill *et al.* 2000). It has also been used in combination with a stimulant in the treatment of children with ADHD who cannot tolerate the sedative or rebound side-effects of clonidine. As yet only open trials have been published (Hunt *et al.* 1995), and this drug is not licensed in the UK.

Benzodiazepines

Benzodiazepines may be used on a short-term basis (few weeks) for anxiety symptoms in rare circumstances. Despite their anxiolytic properties, benzodiazepines have significant dependence-producing potential in adults and should be used with caution in children, although there have been no studies of dependence in young people. In general, pharmacological management has a relatively minor role in the treatment of anxiety disorders in children and adolescents (Labellarte *et al.* 1999). Case reports and several studies indicate that alprazolam is useful in treating anxiety symptoms in children and adolescents. In an open label trial, small doses of alprazolam were found to be effective for anticipatory and acute situational anxiety in paediatric oncology patients undergoing bone marrow aspirations and spinal taps (Pfefferbaum *et al.* 1987). However, a double-blind placebo-controlled study of 30 children and adolescents with avoidant or overanxious disorders failed to show any statistically significant difference between alprazolam and placebo (Simeon *et al.* 1992), as did another small double-blind cross-over study of 15 children with anxiety disorders comparing clonazepam with placebo (Graae *et al.* 1994). Adolescents with panic disorder treated with clonazepam experienced a decrease in the frequency and level of anxiety symptoms after 2 weeks of treatment (Kutcher & MacKenzie 1988).

Buspirone

Buspirone is a full 5-HT_{1A} agonist at the somatodendritic auto-receptor and a partial agonist at the post-synaptic 5-HT_{1A} receptors, acting therefore on the noradrenergic, serotonergic and dopaminergic systems. Side-effects are uncommon and usually very mild and include nausea, headaches, daytime tiredness and weight gain. Buspirone has been reported to improve hyperactivity, anxiety, stereotypy, irritability and global behaviour in open trials (Buitelarr *et al.* 1998), but there have been no controlled studies in children or adolescents. Recently, an open trial showed buspirone to produce global improvement in symptoms of ADHD (Malhotra & Santosh 1998). Case reports suggest that buspirone is effective in treating adolescents with overanxious disorder and school refusal (Kranzler 1989), social phobia and mixed personality disorder (Zwier & Rao 1994). Riddle *et*

al. (1999) review the general case-report studies on the use of buspirone in children and adolescents, some of which suggest improvements in oppositionality, anxiety and school refusal.

Anticonvulsant drugs

Both sodium valproate and carbamazepine have an established role in the management of adult bipolar disorder, and are probably effective as mood stabilizers in early onset forms of this illness (for a review see Ryan *et al.* 1999). As yet there is very little controlled trial evidence for their efficacy in young people, although there have been some promising open studies of sodium valproate in mania (Papatheodorou *et al.* 1995).

There have also been trials of carbamazepine in children with behavioural problems, or high activity levels. Studies from the early 1970s suggested benefit over placebo, but more recent studies in children with aggression showed no advantage over placebo (Cueva *et al.* 1996). A meta-analysis of 10 studies suggests that carbamazepine may be beneficial in ADHD (Silva *et al.* 1996), but methodological limitations make this uncertain and the far from benign side-effect profile make this drug an alternative only for highly resistant cases.

Naltrexone

Naltrexone, an opioid antagonist, has been used in autism, on the hypothetical basis that opioid dysfunction may occur in this condition. The results have been inconsistent but have shown a mild improvement in hyperactivity, impulsivity, restlessness and self-injury (Koleman *et al.* 1995).

In spite of a lack of a sound evidence basis, it is reasonable in certain circumstances, such as in autism, to try one of the medications for which positive claims are being made. In such circumstances it is sometimes illuminating to carry out a double-blind placebo-controlled case study. Many psychotropic agents have been used in autism, and the consensus is that any trials of medication should be part of an overall treatment plan that includes psychosocial, behavioural and language interventions. Despite SSRIs, risperidone and clonidine being reported to increase social relatedness, there is very little evidence that treatment can change the core features of autism. However, pharmacotherapy may decrease the severity of some of the autistic features, help control harmful or dangerous behaviours and may improve the patient's accessibility to psychosocial and language interventions. The first-choice medication is usually determined by the target symptoms that need to be controlled. Thus, if hyperactivity is a target, methylphenidate or clonidine may be chosen; if rituals, self-injurious behaviour or stereotypies are a target, an SSRI such as fluvoxamine or sertraline may be a reasonable choice while clonidine, risperidone, haloperidol or buspirone may be appropriate for treating irritability and aggression (Santosh & Baird 1999). Subjects with anxiety may respond to buspirone, propranolol or clonazepam. At the present time, there is no clear-cut evidence that opiate antagonists are of value in the promotion of social behaviour. There is currently no

convincing evidence to suggest any positive therapeutic effect of megavitamin therapy or dietary manipulation in autism.

Melatonin

Melatonin, a hormone secreted under adrenergic control by the pineal gland, has been the subject of case study and small trials for the treatment of severe sleep disorders. The evidence is weak, but some studies suggest that it is effective in correcting disturbed sleep patterns (Jan *et al.* 1999).

Secretin

Secretin has been advocated as treatment for the maladaptive behaviours of autism, but there is no objective evidence to support this (Volkmar 1999).

Electroconvulsive therapy

The use of ECT presents particular dilemmas in children and adolescents, as there are only limited numbers of case reports or studies on ECT in this population (Rey & Walter 1997). ECT continues to be used in adolescents in many countries despite the various advances in pharmacotherapy, because some patients continue to be drug-resistant. The current practice estimate of ECT use in adolescents is 0.5–1 treatment per million people (Cohen *et al.* 2000).

A cautious recommendation of indications for the use of ECT in adolescents would be to limit its use to treat catatonia, severe resistant mood disorders and intractable acute psychotic disorders. Other rare indications include its use in managing neuroleptic malignant syndrome and status epilepticus. Apart from the diagnoses, the urgency for the need for rapid response, the danger of suicidal or homicidal behaviours, the severity of the psychiatric disorder, the number and adequacy of previous treatments need to be taken into account. ECT can be ethically justified in cases where there is a risk of death or suicide, sometimes even without the patient's consent—using consent from carer, or a second medical opinion (Reiter-Theil 1992). In rare cases, court petition may be necessary when parents' and children's interests are opposed. Although the benefits of ECT are often impressive, the secondary effects—in particular cognitive impairment—need to be considered, as an adequate risk–benefit analysis is currently difficult as studies on cognitive consequences of ECT are unavailable in young people.

Cohen *et al.* (2000) have outlined the various complications of ECT in adolescents as the following.

- 1 Complications of the anaesthetic time: lip-biting, teeth chattering, agitated awakening, face flush and prolonged seizures.
- 2 Early secondary effects are quite frequent but usually only entail moderate discomfort: headache, post-ECT asthenia, nausea, muscular pain and post-ECT confusion.
- 3 Infrequent complications: disinhibition and spontaneous seizures.

4 Cognitive secondary effects have not been prospectively studied in the adolescent population.

There have been no deaths with ECT in children or adolescents reported, probably because of fewer anaesthetic complications in the young.

Despite views of certain organizations and professionals that ECT should be banned for youth (Baker 1995)—based on the ethics of uninformed consent, possible risk of brain damage and misapplication, and inadequate knowledge and equipment—a balanced view dictates that ECT could be used in the rare instances detailed above. There is an obvious need for controlled short-term and follow-up studies on ECT use in adolescents, including its possible effects on cognitive functioning. Techniques such as transcranial magnetic stimulation (TMS) might ultimately replace ECT; TMS is currently only available in research centres but is producing encouraging results in adult mood disorders (Hallett 2000), apparently with fewer side-effects.

Dietary treatments

Exclusion diets are the key to management of certain rare metabolic disorders, such as phenylketonuria (see Skuse & Kuntsi, Chapter 13). More controversially, a variety of diets for supposed metabolic disorders have been proposed without empirical support. In particular, Feingold's hypothesis—of a toxic action of salicylates, and cross-reacting synthetic dyes and preservatives, as a main cause of hyperactivity, autism and mental retardation—has been tested and found not to be correct (Conners 1980; Committee on Toxicity of Food 2000). A weaker hypothesis—that food dyes can worsen the behaviour of certain predisposed children—has had inconclusive evaluation.

However, there is preliminary evidence for an idiosyncratic effect of diet upon the behaviour of certain predisposed individuals (reviewed by the Committee on Toxicity of Food 2000). Two challenge studies have selected children with ADHD; identified suspect foods by trying their effect, one at a time, while the diet is otherwise highly restricted; and then given the suspect foods in a placebo-controlled random-allocation cross-over design. Both found that suspect foods produced more behaviour problems than placebo. Two experimental diet studies have used random-allocation trial designs to compare a control diet with one that eliminates the most common suspect foods identified in the challenge studies. Both found fewer behavioural problems in children with ADHD taking the elimination diet than the control.

There are reservations about these promising findings. They are based on small-scale trials, and highly selected series of children. The foods involved vary from child to child and include 'natural' foods such as eggs, wheat flour and citrus fruit as well as 'artificial' ones such as food dyes. The action appears to be on irritable and non-compliant behaviours rather than specifically on ADHD, and the mechanism of action is unknown. The diets are difficult to prepare, unwelcome to children, and usually infeasible for older children and adolescents. It is not clear how to select children for a trial of diet—except for the finding that re-

sponse was more probable when parents had themselves noted a suspect food (Carter *et al.* 1993).

One can conclude only that parents who have noticed that diet affects their children's behaviour are, probably, sometimes right. Prescription of the diet is not yet justified. However, families who wish to explore the possibility further should be supported—either by assistance in keeping a food diary to identify suspect foods, or by referral to a paediatric dietician for a diagnostic trial of a 'few-food' diet, to identify the specific foods that could be eliminated in the longer term.

Surgery

There have been no controlled studies of the effects of epilepsy surgery on psychiatric symptoms in young people. Descriptive investigations have all shown that positive behavioural outcomes are highly correlated with reduction in severity of seizures. For example, 22 children (all except two had mental retardation) were followed at 19 months post-corpus callosotomy for intractable seizures (Yang *et al.* 1996). Half were reported to have improved attention span and social skills, and reduced hyperactivity. Parents' reports of satisfaction with quality of life was significantly correlated with good seizure outcome. Non-resective surgery (multiple pial transections) has also been reported to improve language and social skills temporarily, in a group of children with epilepsy-related autistic features (Nass *et al.* 1999).

Positive behavioural outcomes have also been reported for resective surgery. Eight individuals followed by Lindsay *et al.* (1987), who underwent hemispherectomy for severe epilepsy, were said to have excellent relief from behavioural disorder. Several earlier studies reported similar findings (reviewed by Goodman 1986) although, by contemporary standards, all of these studies are impaired by lack of systematic behavioural measures.

Temporal lobectomy is the most common surgical procedure for intractable seizures but, once again, behavioural outcomes have been little studied in children. One series (Davidson & Falconer 1975) reported that the underlying pathology is related to positive seizure and behavioural outcome, in this case mesial temporal sclerosis being positively associated. A more recent study of nine children reported no change in neuropsychological measures following temporal lobectomy, and suggested improvement in emotional disturbance and social interaction (Williams *et al.* 1998). Psychosurgery, other than as used in the treatment of epilepsy, has no place in child psychiatry.

Conclusions

Prescribing habits in child and adolescent psychiatry continue to be determined as much by dogma as by evidence. For many interventions there is a lack of objective evidence to support clinical decisions, but in other areas there are increasingly robust clinical trial data to guide rational prescribing. Treatment decisions can only be made on the basis of rigorous assessment and

diagnostic evaluation, and child psychiatry is no different from any other part of medicine in this respect. However, emotions continue to run high in the debate 'for' and 'against' drug treatments in child psychiatry, with ideologies determining treatment in some cases. Worrying findings continue to emerge, e.g. the dramatic increase in the rates of prescribing of psychotropic medication in preschool-age children in the USA (Zito *et al.* 2000), despite there being little evidence for safety or efficacy. Perhaps as the stigma associated with mental illness declines, we will move towards more rational prescribing for children with psychiatric disorders. Routes into mental disorder can be developmental, genetic or environmental (and most likely a combination of these) but aetiology does not generally determine treatment in psychiatry. Clearly, the final common pathway to behavioural, emotional or cognition dysfunction is through alteration in brain function, and an effective part of treatment may be to use drugs which act on the brain. Psychological as well as pharmacological interventions can produce measurable effects on brain chemistry, and all of these powerful tools which are employed in the treatment of children must be carefully evaluated to ensure we do good, not harm.

Introduction

Delinquency, conduct problems and aggression all refer to anti-social behaviours that reflect a failure of the individual to conform his or her behaviour to the expectations of some authority figure, to societal norms, or to respect the rights of other people. The 'behaviours' can range from mild conflicts with authority figures, to major violation of societal norms, to serious violations of the rights of others (Frick 1998). The term 'delinquency' implies that the acts could result in conviction, although most do not do so. The term 'juvenile' usually applies to the age range, extending from a lower age set by age of criminal responsibility to an upper age when a young person can be dealt with in courts for adult crimes. These ages vary between, and indeed within, countries and are not the same for all offences (Justice 1996; Cavadino & Allen 2000).

This chapter sets out to review the historical context of the justice, welfare, treatment, punishment, issues of definition, size of the problem, assessment, range of interventions and the evidence base for efficacy of treatment and outcomes. Of particular interest is the role of mental health practitioners in assessment and treatment of young delinquents, their role in court proceedings, risk and needs assessment and service delivery and the interplay between offending and mental disorder (Bailey 1996).

Historical context

The need to control a small group of very persistent recalcitrant children is perennial. Specific methods have been available since at least the eighteenth century (Hagell *et al.* 2000). In the eighteenth and nineteenth centuries children were seldom distinguished from adults and were placed with adults in prison. In the England of 1823, boys as young as 9 years were held in solitary confinement for their own protection in ships retired from the Battle of Trafalgar. In the nineteenth century, legislation regarding Children's Rights was tied into the need for labour. There have been periodic reactions against convicting, imprisoning and punishing young people. The pioneers who sought to rescue both young offenders and those children offended against provided the beginnings of youth justice, care and child protection. Both community and secure residential innovations in youth justice have been characterized by a pattern of reforming zeal, followed by gradual disappointment fuelled by the results of research evaluations.

Throughout the twentieth century, concerns about levels of juvenile offending increasingly absorbed the attention of public, politicians, practitioners and researchers (Burt 1925; Glover 1960; Rutter & Giller 1983; Rutter *et al.* 1998). Throughout the Western world (Junger-Tas 1994) there has been a growing widespread perception that juvenile crime is inevitable, a fact of life in an increasingly violent society (Shepherd & Farrington 1993). The necessity to curb the spread of serious juvenile crime has clearly acquired a new urgency. A hundred years ago, the conception of juvenile justice in the USA had as its purpose, through the juvenile court, the creation of a whole new system of law for responding to youthful offending based on the developmental premise that young people were still malleable and could be saved from a life of crime. This philosophy held its ground for 90 years until the USA experienced a high tide of youth violence that began in the late 1980s (Zimring 1998). Grisso (1996) commented that in its wake the 'rehabilitative approach to juvenile justice has all but disappeared in the USA in an avalanche of massive legislative efforts to transform it'. These changes are echoed in the overhaul of the Youth Justice System in England and Wales (Bailey 1999a).

Size and nature of the problem

In describing young offenders, the terms 'frequent', 'persistent', 'serious' and 'chronic' have been used to indicate a perceived extreme end of a continuum of juvenile offending. Identifying and providing successful treatment for 'persistent' young offenders is a practical imperative but there is considerable variation in how 'persistence' in offending has been defined (Wolfgang *et al.* 1987; Hagell & Newburn 1994; Farrington 1995; Graham & Bowling 1995).

A picture of 'persistent' offenders emerges that show them to be broadly similar to other offenders but that they show their characteristics to a much greater degree (Farrington & West 1993). They are more likely to be male and have started offending at a young age (Junger-Tas & Block 1988) but the profile of offences does not differ strikingly from that of other young offenders (Weitekamp *et al.* 1996). The focus on frequency over severity of offending raises the possibility of overemphasizing the dangerousness of persistent juvenile offenders. Of relevance to multiagency treatment responses is the emerging pattern of persistent offenders displaying more educational problems, a lack of social integration, more disruptive family

backgrounds, experience of institutional care (Hagell & Newburn 1994) and a group that are more likely to have more developmental difficulties including hyperactivity (Magnusson *et al.* 1994). The proportion of 'persistent' young offenders is likely to be about 3–6% of males in the general adolescent population and this group have been estimated to account for between one-quarter and one-half of juvenile crime. The increased recognition of the heterogeneity of serious antisocial behaviour is leading to the development of possible key differentiations that should in turn inform the direction and development of treatment programmes for a group of young offenders who commit particular crimes (Rutter & Smith 1995; Rutter *et al.* 1998).

Longitudinal research suggests that at least two main groups can be delineated. The more common group involves 'adolescent limited' antisocial behaviour involving one-quarter or more of the general population (Moffitt 1993). 'Life-course-persistent' antisocial behaviour is different in having both an unusually early age of onset and a tendency to persist into adult life. This occurs in some 6% of the population (Stattin & Magnusson 1991, 1996; Moffitt *et al.* 1996; Kratzer & Hodgins 1997). This incidence is comparable to that for antisocial personality disorder in adult males (Robins & Price 1991).

Reviews have reported a rise in antisocial behaviour over recent decades in both Europe and North America (Smith 1995; Elliott *et al.* 1998; Rutter *et al.* 1998). Most juvenile crime is theft related (Junger-Tas & Block 1988; Wikstrom 1990; Snyder *et al.* 1996). Rutter *et al.* (1998) illustrated this with figures showing a fivefold increase in recorded offences in the UK over the period 1950–90; the great majority of such offences will have been committed by those under 25. Elliott *et al.* (1998) reported a steady rise in crime in those under 18 in the USA, noting a particular rise in violent crime in this age group. Smith (1995) reported similar trends in European countries.

The greater male involvement in crime is a universal finding that applies across cultures over time and is evident on all types of measure. However, over the last 40 years the sex ratio for crime has fallen from about 11:1 to 4:1, with the peak age of offending being 18 for young men and 15 for young women. Rates differ by country and by type. Violent crimes form a small proportion of known offending by young people—about 10%—but most very frequent offenders will have a violent offence on their record. Crimes involving the use of a gun by young people are 15 times higher in the USA than in Europe.

Ethnic minorities are overrepresented in official statistics but do not appear to be more antisocial on self-reports, as noted by both Krisberg *et al.* (1987) in the USA and Graham & Bowling (1995) in the UK. This discrepancy between official statistics and self-report data leads to questions about how law enforcement agencies deal with young people from diverse cultural and ethnic backgrounds (Lockman & Wayland 1994).

Self-report procedures (Huizinga & Elliot 1986; Graham & Bowling 1995) have shown high levels of self-reported offending behaviour, with a strong connection between self-report and

official records when more serious offences are considered (Huizinga & Jacob-Chien 1998; Farrington 2000).

Findings from a second sweep of the Youth Lifestyle Survey (YLS; Home Office 2000; Flood-Page *et al.* 2000) provides a recent snapshot of admissions of offending among 12–30 year olds confirming previous findings. One-quarter of young men and one in 10 young women had offended, but the majority reported only one or two minor offences (criminal damage, buying stolen goods). Nevertheless, 12% of men and 4% of women were persistent offenders, and 2% of the whole sample (10% of offenders) were responsible for nearly half the crimes admitted. One-quarter of the young people aged 12–17 who were persistent offenders had been cautioned or taken to court. Other key findings were a rise over time in male violence by 14–17 year olds. The YLS study showed that poor parental supervision, having delinquent friends and acquaintances, persistent truanting and exclusion from school were all predictive of offending. It also showed the importance of lifestyle factors as a link to higher offending rates for males. Drug use was highly predictive across the full 12–30-year-old age range and heavy drinking was predictive for 18–30 year olds.

Risk assessment and management

The adult literature

Predicting the future risk of violent behaviour has a long and difficult history (Dolan & Doyle 2000). There has been a gradual and helpful shift from dangerousness as a subjective concept to risk as a quantitative concept of factors that predict violence, although not in themselves direct indicators of violence. The combination of factors that makes up risk will fluctuate over time and may be modified and managed. Violence risk assessment and management are key components of clinical practice (Monahan 1992).

Clinicians have traditionally assessed risk on an individual basis, using case formulation ('unaided clinical judgement'). Adult research has focused on the accuracy of risk prediction variables in large heterogeneous populations using relatively static actuarial predictions. The debate about clinical vs. actuarial risk prediction has led to the development of violence prediction instruments that combine the importance of static actuarial variables and clinical/risk management items that clinicians take into account in risk assessment of individuals.

The MacArthur Violence Risk Assessment Study (Monahan & Appelbaum 2000) highlighted the significance of clinical factors in the prediction of violent outcomes among non-forensic psychiatric patients discharged from hospital (Steadman *et al.* 1994, 1998). Domains in the MacArthur Risk Assessment Study were grouped under:

- 1 dispositional factors;
- 2 historical factors;
- 3 contextual factors; and
- 4 clinical factors.

Structured clinical judgements are a composite of empirical knowledge and clinical professional expertise. Webster *et al.* (1997) developed the Historical/Clinical Risk Management 20-item (HCR-20) Scale to assess risk of violence in clinical contexts. This and other similar instruments (Douglas & Cox 1999) emphasize the importance in risk assessment of the following.

- 1 Use of well-defined published schema.
- 2 Good agreement among assessors, obtained through training and experience.
- 3 Prediction for a defined type of violent behaviour over a specified period.
- 4 Violent acts predicted should be detectable and recorded.
- 5 All relevant information should be available and substantiated.
- 6 Actuarial estimates should be adjusted only if there is sufficient justification.

Putting systematic risk assessment into practice, Gardner *et al.* (1996) developed a 'regression tree' (structured sequences of yes/no answers that lead to classification of cases as high or low risk, employing a two-stage screening process). Monahan & Applebaum (2000) also developed an iterative classification tree (ICT). These methods appear to be a useful means for violence risk assessments in large populations with relatively low base rates of violence. In smaller samples of high-risk patients or offenders, more in-depth batteries of relevant tools, such as HCR-20, are required to assess future risk of violent recidivism.

Risk assessment in young people

The literature on specific needs and risk assessment in adolescents who offend and/or have mental health problems is developing. The issue of assessment is closely linked to the issues of both prevention and treatment.

Reviewing both prospective and retrospective research, Boswell (1997) suggested that victimization and family breakdown at an early age are associated with an increased risk of later physical abuse and violence. Stiffman *et al.* (1996), in their US longitudinal study, found that a combination of personal variables (gender, substance misuse) and environmental variables (history of child abuse, stressful and traumatic events, rates of unemployment) predicted almost one-third of the variance in adolescent violent behaviour.

Studies of associations between violent behaviour in adolescents and psychosis are rare (Clare *et al.* 2000). Inamder *et al.* (1982) discussed the impact of adolescent developmental crises and how sociocultural factors may mediate the expression of both violence and psychosis. Developmental aspects of violence, criminality and illness are critical considerations.

General principles in managing risk in adolescents include the following.

- Gathering of information from several sources.
- Acceptance that risk cannot be eliminated or guaranteed, but is dynamic and so must be frequently reviewed.

Table 60.1 Approach to risk assessment in young people (Sheldrick 1999).

<i>Index offence</i>
Seriousness
Nature and quality
Victim characteristics
Intention and motive
Role in offence
Behaviour
Attitude to offence
Victim empathy
Compassion for others
<i>Past offences</i>
Juvenile record
Number of previous arrests
Convictions for violence
Cautions
Self-reported offending
<i>Past behavioural problems</i>
Violence
Self-harm
Fire setting
Cruelty to animals
Cruelty to children

- Who does what part in multidisciplinary and multiagency teams. Decisions should not be made by one person alone.
- Some risks are general and others specific, with particular victims.
- Outcomes must be shared but within the boundaries of 'needs to know' and level of confidentiality expected.

Sheldrick (1999) suggested the approach to risk assessment in young people in Table 60.1. Attention should be paid to predisposing situations, triggers, frequency, severity and trends over time. The assessment of empathy with the victim must take into account the emotional and developmental status of a young person and with an understanding of the protective mechanisms of amnesia and clinical denial following a violent offence (see section on juvenile homicide below). Risk escalates when there is failed multiagency risk assessment and management, which in turn includes failure to respond to reported episodes of violence, poor record-keeping and communication, and taking a cross-sectional rather than long-term view of the young person and their behaviour.

More specific needs and risk assessment tools are being developed for young people. The HCR-20 now has a version for boys aged 12 and under (EARL-20B; Augimeri *et al.* 1998). Work is also underway on an adolescent HCR-20. Hare's adult psychopathy checklist (PCL-R) has been used with adolescent offenders (Gretton *et al.* 1997). The Psychopathy Screening Device has been developed for children, and is rated by parent

and teachers (Frick 1996). A second instrument derived from the PCL-R (PCL:YV) is designed to measure psychopathy amongst adolescents (Forth 1995; Forth *et al.* in press).

Any risk assessment should be accompanied by a comprehensive needs assessment. The Salford Needs Assessment Schedule for Adolescents (Kroll *et al.* 1999) identifies 21 areas of potential need, assesses the significance of each need in young people and how each may be met by services. Areas covered include material, familial, social education and psychiatric problems including aggression and self-harm.

Young people are often referred for the assessment of anger and aggressive acts. Attention needs to be paid to *where* the behaviour takes place (home, school, shops, on public transport, in recreational areas) and whether drugs, alcohol or solvents are involved. *Who* else is involved (mother, father, siblings, friends, strangers, neighbours), together with their *reaction*, should be determined. *Frequency, intensity, duration*, form of expression, effect on relationships, effect on school work and the effect on health should all be brought into the risk equation. Once assessment has been made, the practitioner needs to state the risk as specifically as possible and each risk should be stated separately. Risk should only be predicted for the immediate/short-term future. Whatever type of risk assessment is used by the clinician, the multiagency team needs to know the situational factors. Will the behaviour occur in the public/domestic domain, with/without provocation, in the immediate or extended vicinity? Will the victim(s) be perceived by the young person as vulnerable? Will the young person hold hostile attributions to the victim? Will the victim elicit certain meanings for the young person (e.g. authority abuser, bully)? Will the victim be in the immediate or in an extended vicinity? Always list who are potential victims. Finally, does the young person lack an adequate concept of emotion, lack skills (e.g. thinking or non-aggressive coping strategies), abuse substances, engage in other high-risk behaviour and is he or she easily provoked? Risk assessment and management in young delinquents must be informed by those with expertise in developmental understanding of young people. Mental health practitioners have an important role, a role that is likely to increase and which will have particular importance when the young delinquent has 'special needs' and mental health problems.

Interventions

Although current early preventative initiatives, well established in the USA and underway in Europe, have shown promising results with generally disadvantaged children (Olweus 1993; see also Offord & Bennett, Chapter 52), many early intervention programmes with pre-adolescents have been found to be least effective with individuals whose antisocial behaviour is severe and chronic and also for individuals with comorbid conditions (Kazdin 1996, 1997; Le Blanc 1998). This has been confirmed by results from both peer, school and community interventions (Brewer *et al.* 1995).

Andrews *et al.* (1986) put forward the 'risk principle' for those with established antisocial behaviours. Intervention is most effective when the young person being treated has appreciable risk of an adverse outcome. Little & Mount (1999) concluded that the further down the various pathways and psychological problems a child goes, the more predictable his or her behaviour becomes. Results from the Cambridge study of working class boys showed one-third of 8 year olds followed up had been convicted by the time they were 25, but up to 60% of those convicted in adolescence were convicted again in adulthood (Farrington 1995).

In dealing with high-risk individuals, both obtaining their engagement and innovation in intervention is needed. Tolan & Gorman-Smith (1997) concluded that the choice of group to intervene with is a practical trade-off between the likely responsiveness to treatment and the predictability of risk and seriousness of offending. In designing interventions, consideration has to be given to the size of the target population, the choice of risk factors to be tackled and the need for early or late intervention. Multiple interventions at multiple points throughout the life course are required to overcome the problems of those at higher risk, beginning with broad community-based interventions and progressing to highly specific interventions for a small group who require more intensive input.

Multimodal treatments are more like to tackle the multiple causes of severe behavioural problems as well as providing a sufficient 'dosage' to impact on severe and chronic antisocial behaviour (Kazdin 1996). To date, interventions with adolescents show limited results. There is no conclusive evidence regarding the effectiveness of any single intervention. This reflects the inadequacy of evaluations as much as any inherent inadequacy of the intervention itself (McGuire & Priestley 1995). Any intervention has to be theory based, addressing known causal factors, building on a young person's strength as well as tackling antisocial behaviour and antecedent risk factors. Regardless of the treatment setting, the interventions should be carried out in a manner consistent to their original design; treatment integrity affects results. Interventions should address comorbid conditions, such as substance misuse and depression, that aggravate behavioural problems. These features have yet to be incorporated into an evaluation study without methodological flaws. However, multimodal well-structured intensive lengthy programmes that are cognitive-behavioural in orientation are required to provide a sufficient 'dosage' to impact on adolescents with marked levels of antisocial behaviour. Interventions closely tailored to the characteristics of the individual may be more successful than broader population-based strategies. Interventions will need to be lengthy and/or repeated to sustain improved functioning in those at highest risk.

In the long run, multimodal interventions that are well organized, structured and intensive for adolescents at highest risk of offending and adult personality disorder, although initially more costly, may prove more effective (McGuire 1996; Lipsey & Wilson 1998).

Early interventions

There are four types of prevention and early intervention that can reduce juvenile offending (Tonry & Farrington 1995).

- 1 *Criminal justice prevention*: deterrence, incapacitation and rehabilitation strategies operated by law enforcement and criminal justice agencies.
- 2 *Situational prevention*: designed to reduce the opportunities for antisocial behaviour and to increase the risk and difficulty of committing antisocial acts.
- 3 *Community prevention*: interventions designed to change social conditions and social institutions that influence antisocial behaviour in communities.
- 4 *Developmental prevention*: interventions designed to inhibit the development of antisocial behaviour in individuals by targeting risk and protective factors that influence human development.

Successful early interventions for juvenile offending depend on the efficacy of parent training (Bank *et al.* 1991; Webster-Stratton 1994; Smith 1996; Byng-Hall & Putman 1998; see also Offord & Bennett, Chapter 52; and Scott, Chapter 56) and preschool programmes (Schweinhart *et al.* 1993) that enable young people to understand more readily the consequences of their behaviour for self and peers, critically helping them to make safe choices and teach safe autonomy in adolescence. Lipsey (1995) suggested the importance of three strategies:

- 1 primary population-based preventative intervention;
- 2 secondary interventions focused on high-risk groups; and
- 3 programmes centred on tertiary treatment.

'Communities that care' (Joseph Rowntree Foundation 1997) is now established in the UK, modelled on the US programmes (Hawkins & Catalano 1992) and on other UK preventative public health campaigns. A risk-focused prevention programme tailored to the needs of each community targets five main behaviours that are damaging to the lives of adolescents and the communities where they live: youth crime, drug abuse, school-age pregnancy, sexually transmitted disease and school failure.

Treatment qualities

Since the early 1920s, accounts of residential settings for disturbed and delinquent adolescents have focused on theoretical considerations and treatment models but there are core general factors that cut across both theoretical orientations in both residential and community treatment programmes. These are:

- 1 good leadership;
- 2 good discipline, firmness;
- 3 special education;
- 4 work programme;
- 5 recreation programme;
- 6 adolescent-adolescent relations;
- 7 staff-adolescent relations;
- 8 staff-staff relations;
- 9 milieu — warmth and harmony; and
- 10 milieu — organization, practicality, high expectations.

Adolescent-adolescent and staff-adolescent relationships should be fostered, seeking to encourage positive rather than negative features. Staff-staff relationships require attention, communication, working co-operatively, and being work orientated, together with no avoidance of conflicts, rivalries and negative attitudes that could undermine the operation and morale of the programme (Harris *et al.* 1987).

Social skills interventions have focused on microskills, such as eye contact, body posture and tone of voice, and macro skills, such as techniques to walk away from physical confrontation. These have led to changes in institutional performance but with less certainty about a reduction in future offending. More promising are the changes that can be brought about by cognitive-behavioural programmes, in particular multimodal programmes incorporating elements of self-control, self-instruction, anger control, role taking, social problem-solving and programmes derived to increase the young offender's moral reasoning ability, during and after detention in secure facilities (see Brent *et al.*, Chapter 54; Compas *et al.*, Chapter 55).

Overall factors influencing successful outcomes of community or institutional programmes include the following.

- 1 Avoidance of indiscriminate choice of treatment foci.
- 2 The use of more structured and focused treatments.
- 3 The inclusion of a cognitive component that includes tackling the attitudes, values and beliefs that support antisocial behaviour.
- 4 Interventions that are conducted in the community; residential programmes, however, can be effective when structurally linked with community-based interventions (Hollin 1993).

Specific treatment

Cognitive-behavioural therapy

Cognitive-behavioural therapy (CBT) involves strategies with roots in behavioural, social learning and cognitive theories. There is an explicit emphasis on learning, and on personal and situational influences on learning. Personal factors include both biological and developmental features (Kendall 1993). Offending is shaped by the social environment extending across family, peers, neighbourhood and culture. The young offender has failed to acquire or to use certain skills, or has learnt inappropriate ways of behaving. A strength of CBT should be its ability to bridge the gap between behaviour modification and traditional insight-orientated therapies (Hollin 1990; Wilde 1996).

Specific measures, e.g. Adolescent Cognition Scale (Hunter *et al.* 1991) and the Multi-phasic Sex Inventory (Nichols & Molinder 1984), are used to assess beliefs, attitudes and cognitions in adolescent sexual abusers. Establishment of a baseline, with respect to the overall level and fluctuations in frequency and intensity, enables intervention effects to be determined more clearly. Functional analysis (see Herbert, Chapter 53) can be used across a range of situations to assess factors that foster or inhibit anti-

social behaviour in each individual. Combined with regular reviews of programme effectiveness, this creates a needs- and risk-driven therapeutic culture that should shape clinical decision-making (Epps 1997).

The 1990s saw the expansion of CBT from institutional to community settings, following a succession of reviews of the effectiveness of CBT in reducing recidivism in young offenders (Hollin 1993; Lipsey 1995; Losel 1995; Home Office 1997). The dual goals are:

- 1 to increase and strengthen self-control; and
- 2 to develop the capacity of the young offender to understand the perspective of others.

The most commonly employed CBT intervention is that of Anger Management Training (Novaco 1994), designed to reduce angry arousal and to improve coping strategies. Comparisons across programmes are difficult when they have been employed across a wide variety of settings, and when terms such as 'violence', 'aggression' and 'sexual force' are used interchangeably. Core to such programmes (Feindler & Ecton 1986; McGuire 1996) are:

- helping the young person to recognize feelings of anger and its associated physiological and cognitive sequelae;
- challenging beliefs that support triggers for aggression, in order to foster techniques for self-control;
- aiding relaxation;
- increasing motivation to avoid angry aggression; and
- understanding negative consequences of angry aggression for self and others.

It has long been recognized that young offenders are poor at, and inflexible in their approach to, solving interpersonal problems, lacking skills and strategies taken for granted by others (Bandura 1973). Poverty of thought and poor verbal reasoning skills can be present in spite of an average overall IQ. There are five steps for individual practice (D'Zurilla & Godfried 1971).

- 1 Development of a general orientation or set to recognize the problem.
- 2 Definition of the problem specifics and what needs to be done.
- 3 Generalization of alternative courses of action.
- 4 Exploration of the consequences, benefits and risks of the alternative courses of action.
- 5 Checking that chosen alternatives are achieving the desired outcome.

Self-instructional training

Self-instructional training, whereby children regulate their behaviour through overt and then covert speech (what they say to themselves), has been applied successfully to problems such as aggression and impulsivity (Kendall 1993). The ability to delay gratification is impaired in delinquents. Failures in the components for self-control, goal-setting, self-monitoring, self-education and self-reinforcement undermine self-control. Lacking confidence in achieving conventional goals, delinquents choose antisocial goals and are more likely to have

an external locus of control, believing they have little control over events.

Self-management training for delinquents

This focuses on educational, vocational and interpersonal skills. Deficits in perspective taking are prominent among delinquents, and role-play may be a useful treatment technique. Teaching offenders to identify the emotional state of others (affect identification), to understand the other person's point of view (perspective taking), and to experience within themselves the emotions felt by others (emotional responsiveness). Empathy skill training is particularly important in treatment with delinquents at high risk of adult antisocial personality disorder (McGuire 1996; Feshbach & Feshbach 1982).

Aggression replacement therapy

This has been used with violent young offenders in institutional secure facilities and community settings (Goldstein & Soriano 1994). This approach brings together social skills training, self-instructional and anger control training and moral reasoning enhancement (Goldstein & Glick 1987) and may be useful for a wide range of problems (McGuire 1996).

Multimodal interventions

These combine a range of behavioural and cognitive components.

Reasoning and rehabilitation programmes

The programme used in the Correctional Services of Canada (Ross & Ross 1995) has also been employed in the UK, including the Thinking Skills programme in Young Offender Institutions and the Straight Thinking Probation (STOP) programme (Knott 1995).

Whereas these interventions reduce the risk of re-offending among 'ordinary' young offenders, current programmes do not provide an adequate means to address the needs of or risks presented by young people exhibiting serious antisocial behaviour or who have complex mental health problems.

- Outcomes are related to crime more than to antisocial behaviour *per se*.
- Both prevention and intervention programmes are geared to the common antisocial features rather than to serious antisocial behaviour (see Earls & Mezzacappa, Chapter 26).
- Programmes are largely directed towards males.
- Programmes use techniques that are primarily risk focused rather than taking a holistic approach, addressing quality of life and current mental health needs.
- The overall approaches do not always encompass individual development and psychopathology.
- There remains a need for specialist treatment and care for the group exhibiting serious antisocial behaviour.

Multisystemic therapy

Multisystemic therapy (MST) was developed in the USA by Henggeler *et al.* (1998) and Henggeler (1999) and offers intensive and comprehensive input designed to overcome the limitations of traditional interventions for young people with behavioural and mental health problems. At the core of MST is directing the intervention not just at the young person but towards the social contexts in which he or she lives. The range of treatment approaches are therefore directed at the young person, family, school peer group and local community. Problem behaviour is viewed as a function of difficulty within and at the interface between each of these systems. MST involves nine key principles. Interventions should:

- 1 provide an assessment designed to understand the fit between the identified problems and their broader systemic context;
- 2 emphasize the positive and use systemic strengths as levers of change;
- 3 be designed to promote responsible behaviour and to decrease irresponsible behaviour among family members;
- 4 be present-focused and action-orientated, targeting specific and well-defined problems;
- 5 target sequences of behaviour within or between multiple systems that maintain identified problems;
- 6 be appropriate to the developmental needs of the young people;
- 7 be designed to require daily or weekly effort by family;
- 8 include continuous evaluation of effectiveness from multiple perspectives, with providers assuming accountability for overcoming barriers to successful outcomes; and
- 9 be designed to promote treatment generalization and long-term maintenance of therapeutic change by empowering caregivers to address the needs of family members across multiple systemic contexts, with specific implementation guidelines.

Service delivery characteristics include:

- low case loads (five families per clinician);
- delivery of service in community settings;
- time limited treatment (4–6 months);
- 24 h a day access to therapists to enable crisis intervention;
- provision of comprehensive services.

Strict adherence to the MST principles and guidelines demonstrate positive long-term outcomes; poor adherence predicts high risk of re-arrest and incarceration (Henggeler *et al.* 1997).

Efficacy of interventions

Given the range of treatments and interventions available, is offender treatment of practical significance? McGuire (2000) set this important question in the context of other ‘medical’ treatments. The key point is that many well-established medical interventions (such as the use of aspirin to prevent heart attacks or chemotherapy for breast cancer) have smaller effects than those for delinquency. Between 1985 and 2000, 18 meta-analytic reviews were published. Cumulatively they incorporate

more than 2000 ‘primary studies’. The majority deal with offenders in the age range 12–20 and, although modest, the ‘mean effect size’ is positive in the 0.10–0.29 range.

Custodial approaches

Official reconviction rates show that custody is relatively ineffectual in reducing offending. Home Office figures in England and Wales 1997 (Home Office 1999) showed that 88% of 14–16-year-old males, and 82% of 17 year olds, were reconvicted within 2 years of release from prison; Kershaw *et al.*’s (1999) findings were similar. Reconviction rates are highest for younger male offenders and for crimes most commonly linked with youth (theft and burglary).

During the 1990s several meta-analyses showed that correctional treatments could be effective if they supported clinically relevant and psychologically informed principles of human service, risk, need and general responsivity. These apply to female as well as male offenders and are effective in reducing both general and violent recidivism (Dowden & Andrews 1999). Their meta-analysis of 134 primary studies of correctional treatment largely concerned male offenders. The overall mean effect size for the studies was 0.09 with a 95% confidence interval of 0.07–0.12 suggesting that the effects of correctional interventions were positive but small. The introduction of human service within a justice context was associated with substantial reductions in the re-offending levels of young offenders (effect size of 0.13 for 175 studies). Programmes that used a ‘fear of official punishment’ yielded a significant negative relationship (effect size of –0.2 for 54 studies).

The way in which an institution is run affects outcomes for young people. Rutter *et al.* (1998) found that whereas the deterrent and incapacitation effects of incarceration were negligible, beneficial effects derived from:

- education and training that could open up new opportunities on release from custody;
- help with drug abuse/misuse, with no access to drugs during custody;
- the maintenance of a prosocial ethos with good relationships and models for behaviour;
- enhancement of self-efficacy; and
- encouragement of strong regular links with families.

Family participation in the residential experience (Sinclair & Gibbs 1998) and co-operation with community agencies are important factors in successful outcomes.

Delinquency and mental illness

Prevalence of mental disorders in juvenile justice populations

Cocozza (1992) noted the very limited evidence on the prevalence of mental disorders among delinquents in either community or residential settings. In a recent review, Kazdin (2000) noted

that most studies did not use standard diagnostic interviews, samples were small and usually restricted to just one location. Although some data derived from epidemiological studies using diagnostic interviews, comparisons were difficult because of variations in criteria, informants used, ages and ethnicity of subjects and geographical location.

Kazdin (2000), putting together evidence from a range of studies, concluded that mental disorders of all kinds were several times as frequent in delinquents than in the general population. Some one in five children and adolescents in the general population suffer significant developmental, emotional or behavioural problems. The proportion of ‘incarcerated adolescents’ with some form of psychiatric disorder in North American studies has been found to be much higher—about four out of five. A comprehensive study of over 1200 delinquents (aged 10–17) in juvenile detention centres, using the Diagnostic Interview Schedule for Children, found that some 80% had at least one mental disorder (Teplin *et al.* 1998). Systematic standardized mental health screening for young offenders is still not readily available (Kurtz *et al.* 1998). Nevertheless, studies of juveniles presenting to juvenile courts in North America and Europe have all shown high levels of psychiatric disorder, family psychopathology and inadequate resources to deal with these problems (Doob *et al.* 1995; Dolan *et al.* 1999; Doreleijers *et al.* 2000; Vermeiren *et al.* 2000). Nicol *et al.* (2000) found marked similarity in the level of need in adolescents whether in penal or welfare establishments. Studies of incarcerated adolescents in England and Wales (Maden *et al.* 1995; Lader *et al.* 2000) have all demonstrated high rates of psychiatric disorder, particularly in those facing the stress of incarceration while awaiting trial. Studies have highlighted the particular needs of adolescents from diverse ethnic groups (Lockman & Wayland 1994) and of the difficulties faced and posed by adolescent female offenders (Jasper *et al.* 1998; Lenssen *et al.* 2000). Caution needs to be exercised in interpreting these various figures because rates of disorder will be influenced by numerous aspects of delinquents’ backgrounds and by definitions of disorder. Thus, for example, the figures on drug abuse will be affected by how abuse is conceptualized and by the range of substances included (Weinberg *et al.* 1998). What is clear, however, is that the overall rate of psychopathology in delinquents is substantially raised. Its clinical implications will depend, amongst other things, on the extent and type of comorbidity (Kazdin 1996; Rutter 1997; Ulzen & Hamilton 1998), the degree of chronicity, and developmental impact.

Relevance of specific disorders to juvenile offending

Hyperactivity and attention disorders predispose to both antisocial behaviour in childhood/adolescence and antisocial personality disorder in adult life (Barkley 1990, 1997). It seems that disinhibition, poor impulse control and educational difficulties are all implicated in this risk. Some youths respond by seeking acceptance and feelings of mastery by joining delinquent groups. Affective disorders play some part in youth violence

(Pliszka *et al.* 2000). Depression in adolescence can manifest itself as anger, which in turn is correlated with aggression. Anxiety and post-traumatic stress disorders show raised rates in delinquent populations (Boswell 1995, 1997). Part of the pattern of stress reactions includes a heightened sensitivity to potential threat, which can in turn involve the risk of a young person acting explosively or unexpectedly. Psychotic disorders occur only infrequently (Clare *et al.* 2000; Kazdin 2000). Pre-psychotic problems in the form of borderline and schizoid personality disorders may be important because their difficulties with interpersonal relationship have a role in their delinquencies. Neurodevelopmental dysfunction may be relevant, through leading to impairments in the youths’ ability to adapt to stress, to recognize the consequences of their actions, and to exercise impulse control. Serious mental disorders may have similar effects.

Although there has been progress in other aspects of youth justice, there are continuing difficulties in recognizing and providing treatment for mental health problems. Juvenile justice facilities are not clinical facilities. There has been a noticeable lack of standardized screening tools for young offenders that can assist non-clinical staff to collect information speedily to inform decision-making with respect to referral to mental health professionals. The Massachusetts Youth Screening Instrument (MAYSI2) was developed for routine use in juvenile justice facilities (Grisso 1999). It focuses on symptoms covering a range of mental disorders. The identification of youths with potential health needs may lead on to the use of more in-depth evaluation, such as the Minnesota Multiphasic Personality Inventory Adolescent (Butcher *et al.* 1994), the Millon Adolescent Clinical Inventory (Millon 1993) and the continuing refinements of the Child Behaviour Checklist (Achenbach 1991). Needs assessment tools, such as the Salford Needs Assessment Schedule for Adolescents (SNASA) (Kroll *et al.* 1999), can assist multiagency planning and service delivery as a young offender with greater or lesser degrees of mental health problems moves within and between systems.

Treatment interventions for young offenders with psychiatric disorders

Affective disorders

Depression is commonly present in delinquents. Clinic attenders with conduct disorder have rates of depression of between 15 and 31% (Goodyer *et al.* 1997; Kovacs & Devlin 1998). As antisocial youths are generally viewed as difficult and disruptive, the risk is that depression will go unrecognized by non-mental health agencies. Where depression and conduct disorder co-exist, the risk of substance (especially alcohol) misuse is high in female offenders. Young offenders with comorbidity for depression and conduct disorder are particularly vulnerable to suicide attempts (Shaffer *et al.* 1996).

Treatment of depression, as in any young person, will depend

on its severity, the person's psychosocial circumstances and the capacity and ability of the system to engage him or her. Use of interpersonal therapy (IPT) may be of benefit as an acute intervention. In addition to CBT approaches geared to reduce offending behaviour, CBT can be used to challenge and restructure the distorted negative cognitions that depressed adolescent offenders hold about themselves. Where young offenders have severe depression with persistent symptoms, medication may be indicated. When depression is severe, a combination of pharmacological and psychological interventions is called for, with continuation for 6–12 months (Harrington *et al.* 1998; see also Harrington, Chapter 29). Mental health screening in the young offender population may also be important to ensure the early detection of subthreshold cases of mania where there can be chronic and rapidly fluctuating symptoms of irritability, emotional lability, increased energy and reckless behaviours (American Academy of Child and Adolescent Psychiatry Official Action 1997).

Early onset psychosis

A prodromal phase of non-psychotic behavioural disturbance occurs in about half of early onset cases of schizophrenia, and can last between 1 and 7 years (Maziade *et al.* 1996). It includes externalizing behaviours, attention deficit disorder and conduct disorder. Mental health screening should include a focus on changes in social functioning (often from an already chaotic baseline level) to a state including perceptual distortion, ideas of reference, and delusional mood. As in adult life (Taylor & Gunn 1999), most young people with schizophrenia are non-delinquent and non-violent. Nevertheless, there may be an increased risk of violence to others when they have active symptoms, especially when there is abuse of drugs or alcohol. The risk of violent acts is related to subjective feelings of tension, ideas of violence, delusional symptoms that incorporate named persons known to the individual, persecutory delusions, fear of imminent attack, feelings of sustained anger and fear, passivity experiences reducing their sense of self-control and command hallucinations. Protective factors are responding to and compliance with physical and psychosocial treatments, good social networks, a valued home environment, no interest in or knowledge of weapons as the means of violence, good insight into the psychiatric illness and any previous violent aggressive behaviour and a fear of their own potential for violence. These features require particular attention but the best predictors of future offending in mentally disordered young people are much the same as in the general population (Clare *et al.* 2000).

Autistic spectrum disorders

These are being increasingly recognized but are often overlooked in forensic groups (see Lord & Bailey, Chapter 38). Their identification is critical to the understanding of offending, especially in adolescents with a learning disability. This is par-

ticularly so when an offence or assault is 'bizarre' in nature, the degree or nature of aggression is unaccountable and when there is a stereotypic pattern of offending. Howlin (1997) proposed that offending and aggression in autistic persons can arise by four means.

- 1 Their social *naïveté* may allow them to be led into criminal acts by others.
- 2 Aggression may arise from a disruption of routines.
- 3 Antisocial behaviour may stem from a lack of understanding or misinterpretation of social cues.
- 4 Crimes may reflect obsessions, especially when these involve morbid fascination with violence. There are similarities with the intense and obsessional nature of fantasies described in some adult sadists (MacCulloch *et al.* 1983).

Learning disability

Surprisingly little is known about criminal behaviour in individuals with a learning disability (Lyll *et al.* 1995; Holland 1997). The clinical issues that arise concern the additional care needed in interviewing and at assessment, as much as the possible special implications with respect to antisocial risk that arise from their cognitive level or profile. Associated psychopathology, life experiences and personal background should constitute part of the assessment. Treatment programmes often need to be carried out over a long time period, balancing inherent vulnerability with continued level of risk to others (O'Brien 1996).

'Prodromal' personality disorder

Models used to describe severe personality disorder in adults (Royal College of Psychiatrists 1999) may also be applied to young people (see J. Hill, Chapter 43). Hare (1993) differentiated between 'psychopathic personality', characterized by an unemotional and callous interpersonal style, and 'antisocial personality disorder' in which the key elements are poor impulse control and antisocial behaviour. O'Brien & Frick (1996) argued that these two groups have a different aetiology. Christian *et al.* (1997) described a group of children with a callous unemotional interpersonal style, who lacked guilt and who did not show empathy or emotions. The pathway to their serious antisocial behaviour (Zoccolillo *et al.* 1992) and interpersonal violence was thought to lie in family features, evolving personality and situational context. A parallel may be drawn with reactive attachment disorder (Fahlberg 1994; Delaney 1995; but see O'Connor, Chapter 46 for a discussion of the lack of precision in this diagnostic concept). Individual psychotherapy may be needed alongside traditional multimodal interventions, and long-term support to multiagency services may constitute a key role for emerging specialist forensic psychotherapy services (Bailey 2000d). Bailey (1997) and Bailey *et al.* (2001) have summarized the features involved in the pathways to serious antisocial behaviour under three headings: family features, personality features and situational features.

Family features

Parental antisocial personality disorder.
Violence witnessed.
Abuse, neglect, rejection.

Personality features

Callous unemotional interpersonal style.
Evolution of violent and sadistic fantasy.
People viewed as objects.
Morbid identity.
Paranoid ideation.
Hostile attribution.

Situational features

Repeated loss and rejection in relationships.
Threats to self-harm.
Crescendo of hopelessness and helplessness.
Social disinhibition in group settings.
Substance misuse.
Changes in mental state over time.

Medicolegal assessment

There are common core principles that should be applied to medicolegal assessments of juveniles. Key questions concern the young person's 'fitness to plead' and capacity to 'effectively participate in the proceedings' (Grisso & Schwartz 2000). The European Court of Human Rights has made explicit that the right of an accused to a fair trial has to include children. Two key suggestions for practice emerge from a review of international practice.

1 All young defendants, including those charged with serious offences, should be tried in youth courts (with permission for adult sanctions for older youths if certain conditions are met). This should enable a mode of trial for young defendants to be subject to safeguards that can enhance understanding and participation.

2 The maturity of young defendants' cognitive and emotional capacities should be assessed before a decision is taken about venue and mode of trial.

One fundamental distinction in the criminal law is between conditions that negate criminal liability and those that might mitigate the punishment deserved under particular circumstances. Very young children and the profoundly mentally ill may lack the minimum capacity necessary to justify punishment. Those exhibiting less profound impairments of the same kind may qualify for a lesser level of deserved punishment even though they meet the minimum conditions for some punishment. Immaturity, like mental disorder, can serve both as an excuse and as mitigation in the determination of just punishment. Capacity is sometimes thought of as a generic skill that a person

either has or lacks; however, that is not so. To begin with, it is multifaceted, with four key elements.

1 *Understanding*: the capacity to understand information relevant to the specific decision at issue.

2 *Appreciation*: the capacity to appreciate one's situation as the defendant is confronted with a specific legal decision.

3 *Reasoning*: the capacity to think rationally about alternative courses of action.

4 *Choice*: the capacity to express a choice among alternatives.

The second key point is that capacity is a feature that is both situation-specific and open to influence—as brought out in discussions of the assessment in relation to children's consent to treatment (British Medical Association 2001), participation in research (Royal College of Psychiatrists 2001) and criminal responsibility (Justice 1996). Young children may well appreciate the difference between right and wrong but yet not understand the seriousness of some forms of irresponsible behaviour. With respect to their ability to understand legal procedures (as distinct from their crime), much can be done to aid their understanding (Ashford & Chard 2000).

Any evaluation of competence (Grisso 1997) should include assessment of possibly relevant psychopathology, emotional understanding as well as cognitive level, the child's experiences and appreciation of situations comparable to the one relevant to the crime and to the trial, and any particular features that may be pertinent in this individual and this set of circumstances. The clinician should also be alert to possible treatment needs, and should be aware of how these might be met for this individual, given the forensic situation. Before the evaluation it is important to be sure that the rules and limits of confidentiality for the evaluation are clear and that the child and the family understand them (Bailey 2000a). The appropriate level of clinical thoroughness and detail will vary with the intrinsic clinical complexity of the case, with the specific legal context and with the consultant's role in the legal system. The general principles to be used in the assessment are broadly comparable to those employed in any clinical evaluation (see Rutter & Taylor, Chapter 2). However, particular attention needs to be paid to developmental background, emotional and cognitive maturity, trauma exposure and substance misuse. The likely appropriate sources for obtaining clinical data relevant to assessment of a juvenile's competence to stand trial will include a variety of historical records, a range of interviews and other observations and, in some cases, specialized tests.

Records of the child's school functioning, past clinical assessment, treatment history and previous legal involvements need to be obtained. In coming to an overall formulation, there should be a particular focus on how both developmental and psychopathological features may be relevant to the forensic issues that have to be addressed.

Evaluation of functional capacities

Here the main focus is on the youth's ability to understand and cope with the legal process. This comes from three sources:

direct questioning of the defendant, inferences from functioning in other areas and direct observation of the defendant's behaviour and interaction with others. It is useful to enquire about the youth's expectations about what the consequences of the court involvement might prove to be. Because the course of juvenile proceedings can vary so widely, with consequences ranging from the extremely aversive to extremely beneficial, rational understanding will necessarily involve a high degree of uncertainty.

Potentially relevant problems include: inattention, depression, disorganization of thought processes that interferes with the ability to consider alternatives; hopelessness, such that the decision is felt not to matter; delusions or other fixed beliefs that distort the understanding of options (or their likely outcomes); maturity of judgement; and the developmental challenges of adolescence.

Gudjonsson (1992) and Gudjonsson & Singh (1984) found that adolescents were more prone than adults to offer inaccurate information to persons in authority when they were pressured. Younger adolescents were significantly more likely to change their stories to give answers that were less accurate than their original descriptions. This has practical implications for interviewing by police and lawyers. The ability to take another person's perspective is important for effective communication, an ability that has matured by middle adolescence but is less reliably found in early adolescence.

Concerns about a youth's conduct may sometimes be raised as potentially significant to his or her competence (Barnum 2000). A youth may be impulsive, loud, angry or disruptive during trial and it may be suggested that these tendencies may undermine the formality or integrity of the proceedings. In addressing this question, it is important to be clear about the general clinical basis for any expected functional problems and even more important to be clear about specific implications of potential disruptiveness for the relevant features of competence. If a youth's impulsiveness may be expected to interfere with his or her attention to the proceedings in the courtroom and if this attention to those proceedings actually matters to his or her understanding and effective collaboration with counsel then it will be important to characterize these expectations or implications. For instance if the youth is so angry and disruptive that he or she seems unable to sit and confer with counsel this may have important implications for his or her ability to understand the issues and respond helpfully to them. The clinician therefore needs to attend to these issues and show how they stem or do not stem from clinical disorder or developmental deficit.

In providing information to the court, written reports have the advantage of a standard format that helps the consultant to be sure that he or she has considered all the relevant questions; it also provides a familiar structure for readers. In essence, for the sake of consistency and clarity, competence reports need to cover the following areas.

- 1 Identifying information and referral questions.
- 2 The description of the structure of the evaluation including sources and a notation of the confidentiality expectations.

3 The provision of clinical and forensic data.

4 Discussion and presentations of opinions.

The assessment of competence to stand trial presents challenging questions. Consultants need to appreciate the systems implications of competence questions and must be able to provide opinions and recommendations that match the legal and systems circumstances of individual cases. This area is full of uncertainty and the complexity of these challenges can sometimes seem overwhelming. However, in responding carefully and thoughtfully to questions posed, consultants can contribute to the development of a potentially important aspect of legal and clinical practice (Zimring 2000).

Treatment and special crimes

Violence and juvenile homicide

Violent behaviour often involves a loss of sense of personal identity and of personal value. A young person may engage in actions without concern for future consequences or past commitments. Loeber & Hay (1994) described four groups of young people:

- 1 those who desist from aggression;
- 2 those whose aggression is stable and continues at the same level;
- 3 those who escalate in the severity of their aggression and make the transition into violence; and
- 4 those who show a stable pattern of aggression.

Violence denotes the 'forceful infliction of physical injury' (Blackburn 1993). Aggression involves harmful, threatening or antagonistic behaviour (Berkowitz 1993). Longitudinal studies are invaluable in mapping out the range of factors and processes that contribute to the development of aggressive behaviour and in showing how they are causally related (Farrington 1995). However, in attempting to work with any individual who has committed a violent act, the question to be answered is 'Why has this individual behaved in this unique fashion on this occasion?' (Lipsey 1995).

Studies show that children and adolescents who murder share a constellation of psychological, cognitive, neuropsychiatric, educational and family system disturbance (Cornell *et al.* 1987; Myers *et al.* 1995; Myers & Scott 1998). In the UK, young people who commit grave sadistic crimes including juvenile homicide are liable to periods of lengthy incarceration. Detention itself can provide time for further neurodevelopmental, cognitive and emotional growth. Irrespective of treatment models, the provisions of education, vocational training, consistent role models and continued family contact are of critical importance.

The majority of young persons who have killed initially dissociate themselves from the reality of their act, but gradually experience a progression of reactions and feelings akin to a grief reaction. The young person, while facing a still adversarial and public pretrial and trial process, has to move safely through the

process of disbelief, denial, loss, grief and anger/blame. Post-traumatic stress disorder arising from the participation in the sadistic act (either directly or observing the actions of codefendants) has to be treated, as does trauma arising from their own past personal emotional, physical and/or sexual abuse.

A combination of verbal and non-verbal therapies are effective, but qualities such as previous frequent and severe aggression, low intelligence and a poor capacity for insight weigh against a safe outcome (Myers *et al.* 1995; Bailey 1996; Myers & Scott 1998). In understanding the role of violence and sadism in a young person's life, one has to understand the depth of their sensitivity and reaction to perceived threat and their past maladaptive behaviours aimed at allowing them to feel in control of their lives. In coming to terms with their internal rage, addressing victim empathy saying sorry and reattribution of blame, expression of anger and distress within sessions is expected and is often sexualized in both form and content. This can spill outside sessions when the young person and carers can become collusively dismissive and rejecting of therapists. Heide (1999) and Bailey (2000c) emphasized the importance of intensive work to prepare the young person for transition from long-term incarceration and re-entry into the community together with extended aftercare.

Delinquents who sexually offend

Sexually inappropriate behaviour in children and adolescents constitutes a substantial health and social problem (James & Neil 1996). Most, but not all, abusers are male, often come from disadvantaged backgrounds with a history of victimization, sexual and physical abuse (Skuse *et al.* 1998) and show high rates of psychopathology (Dolan *et al.* 1996; Graves *et al.* 1996; Hummel *et al.* 2000; see also Glaser, Chapter 21, and Emery & Laumann Billings, Chapter 20). Of particular concern are a significant subgroup with mild learning disability whose treatment programmes have to be tailored to their level of development and cognitive ability. Young abusers come within the criminal justice system but should also be considered in their own right within the child protection framework. Most adult sexual abusers of children started their abuse when adolescents and yet neither ICD-10 nor DSM-IV has a diagnostic category for paedophilia in those under 16. Vizard *et al.* (1996) suggested the creation of a new disorder 'sexual arousal disorder of childhood' to help identify this vulnerable group who in turn place vulnerable others at risk. Langstrom *et al.* (2000) advocated the development of empirically based typologies for this offender group.

A structured carefully planned multiagency approach is required when working with sexually aggressive younger children and sexually abusive adolescents. The three stages of assessment of juvenile sexual offenders (O'Callaghan & Print 1994; Vizard *et al.* 1996; Becker 1998) are:

- 1 clarification and rapport building;
- 2 mapping the abuse: the fantasies, strategies and behaviours; and
- 3 the future, placement treatment and personal change.

Increasing awareness of the existence of young sexual abusers has been accompanied by a proliferation of treatment programmes (Becker 1990). Treatment can include work with the individual, group work, work with the family and support for the professional network. A review of treatment approaches (Sirls *et al.* 1997) concluded that 'multiple theoretical approaches and treatment modalities have been found useful for intervention but all programmes reviewed contained a cognitive behavioural approach to assessment (Calder 1997). With respect to family treatment, Bentovim & Williams (1998) emphasized the importance of 'assessment of potential to engage in treatment', describing the treatment processes in terms of:

- 1 the crisis of disclosure;
- 2 family assessment;
- 3 therapeutic work in a protective context for the victim; and
- 4 reconstruction and reunification of the family.

The 'family' (Bentovim 1998) in this context may include foster carers or long-term residential carers.

Firesetting/arson

Arson can have a devastating impact on the victim and the wider society. Juvenile arsonists are not a homogeneous group, with a wide range of familial (Fineman 1980), social (Patterson 1982), developmental interpersonal (Vreeland & Levin 1980), clinical and 'legal' needs. Kolko & Kazdin (1992) highlighted the importance of attraction to fire, heightened arousal, impulsivity and limited social competence. As with other forms of serious antisocial behaviours, no single standard treatment approach will be appropriate for all individuals (Repo & Virkunen 1997). In addition to the general assessment of antisocial behaviour, the specific domains to be considered include:

- history of fireplay;
- history of hoax telephone calls;
- social context of firesetting (whether alone or with peers);
- where the fires were set;
- previous threats/targets;
- type of fire, single/multiple seats of firesetting;
- motivation (anger resolution, boredom, rejection, cry for help, thrill-seeking, fire fighting, crime concealment, no motivation, curiosity and peer pressure).

For recidivistic firesetters therapy may include:

- psychotherapy to increase the understanding of the behaviour, including antecedents defining the problem behaviour, and establishing the behavioural reinforcers;
- skills training to promote adaptive coping mechanisms;
- understanding environmental factors to manage or self-trigger solutions;
- counselling to reduce psychological distress;
- behavioural techniques to extinguish the behaviour;
- education to promote understanding of cause and effect; and
- supervision for the staff caring for the adolescent.

Early modelling experiences and early exposure to related phenomena militate against a good outcome.

Approaches to service delivery

Forensic mental health includes the assessment and treatment of those who are mentally disordered and whose behaviour has led or could lead to offending. Defining forensic psychiatry in terms of the assessment and treatment of the mentally abnormal offender delineates an area of concern that could potentially engulf much of mental health. Making available mental health expertise to address the mental health component of social problems should not conflict with tradition and medical practice if the aim is to identify and relieve disorder primarily to benefit patients but also, through their more adequate care and management, to benefit those they potentially threaten. Public health policy has long recognized the government's obligation to attend to the basic health needs of prisoners and the importance of meeting the health and mental health needs of children. Traditionally, child and adolescent mental health practitioners have continued to work as generalists. Within their specialism they may include forensic work, not only child care proceedings, but also direct forensic medicolegal work where the young children are the alleged perpetrators rather than the victims.

Child psychiatrists need to be closely involved with developing specialist community and inpatient resources, including secure facilities for children and adolescents who may be:

- mentally disordered offenders;
- sex offenders and abusers;
- severely suicidal and self-harming adolescents;
- very severely mentally ill adolescents;
- adolescents who need to begin psychiatric rehabilitation in secure circumstances; and
- brain injured adolescents and those with severe organic disorders.

Weaving together local generic and more regional specialist services allows for multidimensional concepts of problems encountered by these young people to be tackled by the local mental health services in conjunction with other agencies (Bailey 2000b). Local specialist child and adolescent mental health services can be augmented by advice and training offered by an identified peripatetic outreach team that is based in, and works from, specialized centres of expertise in forensic child and mental health. The primary responsibility would remain with the staff of local services and the role of the outreach services would be supportive and consultative. Very specialized peripatetic services would be outreach services in which the young people are seen directly by members of an outreach service.

There has to be a seamless delivery of service between general child and adolescent services and specialist forensic provision, with solutions tailored to local need. Services delivered directly to patients and their families by centres of specialist expertise in forensic child and adolescent mental health would include specialist community assessment and treatment services providing input not only to other child and mental health services but working with secure social care units, young offender institutions/correctional institutions and juvenile justice services in the community.

A range of inpatient provision is required including medium-secure inpatient psychiatric units for adolescents with early onset psychosis and serious risk to others. There may well be a small need for an adolescent forensic inpatient unit offering maximum security (Bailey & Farnworth 1998).

For services to develop successfully there needs to be:

- staff wanting to and suited to working in this field;
- systems in place to offer comprehensive appropriate training programmes;
- such programmes and interventions have to be evidence-based; and
- adolescent forensic mental health research and development networks nationally and internationally should be established to ensure that what is learnt from research is put promptly into practice.

Farrant (2001) (Prison Reform Trust), representing the view of agencies outside health, stressed the importance of an approach to young offenders that is not dependent on adult mental health services, together with an emphasis on delivering mental health training to non-mental health professionals. The latter will improve the ability of non-health professionals to identify early indicators of mental health vulnerability in high-risk young people. Interagency training is the best way of ensuring a balance is struck between overloading child and adolescent mental health services with inappropriate referrals and vulnerable young people being missed in the system who then present with severe mental health problems in crisis and late in their offending career.

Gender-specific issues

Any national strategic framework offering treatment for young offenders must consider appropriate provision for the special needs of young females who constitute an important minority of offenders (Zoccolillo 1993; Miller *et al.* 1995; Bailey 2000e). The thinking patterns of violent girls are similar to those of violent boys (Jasper *et al.* 1998; Lenssen *et al.* 2000). Specific consideration should be given to sexual and reproductive health, including education, contraceptive advice, information about help for sexually transmitted diseases, appropriate support for problems around menstruation, support and access to relevant resources in the event of a pregnancy. When the adolescent female is ready to engage in it, post-abuse counselling from an appropriate adult should take into account the gender of the therapist. Medical and psychiatric assessment followed by appropriate treatment of parasuicidal behaviour, remembering the distraction and attention provided by the emergency may be an important component in reinforcing the use of this behaviour as a coping strategy. Different leisure pursuits in girls, and a recognition that eating problems are far more common in girls (see Steinhausen, Chapter 34) may be relevant.

Substance misuse

Drug abuse among young people has increased rapidly over the

past 10 years (Weinberg *et al.* 1998). The interaction between offending or high-risk antisocial behaviour and substance abuse is complex and has bidirectional influence, with possible connections among substance use, including alcohol abuse, executive cognitive functioning, aggressivity and impulsivity (Giancola *et al.* 1997; Myers & Scott 1998). Intensive forms of intervention for drug users with complex care needs may require specialist residential (as well as community) services and the involvement of mental health teams, following the principles such as those applied in MST.

Key principles

Because young offenders vary greatly, flexibility in service response is essential. Nevertheless, a strategic, comprehensive and integrated interagency approach to their mental well-being is needed (Kurtz *et al.* 1998). Service delivery has to recognize the high geographical mobility of delinquents, their poor planning, and the changing and diverse nature of their needs.

Youth justice services and mental health services, even in the era of 'joined-up working', have to face the fact that each may not have the same shared purpose. Youth justice services has at its heart the reduction of offending, whereas mental health services focus on fostering the mental health of young people. Bridging that gap may pose real challenges.

This can only be achieved with a shared common language when working with a client group whose needs do not conform to usual academic or administrative boundaries. They fuse together and often coalesce to produce new needs, which in turn impact on risk. Disagreement remains among practitioners and policymakers about definitions used in the development of a common language. Evidence-based research has to place 'evidence' in the wider context of legal, moral, pragmatic and consumer concerns when dealing with young offenders (Dartington Social Research Unit 1998; Little & Mount 1999).

A better understanding of the process of moral development through childhood and adolescence will inform interventions with young offenders. Risk and offence reduction is most likely to be achieved through a comprehensive needs assessment (Kroll *et al.* 1999) linked into an integrated standardized review of prosocial and antisocial behaviour that includes the internal attributional thinking of the young person.

Multiagency research in this field will best inform treatment interventions by integrating qualitative and quantitative methods in the study of developmental psychopathology (Sullivan 1998). Developmental understanding has to underpin treatment programmes for young offenders.

Young offenders have a right to a full range of mental health services. The right of 'children' to be involved in decisions about their own treatment for either physical or mental illness is set within complex child care, mental health, criminal and European human rights legislation. Governments will continue to demand cost-effective youth justice services.

Prevention and early intervention programmes to reduce rates of offending in young people may take a minimum of 10

years to demonstrate direct results. Denying mental health and social services benefits to children and adolescents today to save money will only ensure that the future prison population will grow (Bailey 1999b).

Conclusions

The major challenge of altering the trajectories of persistent young offenders has to be met in the context of satisfying public demands for retribution, together with welfare and civil liberties considerations.

Treatment of delinquents in institutional settings has to meet the sometimes contradictory need to control young people, to remove their liberty and to maintain good order in the institution, at the same time as offering education and training to foster future prosocial participation in society and meeting their welfare needs. At least in England and Wales, the recent legislative overhaul of youth justice (Crime & Disorder Act 1998) has mandated practitioners to bridge the gap between residential and community treatments and to involve families using youth offending teams (YOTs) to meet this complex mix of needs.

Over the last 30 years there has been a gradual shift in opinion regarding effectiveness of intervention with delinquents, from the 'nothing works' approach to a 'what works' approach. The jury is still out for 'what works' in the long term but the evidence base that can be placed before the jury is growing. In practice, the pressure from politicians and public will remain, for a quick fix solution to problems that span cultures, countries and generations. The most important childhood predictors of adolescent violence include troublesome and antisocial behaviour, daring and hyperactivity, low IQ and attainment, antisocial parents, poor child-rearing, harsh and erratic discipline, poor supervision, parental conflict, broken families, low family income and large family size (Farrington 1999). Important policy implications are that home visiting programmes, parent training and skills training programmes singly and in combination should be implemented at an early stage to prevent adolescent high-risk behaviour and offending. The best knowledge about risk factors has been obtained in longitudinal studies and the best knowledge of effective programmes has been obtained in randomized experiments.

The apparent adversity of the current response to young delinquents should be seen as an opportunity to take advantage by combining experimental methods with preventive experiments in longitudinal studies. Provision of appropriately designed programmes can significantly reduce recidivism amongst persistent offenders. The mode and style of delivery is important; high-quality staff and staff training are required together with a system for 'monitoring integrity'. Where comparisons are possible, effect sizes are higher for community-based than institution-based programmes. In prison settings, the strongest effects are obtained when programmes are integrated into the institutional regimes.

Our knowledge of true prevalence rates of mental disorders in

a young offending population has to be developed further (Kazdin 2000) so that mental health issues can be addressed. Child and adolescent mental health practitioners have the skills to set the understanding of delinquency in a developmental context (Moran & Hagell 2000) and to assess and treat those young offenders with mental disorders.

Provision of Intensive Treatment: Inpatient Units, Day Units and Intensive Outreach

Jonathan Green

Introduction

The last decade has seen a rapid evolution in the structure and delivery of mental health services in many countries. The use of inpatient beds has declined in many systems and there is an increasing interest in evaluating other models of service delivery, such as day provision or intensive outreach, as well as modified models of inpatient care. In parallel, the context within which children's mental health disorders are seen has progressively widened to encompass the context of the family, school and wider community. A stage emphasis in personality and social development, which provided a rationale for intensive episodic interventions, has been complemented with a new appreciation of chronicity and long-term pathways in the evolution of many disorders. Acute episodes of intensive treatment have therefore to be considered now in the current contexts of both family and local environment as well as in the longitudinal context of what is known about the natural history of particular disorders. This chapter reviews new developments in current practice and the evidence base for intensive treatments in the light of these considerations, before suggesting prospects for the future.

Inpatient treatment

Historical roots

Two broad forms of residential mental health care for young people emerged in the early twentieth century. The first was based on the idea that a self-contained social environment could act as a 'therapeutic milieu', effecting personality and behaviour change (Kennard 1983). Examples in the UK were Homer Lane's 'Little Commonwealth' (Bazeley 1928) and residential therapeutic schools, such as the Mulberry Bush and the Cotswold Community; in the USA, the work of Bettelheim (1955). A second historical root was the adaptations made for children within the asylums of the nineteenth century (Parry Jones 1998) and the accelerated development of specialized medically based psychiatric units for children following the encephalitis epidemic in the USA in the 1920s (Beskind 1962). Such hospital units developed to provide a comprehensive approach to assessment and treatment based on a biopsychosocial model (Cameron 1949). Here the hospital environment is the *location* for assessment and treatment rather than its *primary agent*.

The decades after the Second World War saw a rapid expansion of inpatient units, usually combining elements of both models. Recent years have seen a plateauing or reduction in numbers and increasing specialization alongside an awareness of the potential negative effects of residential treatment (Wolkind 1974). However, the two historical themes remain a useful way of conceptualizing inpatient treatment process.

The ward as a therapeutic environment

The 'therapeutic milieu' is a term subject to numerous reinterpretations but little empirical research (Green & Burke 1998). Early psychodynamic formulations (Bettelheim 1955) contained an assumption that the milieu substituted for a lack in the child's previous experience—particularly, sensitive parental type care. This model emphasized a total environment and intense efforts of care staff over long treatments. Later systemic models (Woolston 1989) have emphasized the ward's 'open system' character and its potentially mediating role in improving the 'goodness of fit' between young people and their environment. The focus here is on collaboration with other agencies and the family; parents often take an active part in the ward caregiving.

Other models have emphasized the ward environment as a corrective emotional experience with high levels of warm staff communication, peer contact and active behavioural control (Cotton 1993), while a few specialized developments have involved admitting whole families (Lynch *et al.* 1975). Five-day residential patterns have become common (Green & Jacobs 1998). Recent developments—notably driven by managed care in the USA (Nurcombe 1989; Harper 1989)—have in contrast reduced the ward environment to its most minimal form. The emphasis here is on symptom stabilization and 'minimum necessary change' before rapid discharge. Stays are often under 2 weeks: a radically different form of milieu from the 3-year or more stays described by earlier writers. In this recent model, the therapeutic milieu as historically understood has essentially disappeared and inpatient care has returned to its root in acute hospital practice.

While adult psychiatric research has addressed the character and effect of different forms of residential milieu, there has been virtually no equivalent work in child and adolescent psychiatry. A Ward Atmosphere Scale (WAS) identified six styles of treatment environment in 144 adult psychiatry units in the USA (Price & Moos 1977) which can be associated with differential outcomes (Moos *et al.* 1973). Just one published study (Steiner

et al. 1991) has reported on an adaptation of the WAS for an adolescent setting. Systematic research into the efficacy of different milieu solutions for children and adolescents is long overdue and has been identified as a priority in a number of reviews (Pfeiffer & Strzelecki 1990; Pottick *et al.* 1993).

Social functioning and education

Admission can have value as a removal from external difficulty as well as an exposure to an active treatment environment. By the time of admission, a young person's social adaptation in their community has often broken down, sometimes in all areas of school, family and community life. Widespread social difficulties were found in 58 consecutive general admissions in New Zealand, including a moderate to severe language handicap in 40% of cases (Paterson *et al.* 1997). A study of 126 hospitalized children and adolescents in the USA (Luthar *et al.* 1995) similarly found severe impairments in the Vineland social competency scores of inpatients admitted with externalizing and mixed internalizing/externalizing disorders. Social competency here was associated with specific reading scores rather than broad IQ. These findings have practical implications. The traditional therapeutic milieu contains elements of group living, peer relationships and intensive staff–patient contact. Removal from social difficulties in the external environment and exposure to such a milieu can produce rapid gains in functioning and self-esteem. However, children with significant social impairments may not be able to make effective use of such a socially oriented therapeutic environment. Assessing and targeting social difficulties more precisely and defining the effective milieu characteristics for different problems is an important task for future developments in milieu treatment.

Similarly, many inpatients have a history of school failure or acute school breakdown. The individualized assessment and intensive educational input possible within the inpatient unit can make a radical impact (French & Tate 1998). Green *et al.* (2001) found a rapid reduction in teacher ratings of behavioural disturbance in the classroom from pre-admission to 1 month post-admission in a consecutive sample of 55 child admissions, persisting when reassessed at 6-month follow-up.

Such rapid gains in socialization and academic achievement represent two of the potential therapeutic strengths of residential treatment. They can be used as a platform from which to reintegrate patients into their own communities with enhanced resilience, as long as there is good linkage into aftercare. However, such targeted interventions take time and are not compatible with ultra-short inpatient stays.

Admission practice

Admission rates into inpatient care differ greatly between countries. A national survey of young people receiving mental health treatment in the USA during 1986 (Pottick *et al.* 1993) found that 5% of the children (6–12 years) and 30% of the adolescents (13–18 years) were being treated in inpatient facilities (com-

bined proportion 20%). In the UK, admission rates are much lower, estimated at around 1% of the clinical pool of children under 12 in one area (Maskey 1998), a fifth of the US rates. Current recommended provision in the UK is for two to four child and four to six adolescent beds per district of 250 000 population, to be provided in subregional units of 15 beds for children and 25 for adolescents (Royal College of Psychiatrists 1997).

Studies have addressed the criteria for admission. Costello *et al.* (1991) studied 389 children between 2 and 12 years referred for inpatient evaluation in the USA. Factors leading to admission included deterioration despite outpatient treatment; increasing aggressiveness; difficulties with assessment or diagnosis; family difficulties in the context of psychiatric disorder making treatment impossible; and the need for 24-h observation or nursing care. Two UK-based studies of children (Garralda 1986; Wolkind & Gent 1987) formulated similar criteria. A prospective study of 276 admissions to adolescent units (Wrate *et al.* 1994) characterized diagnostic formulations accounting for most admissions. However, Pottick *et al.* (1995) found that the strongest influence on admission in the USA was the presence of insurance cover: a cut in insurance benefit between 1978 and 1983 also coincided with a significant drop in US inpatient usage (Patrick *et al.* 1993). Proximity to a specialist centre increases referral rates (Gutterman *et al.* 1993) and Blanz & Schmidt (2000) describe how devolution of inpatient care to smaller local units in Germany reduced admission times and changed admission practice.

A pragmatic model of the process of admission (Bruggen & O'Brien 1987) describes common practice—a negotiation between referrer, family and admitting unit around which specific needs of each party could be met by admission. In the future it is to be hoped that an increasing part of such decision-making will be the empirical evidence regarding the effectiveness of inpatient treatments in particular situations and for particular disorders (see below). Whereas the inpatient resource is rightly held in reserve for the most complex and severe cases, referral should not be overdelayed: a well-timed intensive treatment may often prevent further deterioration in an acute disorder.

Admissions generally fall into a number of broad categories.

- 1 The need for detailed assessment in complex cases when the formulation is unclear. The combination of the medical setting with the range of health professionals makes the ward particularly well able to address the interaction of biological, psychological and social aspects of disorders.
- 2 When it is useful for assessment or treatment to take place away from the family. This can be crucial when the role of family in a presentation may be unclear, e.g. when fabricated or induced illness is suspected, or when complex symptoms seem confined to home.
- 3 When psychiatric symptomatology is escalating, despite the most intensive outpatient treatment available, the ward gives access to intensive nursing in a controlled environment. This will include acute risk management of self-harm or family disruption associated with psychiatric disorder.
- 4 For controlled trials of specific interventions.

Pre-admission evaluation is thus a crucial area. The admission must be seen within the context of a continuum of service use and the developmental trajectory of the child, because it will be a brief episode in both these areas. Many of the key predictors of inpatient outcome lie in details of previous family adaptation, child social functioning and child symptomatology (see below): assessment should thus focus on these aspects as well as the needs and motivation of patient and family. Pre-admission evaluation may lead to a decision not to admit. Many children with social and behavioural difficulties, for instance, may be more appropriately cared for within the social care system with psychiatric input.

Emergency admission

Studies of referrer attitudes emphasize the high priority given to the specialist unit's responsiveness and capacity to admit emergencies (Gowers & Kushlick 1992). Good and responsive consultation around the emergency may meet the need without admission (Cotgrove 1997), and Dimond & Golberg (1999) gave a helpful perspective on this from a referring team. However, provision of acute beds is likely to be an increasing priority and will shape service provision. The use of acute admission to paediatric and adult psychiatry beds is often used as an alternative in this area, and is beyond the remit of this chapter—but forms an important aspect of health care planning.

Discharge and aftercare

Discharge planning should receive equal attention to admission planning. Many studies point to the crucial role of aftercare in the maintenance of treatment gains made during admission (Pfeiffer & Strzelecki 1990). In a minority of cases admission may prove to be a stepping stone towards longer term alternative care or residential schooling. Because of the multifaceted nature of inpatient problems the team will need to liaise with a wide variety of local services in education, social services and mental health. In adolescents a 'care programme approach' may be used along lines developed in adult mental health as an aid to transition into adult services. A recent study of service use (Hoagwood 2000) showed that a limited period of intensive specialist treatment resulted in a more effective use of other services thereafter and may explain some ' sleeper' effects. It is to be hoped that inpatient treatment could catalyse similar improvements in service usage during aftercare—presuming such services are available.

Unwanted effects of inpatient treatment

There is little systematic research in this area. Potential unwanted effects can usefully be grouped into those consequent on:

- 1 loss of support from the child's local environment;
- 2 presence of adverse effects within the inpatient environment; and
- 3 the effects of admission on family life (Green & Jones 1998).

Losses consequent on admission

Reporting bias towards acute problems during pre-admission assessment can obscure hidden sources of support and resilience in the local environment—within the extended family, peers or school. Pre-admission assessment should therefore actively focus on strengths as well as difficulties and identify key areas of individual resilience. Admission may also result in the loss of important local professional input, which should be ameliorated by good communication between unit, referring teams and local services. These factors need particular attention from inpatient clinicians because they may be less obvious than active effects from within the inpatient environment itself.

Impact of the inpatient environment

Some young people may enter the ward with a profound sense of relief but others may find it at least initially frightening and bewildering. Patient ratings after inpatient psychiatric care (usually collected by the units themselves) generally show positive evaluation of the treatment. However, parents are often concerned that their child may be negatively affected ('contaminated') by other patients' problems. Units must be constantly vigilant to the possibility of peer abuse. To counter such potential problems, Newbold & Jones (1998) suggested a proactive emphasis on child welfare and rights throughout a unit, embodied in the appointment of a 'welfare co-ordinator', with a role to investigate any complaints. This is performed in the context of procedural agreements with local child protection agencies and a continuing programme of awareness training and education of staff.

There have been no specific studies into institutionalization in child or adolescent psychiatry units, but attitudes may be influenced by studies of non-medical residential care, even though these environments may be very different. Colton (1988) found residential children's homes performing extremely badly on measures of staff relationships, physical environment and community involvement in comparison with children in foster care. Well-publicized episodes of abuse in residential social care environments (Levy & Kahan 1991) may also be generalized into attitudes towards residential psychiatry treatments by families, although it is to be hoped that the intensity of monitoring and supervision in the latter makes such disasters less likely.

Effect on families

Much professional concern has focused on the disruptive effect of admission on family dynamics, e.g. the reinforcement of 'scapegoating'. This may indeed be a contraindication to admission, although equally a scapegoated child has a right to the best possible assessment and care—and this may involve admission. As the child engages with the ward there can also be a danger that the parents feel deskilled (Green 1994). Good family contracting pre-admission and sustained family work can counteract these negative effects. A family's commitment to intensive

treatments can be disruptive and expensive and on occasion threaten employment. It is essential to anticipate this by building support for family travel into the contracting around the case and actively to support the family in relation to employers.

Given the powerful intervention and therapeutic potential of inpatient treatment, some associated unwanted effects are likely. There is a need for their systematic study—rather than reliance on purely theoretical concerns or anecdote. Along with general standards of good practice, systematic procedures of anticipation, prevention, recognition and repair should minimize unwanted effects (Green & Jones 1998)—but again this needs to be studied.

Characteristics of day units

The concept of psychiatric day care emerged from the therapeutic elaboration of school provision for young children (Zimmet & Farley 1985) and psychiatrically orientated day hospital units have grown up as an intermediate form of treatment between outpatient and residential work (Connell 1961). Relieved of the need to provide residential aspects of care, day unit environments have been able to evolve in a host of different directions. These have ranged from specific day programmes for young children with developmental problems, as an adjunct to specialist school provision, to intensive 5-day-a-week treatment interventions with whole families. The range is now too great to summarize neatly. Of UK day hospital units, 46% are now associated with inpatient residential units (Bailey, V., personal communication). This combination has the advantages of sharing staff and expertise and allowing a flexible use of day care as a transition out of and into residential care. The advantages of independent day units relate to flexibility in the use of staff. The reduced need for a shift system to cover nights allows ward staff to work predictable hours and be available regularly for liaison sessions and outreach work. Partial attendance also means that staff can have days free for supervision and continuing education.

Amid the variety of day unit functioning, a number of broad themes may be distinguished.

1 Day units for the treatment of disruptive behaviour. A number of programmes have been developed in this area. They usually use multimodal treatment packages with a combination of individual family and liaison intervention together with psychopharmacology. Grizenko (1997) and Rey *et al.* (1998) have reported outcomes of such programmes.

2 Some units have specialized in the management of younger children with developmental disorders such as autism, speech and language disorders or neuropsychiatric disorder. These provide centres for comprehensive assessment and initiation of treatment management involving family and school liaison.

3 Units whose prime aim is to influence family functioning in situations of family breakdown or child maltreatment. A number of influential programmes of this kind have been described (Asen *et al.* 1982).

The partial milieu of the day unit shares care with family or local school to a greater extent than residential units. Thus liaison takes up correspondingly more time and contact with parents may be more frequent. The day unit has the opportunity to generate treatment programmes that link very closely with parental care. The emphasis on education means that the academic focus of the milieu in day care can be fully exploited. Educationally, therefore, inpatient and day unit treatment can be identical.

Disadvantages of the day unit milieu mirror these advantages. Many day units may not have the facility to mount a full educational programme and make do with sessional teacher inputs. This may not in itself be enough to achieve the key academic goals necessary for a child failing in school. Secondly, if the school provision is complete then there is little time left during the day for other kinds of therapeutic programming, which might take place in the evening on the inpatient unit. The day unit will have to achieve a balance between adequate intense academic input on the one hand and the socialization and therapeutic experience on the other. They may find that they have insufficient time to do both properly with complex children. The child may have to make multiple adaptations to different environments during the week and in many areas the daily transport to and from the unit can be complex and tiring. The opportunities for completeness and intensity of treatment and observation are less.

The milieu on the day unit can be investigated in precisely the same way to that of the inpatient unit. As it does not contain the total residential care element it tends to focus on specific adaptive behavioural issues. The focus is likely to be less on the relationship between the child and the institution and more on the relationship between child, family and school of origin. The provision of staff can be flexible and draw on sessional input from a wide range of professionals. There is less need for a core nursing provision. In many units the parents are engaged in providing much of the shared care in the unit.

Common aspects of day unit and inpatient treatment

Therapeutic alliance

Therapeutic alliance is poorly researched in child psychiatry when compared to adult mental health treatments (Hougaard 1994), yet proxy measures of therapeutic alliance such as ‘parental co-operation’ commonly provide the most significant predictor of inpatient and day patient outcome (Sourander *et al.* 1996; Grizenko 1997). Kroll & Green (1997) reviewed the complexity of the therapeutic alliance in inpatient and day patient care. Alliances form between child and parents separately and members of a complex inpatient team. The team itself acts in a number of different roles, ranging from a quasi-parenting role in relation to a child’s basic needs to a therapeutic role while undertaking specific programmes; from a ‘collaborative’

role with parents to a ‘patient’ status for adults within family therapy. Adult studies find that therapeutic alliance relates to pretreatment social adaptation (Hougaard 1994) and social competency is found to be a key variable predicting adaptation into an adolescent inpatient treatment environment (Luthar *et al.* 1995). Such findings emphasize the importance of pre-admission work for building a therapeutic alliance. Techniques for maximizing alliance independently with both child and parent need consideration. In a prospective study of 55 patients in inpatient and day patient care (Green *et al.*, 2001), child and parental alliance were independent of each other and it was the alliance with the child that predicted health gain during admission, including good outcome in externalizing disorder.

Assessment strategies

The ward environment creates opportunities for detailed assessment of biological and psychological aspects of disorder. Covert causes of behavioural difficulties can be elucidated, e.g. a study of unselected adolescent admissions (Szabo & Magnus 1999) revealed 4% of patients with undiagnosed complex partial seizures. Wards need ready access to the full range of biological investigations, including scanning, EEG and clinical chemistry; a range of developmental assessments such as detailed speech pathology, occupational therapy and psychometric evaluation; and the opportunity for paediatric and neurological liaison. There are unique opportunities for observational studies in settings ranging from highly structured individual assessments to naturalistic observations during ward and school activities. Making best use of these opportunities requires good planning because important observations are often made by the least experienced staff and multiple assessments have to be integrated into a whole. One solution is to have structured assessment protocols for particular problems in which different staff have defined tasks towards a common end (Green 1996). Assessments performed in this way are always challenging—initial assumptions based on limited information can be examined critically in the light of different staff perspectives; this is one of the strengths of multidisciplinary working in the ward environment. Staff will use specific skills from their core profession as well as skills developed within the team to serve these tasks. The team thus needs a programme of generic skill development to meet the priorities of the unit.

Planning treatment goals

The concept of treatment goal planning was elegantly outlined by Shaw (1998) and has many attractive features. It acts to organize thinking and focus treatment in complex cases and counters therapeutic drift. However, it is deceptively simple and depends on significant assessment and engagement with the family. Shaw suggested that treatment goals should be understandable, ideally framed in the child’s own words, achievable and measurable: they are distinguished from the *staff hypothesis*

(a professional formulation of the case) and the *treatment plan* established by the staff group on the basis of this hypothesis. Rothery *et al.* (1995) made an audit of treatment goals in admissions to four adolescent units. They found that the majority of treatment goals reflected relationship and maturational aims rather than symptom change alone. Improvement across such goals was noted during treatment. Goals should be flexible enough to be able to evolve in potentially unexpected directions when necessary during treatment.

Adapting treatments to the inpatient and day patient setting

In addition to individualized treatments, there remain generic aspects of ward management. Behavioural management on any unit is a key area, requiring ward policies on the management of aggression, use of seclusion or restraint, bullying and runaway behaviour (American Academy of Child and Adolescent Psychiatry 2000). Minimization of problems begins with thorough initial risk assessment and treatment planning, but equal emphasis needs to be placed on the overall culture of the unit, staff behaviour and the ongoing use of social skills and anger management programmes (Cotton 1993; Higgins & Burke 1998). The American Academy of Child and Adolescent Psychiatry review commented that the trend to brief treatment stays can undermine such a culture. Luisielli *et al.* (1998) applied a behavioural analysis to incidents of mechanical restraint in a US unit and concluded that such extreme measures were often the result of a failure of preplanning, unit policy or staff awareness. Antecedents to restraint were commonly an escalation of conflict initiated by staff behaviour rather than child behaviour and based on unrealistic staff expectations of child compliance. The authors advocated a comprehensive functional assessment, proactive treatment planning and the use of short time-out procedures in which the child has control as to duration. When prevention fails, crisis intervention techniques can range from de-escalation strategies and seclusion to brief carefully trained physical holding. More controversial techniques include use of medication and mechanical restraint (papoose boards or holding blankets) and are contraindicated for younger ages and where there is previous trauma related to confinement (American Academy of Child and Adolescent Psychiatry 2000). There are no comparative studies of the relative value of these techniques and the whole area is relatively underresearched and subject to clinical fashion (Angold & Pickles 1993). However, careful reviews of available evidence and explicit clinical guidelines, such as those from the American Academy of Child and Adolescent Psychiatry, form the best current safeguard for patients and professionals alike.

Individual treatments, such as cognitive-behavioural therapy (CBT) and individual psychotherapy, are incorporated into individualized treatment planning. The trend towards shorter treatment stays favours brief and focal treatments, such as CBT. The detailed assessments provided by individual psychotherapy have continuing value but there are particular challenges in

adapting psychotherapeutic treatment techniques to the modern treatment milieu when stays are relatively short (Leibenluft *et al.* 1993; Magagna 1998).

The challenge of mounting family therapy in the context of a busy inpatient unit was reviewed by Lask & Maynerd (1998). Pre-admission family functioning has been found to be a predictor of health gain during treatment in a number of studies (Pfeiffer & Strzelecki 1990) but Green *et al.* (2001) found that family functioning did not improve during admission in their study. An option may be for the formal family therapy to take place at the local site of referral in partnership with the inpatient team. The ward staff provide a form of psychological care which inevitably has elements of substitute parenting, especially for younger children, and has the opportunity to pioneer the development of specialized forms of care for extreme difficulties. In wards taking multiple diagnostic groups, flexibility and thoughtfulness is needed; the management of a behaviourally disturbed child with attachment disorder will be very different to superficially similar behaviours in a child with pervasive developmental disorder or obsessive-compulsive disorder (OCD).

Consent and motivation

The United Nations Convention on the Rights of the Child (UNICEF 1995) and national legislation with regard to children (e.g. the UK Children Act, White *et al.* 1990) have significant implications for practice. The trend is for consent to be increasingly explicit, treatment-specific and involving of the child. Developmental issues around competency have been reviewed (Shaw 1998). Within residential units, the social and linguistic impairments of patients, described elsewhere in this chapter, need to be carefully considered. In a useful study of competency in a consecutive series of 25 psychiatric child inpatients, Billick *et al.* (1998) found that 'legal competency' (the ability to understand legal rights and the principle of consent) was associated with the achievement of a 5th or 6th grade (12 years' equivalent) reading level.

Another principle of consent should be collaboration with parents. A generic consent to treatment can be obtained early in admission in conjunction with treatment goal planning, based on what is likely to happen within a particular programme of care. Such an approach combines the best principles of both consent and treatment goal planning. In the case of enforced treatment there is debate as to whether various aspects of children's legislation or adult-orientated mental health legislation is best used in particular circumstances (Cotgrove & Gowers 1999).

The staff team

As treatment approaches become more sophisticated, the staff team in both inpatient and day patient care have increasingly complex tasks to perform. In many countries, nurses with mental health and/or children's qualifications form the main ward staff group, but play specialists, trainee psychologists and vol-

Table 61.1 Factors indicating the need for higher shift ratios. (Adapted with permission from Cotton 1993.)

1	<i>Patient heterogeneity</i>
	Greater number of patients
	Broader range of ages
	Variation in levels of developmental functioning and diagnosis (e.g. combining cognitively impaired or psychotic children with brighter behaviourally disordered children)
2	<i>Case severity</i>
	Greater severity and pervasiveness of impairments
	Severity of symptoms, such as suicidality, aggressiveness, sexualization
3	<i>Lack of family or support systems outside the hospital</i>
4	<i>Poor therapeutic alliance</i> (e.g. families with statutory orders or referred from courts)
5	<i>Frequent staff turnover</i>
6	<i>Shorter lengths of stay</i> (more acute admissions and an inability to develop routines and relationships)

unteers can also usefully add to the skill mix. Guidance from both the USA (American Academy of the Child and Adolescent Psychiatry 1990) and the UK (Royal College of Psychiatrists 1999) emphasizes the wide variety of professionals that should be represented in well-running inpatient or day patient units. These will include consultant child and adolescent psychiatrists, social workers, psychologists, speech and language therapists, occupational therapists, family therapists and psychotherapists. Attempts to operate with too few staff are a recipe for stress, burn-out and institutional decay. Staff numbers are best discussed in 'shift ratios' (number of staff per shift) or in sessional terms because this allows application to diverse unit functioning. For nursing staff, factors influencing the shift ratio include skill mix, the task demands of a particular shift (from low-intensity observation at night to high-intensity active therapy) and patient dependency (Table 61.1). Furlong & Ward (1997) have piloted a dependency measure that shows predictable weekly fluctuations and interactions with staffing levels and quality of care. American and UK guidelines (Furlong & Ward 1997) recommend nursing shift ratios of 1:3 for low-intensity activities rising to 1:2 for active treatment and 1:1 for intensive care. Recommendations for other staff include one whole time equivalent (WTE) consultant per 10–12 bedded unit, up to one WTE in clinical psychology and up to 0.5 WTE sessional inputs from social work, psychotherapy, family therapy and occupational therapy. The UK recommendation for specialized teaching is one teacher to four students per lesson.

Models of team management and functioning will vary with the style of the unit. A popular current style is a model of 'matrix management', which combines different disciplines with multiple tasks in a flat hierarchy with task-focused 'mini teams' (Maskey 1998). Whatever the organization, responsive and adequate staff supervision is vital.

Effectiveness of inpatient and day patient treatment

Generic outcomes

Inpatient and day units are considered as a single entity for the purposes of administrative planning and therapeutic organization and many studies have investigated generic outcomes across a range of disorders. Pfeiffer & Strzelecki (1990) reported an important meta-analysis of 34 such inpatient outcome studies and there have been subsequent reviews (Curry 1991; Pottick *et al.* 1993) and individual reports. These studies point to the overall efficacy of inpatient care and have been able to identify quite robust predictors of outcome. However, the reviews have also highlighted significant methodological limitations. Few early studies included control groups or standardized outcome measures and sample sizes have often been insufficient to overcome problems of patient heterogeneity. Pottick *et al.* (1993) argued for more experimental designs to investigate the value of the residential component of care against other components and prospective randomized trials of inpatient vs. other forms of treatment for particular disorders are now beginning to appear (see below).

Outcome measurement is also becoming more sophisticated with ‘triangulation’ methods to measure multiple perspectives on outcome (Jensen *et al.* 1996). Use of change-sensitive common methodologies in future studies will greatly help progress. It will also be necessary to be creative in the variables measured: markers such as social competency may be more relevant for treatment and outcome than diagnostic groupings *per se*.

Predictors of outcome

Pfeiffer & Strzelecki (1990) identified a number of robust predictors of inpatient outcome, which have received support and extension in subsequent studies. High levels of aggressive antisocial behaviour and ‘organicity’ of *symptoms*, as in schizophrenia, predict poor outcome; emotional disorders do better. *Well-organized treatment*, *positive alliance* and *good aftercare* are common positive predictors. *Intelligence* measured as IQ shows a moderately positive effect, but the study of Luthar *et al.* (1995) suggested that functional achievement may be the more critical variable. Pretreatment *family functioning* is a strong predictor of outcome, but the effects may be complex and disorder-specific. In a study of anorexia nervosa, North *et al.* (1997) found that the child’s perception of family functioning was prognostic but parents’ perception was not. *Gender*, *age* and *emergency or elective admission* were found to have little predictive value.

Length of stay (LOS) had only a modest association with outcome in Pfeiffer & Strzelecki’s (1990) review. However, interest in treatment lengths has been increased by the rapid progress in the USA and elsewhere towards managed care and very short hospital stays. Influences on LOS are complex. A retrospective

case note study of pre-admission variables in 100 children in one private US unit (Gold *et al.* 1993) found that longer LOS was predicted by greater global impairment, post-traumatic symptoms and psychosocial stressors; diagnosis of adjustment disorder predicted shorter stays. In contrast, Christ *et al.* (1989) found that LOS was predicted by funding constraints or unit philosophy rather than diagnosis. Mossman *et al.* (1990) achieved significant overall LOS reduction managerially by setting a discharge date early in admission and actively engaging community services regarding aftercare, but they did not study the therapeutic effectiveness of this approach. The clinical lore that symptoms often decline rapidly early in an admission and then worsen—the ‘honeymoon’ effect—was supported by LaBarbera & Dozier (1985) who showed symptom increase from early to late in admission. No measure of pre-admission symptomatology was made here, but the authors argued that shortening admissions beyond a certain limit might well produce spurious health gains based on symptom inhibition early in admission. Alternatively, the fact of admission may relieve contextual causes of symptoms in the young person’s environment and the early symptom reduction may be a valid effect—but the work needed to maintain these positive changes into discharge will take longer. Green *et al.* (2001) showed considerable symptom reduction from pre-admission to 1 month; there was some rise by discharge although not to pre-admission levels. Length of stay in this study did not predict outcome nor was it associated with pre-admission variables.

Further studies of treatment effects through admission should identify better process variables for prediction than the gross length of stay. However, the drive for maximal efficiency of treatment and the financial pressure of managed care will make the issue of LOS of continuing relevance in treatment studies and policy decisions.

Outcome for specific disorders

Eating disorders

There is unresolved debate on the value of inpatient treatment for eating disorders (see Steinhausen, Chapter 34). The anxiety that these disorders induce, the issues around control and the significant mortality often combine to produce a desire for admission as a safe option. Adolescents themselves, however, often resist admission and some of the extreme behavioural methods previously used on units to promote eating continue to cause anger when patients recount their experiences (Shelley 1997). On the other hand, the removal from considerable family difficulties, the group cohesion achieved in many more specialist units and the quality of supervision available can make the residential experience therapeutically powerful.

Studies of the outcome of inpatient treatment show widely differing results. Steinhausen & Seidel (1993) followed 50 patients over 5 years and found a 68% recovery rate with 14% still diagnosable with eating disorder. Saccomani *et al.* (1998) followed 81 children over 9 years and found a 53% good outcome.

But comparisons between outpatient and inpatient treatment (Crisp *et al.* 1991; Gowers *et al.* 2000) have shown little additional benefit from inpatient care. Indeed, the 21 inpatients treated in the latter study did particularly badly, with only 14% having good outcome and a regression analysis of the whole cohort of 72 cases showed that inpatient treatment was a predictor of poor outcome, independent of presenting severity. This was not a randomized study and may have been affected by selection bias because the service reserved admission for the most intractable cases. Potentially mediating variables, such as motivation, family context and therapeutic alliance, were not measured. Others have argued that these latter factors are likely to be more important than severity scores in deciding on admission and predicting its outcome (Wood & Flowers 2000). This issue will only be resolved by well-designed randomized controlled treatment studies and at least one of these is currently underway.

Depression and suicidality

Admission practice following suicide attempts shows great regional variation. A recent large study found that, for similar presentations, 39% of cases in the USA were admitted compared with 12% in Europe (Safer 1996). There are no studies directly comparing hospitalization with other forms of post-overdose care, although a recent UK evidence-based review (Hawton *et al.* 1998) recommended that psychiatric admission should *not* be the intervention of first choice for self-harm.

A number of recent uncontrolled studies have investigated suicide risk following inpatient treatment of depression or suicidality. Twenty per cent of 111 emergency admissions remained depressed and suicidal at 2–4 year follow-up (Ivarsson *et al.* 1998), 18% of 100 patients admitted with depression reported suicidal behaviour at 6-month follow-up (King *et al.* 1995) and 25% of 180 similar admissions attempted suicide within 5 years of discharge (Goldston *et al.* 1999). Predictors of ongoing symptoms were suicide attempts prior to hospitalization, high levels of depressive symptomatology and family dysfunction at inpatient assessment.

Psychosis

Adolescents with first onset psychotic illness will commonly be admitted but there are no studies comparing admission with alternative forms of treatment at this stage. One study of 58 adolescents admitted with psychotic disorder showed that 78% at follow-up after 2 years were continuously ill (Cawthron *et al.* 1994).

Conduct disorder

The presence of unsocialized aggressive or externalizing behaviours at presentation is a consistent predictor of poor outcome for inpatient treatment (Pfeiffer & Strzelecki 1990). However, this reflects the general prognosis for these disorders. Conduct

disorder was a specific exclusion criterion in some units but accounted for 25% of child admissions overall in a study of UK child psychiatry units (Green & Jacobs 1998) and 15% of children and adolescents referred to Finnish inpatient units in 1990 and 1993 (Sourander & Turunen 1999).

Current evidence suggests that the management of conduct disorder is best seen in terms of long-term maintenance rather than episodes of care and the contextual basis of much of the symptomatology supports community intervention as a first choice treatment (Henggeler *et al.* 1999). In spite of these arguments and the often disruptive effect of such children on the milieu, there is good indication for admitting selected patients.

1 For assessment when there are concerns about covert underlying comorbidity relevant to treatment, such as attention deficit, emotional disorder, pervasive developmental disorder, specific learning disability or subclinical seizures (Jacobs 1998).
2 When a trial of treatment is needed within a controlled setting.

Children with externalizing disorders receiving a multimodal day programme showed improvements in adjustment at 5-year follow-up (Grizenko 1997). Another multimodal day programme (Rey *et al.* 1998) also showed improvement over matched controls who had received other treatments; however, both groups showed poor outcome. In a study of inpatient treatment of adolescents with emotional and conduct disorder, patients who completed the treatment showed more progress 1 month post-discharge than patients who were early drop-outs, but these differences had become insignificant at 1- and 2-year follow-up (Wells & Faragher 1993).

Substance misuse

A number of inpatient and day patient addiction programmes have been evaluated. Of 280 adolescents treated in a substance abuse inpatient programme (Dobkin *et al.* 1998), 67 subjects completed 1 month follow-up questionnaires; 19 had improved and 48 had not. The improvers tended to be older with better motivation for social adjustment and less emotional symptomatology; those who did worse were distinguished by more mental state abnormalities at admission. Cornwall & Blood (1998) compared inpatient and day patient programmes in this area and found they showed similar outcomes. A random allocation trial comparing inpatient and intensive community treatment of adolescents with substance misuse and juvenile offending (Schoenwald *et al.* 1996) showed additional benefits for the community treatment. Friedman *et al.* (1993) report a matched study comparing long-term outpatient treatment with short-term inpatient treatment and found benefits in the longer term outpatient treatment.

Obsessive-compulsive disorder

In a prospective naturalistic study (Wever & Rey 1997) examined the effectiveness of combined CBT and psychopharmacology in a group of 57 children and adolescents first diagnosed

with OCD, 20% of whom received inpatient treatment. Factors leading to admission included the severity and type of OCD symptoms, the failure of past therapy, comorbidity, family factors and geographical isolation. The inpatient group had double the rate of comorbid diagnoses compared to outpatient group and they showed a poorer outcome.

Intensive home-based care and outreach services

Recent developments in the USA have seen the increasing use of intensive forms of community support, such as the ‘wrap-around’ model (Vandenberg & Grealish 1996). These programmes address mental health problems but often exclude mental health personnel. At the same time, new research in developmental psychopathology emphasizes the social context of much child psychopathology. Woolston *et al.* (1998) described a synthesis of these developments in an intensive home-based model of psychiatric care. The service is brought to the family home and individualized to the family’s needs. Assessments are made at the level of child and family, the immediate community and the wider environment. The primary outreach team works to identify the smallest possible change in these systems that will create improved and stable functioning and then links with the wider network within the child’s environment to sustain this change. A similar model of multisystemic therapy (MST) has been described by Henggeler *et al.* (1994).

The theoretical paradigm behind these approaches is not new—it is a recasting of the biopsychosocial model that implicitly informs much child psychiatry practice. Indeed, Woolston has argued that, in an age of severely restricted inpatient stays, this model is the best way of preserving the holistic and in-depth approach that characterized the best inpatient tradition. What is new is the platform of delivery of the service and the intensity of the outreach provision. There is, in addition, an underlying rationale—albeit untested—that a small change accomplished with the young person in their own social ecology will be more beneficial than a possibly larger change in a removed setting (Woolston, personal communication; Henggeler *et al.* 1999).

These intensive outreach models need much skilled professional time. Between three and five professional teams, consisting of two senior clinicians or counsellors, provide the home-based assessment and therapeutic input. They are backed up by a multidisciplinary infrastructure described in Woolston’s model as a programme director and medical director, a child psychiatrist, a clinical programme co-ordinator, two senior clinicians and an administrator. This staffing is quoted as sufficient for a caseload of 25 patients. (The seniority and experience of the majority of the professionals is notable). The intensity of the involvement can vary according to need and expense but a 24-h 7-day on-call crisis intervention service is provided throughout the duration of the input. In one study of MST (Schoenwald *et al.* 1996), the average duration of treatment was 130 days (SD 32 days) during which there was an average of 40

direct contact hours between professionals and family (range 12–187 h, SD 28 h). In Woolston’s report the length of provision had a mean of 13 weeks with a range of 1–40 weeks. Woolston emphasized that the intensive home-based services are considered as supplementary to an array or more traditional services, including inpatient and day patient hospitalization and outpatient programmes.

Henggeler *et al.* have conducted a number of experimentally based studies comparing MST with other forms of intervention. These provide some of the first randomized controlled treatment trials in this area of child and adolescent psychiatry, including the first specifically to include cost analysis. Schoenwald *et al.* (1996) randomized MST against service as usual for adolescent substance misusers. The MST treatment resulted in a 46% decrease in the need for residential care at 1-year follow-up and succeeded in reducing dramatically the rate of imprisonment for substance abuse and abuse-related inpatient stays. The cost savings made through this almost compensated for the increased cost of the MST treatment. A recent randomized trial (Henggeler *et al.* 1999) compared MST vs. brief hospitalization for a diverse group of adolescent psychiatric emergencies in a relatively disadvantaged population. MST was given for 4 months while hospitalization was for 2 weeks (only) followed by standard community aftercare. The MST condition involved a mean of 97.1 h of therapy contact time during the study and 24-h 7-day per week availability of staff. Staff had a caseload of three cases each and there was high-frequency psychiatric supervision. By comparison, the hospitalization condition had a mean contact time of 8.5 h subsequent to the admission period. Nearly half of the young people in the MST condition needed psychiatric admission in the initial period and MST only had the effect of reducing out-of-home placement by 50% through the whole study. Given these methodological qualifications, the MST had a significantly greater effect than hospitalization on externalizing symptoms and targeted social outcomes, such as enhanced family cohesion, structure and school attendance. Family and youth satisfaction was also higher. The hospital condition showed a significantly greater impact on youth self-esteem—a result that may reflect the individually orientated treatment model in the hospital group. No follow-up data beyond 4 months are reported. The study concluded that even this highly intense form of ecologically focused care does not substitute for the need for inpatient provision—but it can reduce the need, and results in enhanced outcomes over treatment as usual. It was unfortunate for the design of the study that there was such an imbalance between the treatment intensity in the two conditions. The study—important as it is—does not yet address the question of the added value of the residential component *per se*.

Future directions

A number of contemporary themes and future directions may be summarized. The trend for shorter inpatient stays and the development of intensive care alternatives to residential treatment is

likely to continue but there may well also emerge a reactive emphasis on the value of longer intensive residential treatment experience for selected conditions. The demand for adolescent units to respond to acute emergencies is likely to continue to grow as the severity of presenting psychopathology moves down the age range. In well-provided health services there may be increasing growth of specialist environments, such as specialized eating disorder or forensic units. Referral to intensive care facilities is often thought to follow a bimodal pattern: high when there are relatively few outpatient services, lower as outpatient services are more developed, and higher again when outpatient provision becomes still better and more complex need is identified. This should not imply that the potential demand for inpatient services is endless: epidemiological surveys of children with complex needs suggest that the pool of these problems in communities is finite and measurable (Kurtz *et al.* 1998).

At the complex end of the spectrum, young people are likely to be involved with multiple agencies (Kurtz *et al.* 1998). This implies another necessary development; a more sophisticated integration between mental health care, education and social services to form complementary and mutually supporting provision. Some children who now are admitted to inpatient psychiatric units may be better placed in residential social care institutions with psychiatric input or in specialist residential schools; some children in these other institutions may be better placed in primarily mental health facilities.

It is to be hoped that there will be a burgeoning of randomized controlled trials comparing residential, intensive day and outreach alternatives for particular groups or severity of problems. Along with this we can hope for an increasing delineation of methodologies to measure inpatient and day patient unit process. The result of these two developments may be further clarification of the specific value of residential treatment. The current evidence suggests that the residential milieu has a particular ability to provide stabilization and rapid reduction of symptomatology and risk. In medium-term treatments it provides an environment where treatment and rehabilitation can occur outside the demands of the home environment—this is the historical function of respite. Notwithstanding the efforts that have been made in recent years to engage effectively with families, the residential unit is inevitably largely focused on the individual and individual pathology. This can prove highly advantageous in situations where assessment or treatment of complex individual psychopathology is at a premium but needs to be complemented by an emphasis on the environmental context during pre-admission and follow-up. Reduction in the length of inpatient stays beyond a certain minimum negates any value of the inpatient milieu as a treatment in its own right, but the very fact of removal from a noxious mental environment in the community of origin may still result in temporary benefit.

Intensive outreach programmes are at an early stage of development but have already generated high levels of rigorous treatment programming and evaluation. The face validity of this theory of intervention is strong and in keeping with recent research in the developmental psychopathology of a number of

disorders. The emphasis on changing presumed maintaining factors in the young person's environment may result in longer stabilization of treatment gains—although this has not yet been tested. On the other hand, it should be quite apparent that these outreach solutions are no easy option, either financially or in terms of professional expertise. The first randomized trial including costing shows that the extra cost of the service only approaches being met if non-health cost savings are taken into account and there is evidence that the efficacy of the intervention drops if the intensity of the intervention is not strictly adhered to (Henggeler *et al.* 1994). Nevertheless, the early studies of the effectiveness of MST are impressive and deserve replication outside the developing centre. They suggest that this intensive outreach model does not replace the need for the inpatient option but can reduce its usage. The emphasis in this treatment on the social context of psychopathology is a strength and complementary to inpatient care but runs the risk of overlooking intrinsic problems in the patient.

Day unit care may seem to be a compromise between these two extremes and may often usefully be so. For the most severe problems, however, it may fall between the two and offer insufficient containment for safety or intensive outreach for effectiveness. The great strength of the day unit resource is its flexibility to adapt to different disorders and circumstances. It is unrealistic to believe that the day unit provision can substitute for other intensive treatment modalities.

Thus, in an ideal future, there would be a set of flexible and complementary platforms for the delivery of intensive care for acute and complex disorders. Service providers would identify themselves as 'serious disorder' or 'intensive care' services offering a variety of different modes of delivery. In practice, organization and financial constraints will often lead health services to have to make preferred choices. There is now a greater likelihood that in the future an increased evidence base may inform such decisions.

Acknowledgements

The author would like to thank Dr Andy Clarke, Dr Tony Jaffa and Dr Tony James for helpful advice in the preparation of this chapter.

Introduction

The child mental health consultant must assess the psychiatric status of an ill child in a hospital environment. Nature, nurture, development, illness, pain and anxiety add complexity. Every consultation requires respect for the power of biology, the mediating influence of family and community, and the primacy of personal meaning in defining an experience as bearable or traumatizing (Eisenberg 1995). Assessments involve:

- 1 children with psychiatric disorders leading to medical complications, such as a depressed adolescent admitted for an overdose, or a teenager with anorexia nervosa who is bradycardic and hypothermic; and
- 2 psychiatric manifestations of medical illnesses or treatments, such as central nervous system symptoms associated with HIV, disinhibition following traumatic brain injury or hallucinations secondary to morphine use following lung transplantation.

Children may need to be helped to cope with a chronic medical illness or painful procedures. This may involve working with anxious or difficult parents who complicate the care of their ill child by refusing to consent to necessary procedures or by causing dissension among the team of caregivers. The consultant also supports ward staff, as in helping a treatment team understand divisive dynamics or facilitating as staff voice feelings about a traumatic abuse case or painful death. He or she is an educator, sometimes offering didactic lectures for house staff or parents. The consultant is also an advocate for children working with hospital leadership to develop more psychologically attuned standard practices, such as routine presurgical visits for young children. The consultant can be a researcher asking and answering key questions about efficacy, outcome, quality of life and cost-effectiveness.

Consultations are occurring in a fast-paced ever-changing medical climate with shorter hospital stays, an ever-expanding array of new drugs, new diagnostic tests, treatments and technologies. Yet, in spite of all that is new, the inner world of children remains essentially unchanged. The child mental health consultant often articulates the child's inner world, and echoes the experience of seasoned clinicians who understand that a child and family will need time to build relationships with caregivers, and time to accommodate to the challenges presented by a medical illness. The consultant's challenge is to integrate the distinct and overlapping needs of the child, family, team and hospital setting to the benefit of the patient.

History

Historically, adult consultation psychiatry arose in general hospitals during the 1930s, with a recognition that a mind-body dichotomy was inadequate. Best practice demanded that attention be paid to the psychological issues that impact on medical illness and treatment (Ortiz 1997). As the integral role of psychological factors was established in adult medical care, similar attention was focused on the needs of children.

Although a role for psychiatry with the medically ill child dates back to the 1930s (Work 1989; Lask 1994), even today consultation psychiatry is not available in every paediatric medical and surgical setting. Nevertheless, throughout the world the benefits of collaboration between child psychiatrists and paediatricians are noted (Unger-Koppel *et al.* 1992; Tsai *et al.* 1995; Chan 1996), with encouragement to establish and use consultation services.

Consultation services must be supported financially. In the USA, the National Institute for Mental Health (NIMH) provided grant money in the 1970s to support interdisciplinary paediatric and psychiatric clinical collaborations, thus increasing the number of consultation services nationwide. This seed money supported unreimbursed activities such as comprehensive evaluation and interdisciplinary team meetings. As this support ended in the 1980s, consultation services were forced to decrease the range of activities and services offered (Wright *et al.* 1987).

Clinically, there has been a shift away from looking at the mother-child dyad as the source of psychopathology and towards appreciating the impact of paediatric illness on the entire family. Research has focused on measuring functional adaptation and positive coping skills, while identifying both protective factors and risk factors across multiple diseases, as opposed to chronicling the presence of negative symptoms associated with specific illnesses (Knapp & Harris 1998).

The care of children, like that of adults, is moving toward shorter hospital stays and greater use of outpatient settings for treatment of chronic and life-threatening illness. For example, outpatient oncology chemotherapy units and in-home intravenous antibiotic treatment for cystic fibrosis patients used to be inpatient interventions.

Psychological distress in the paediatric population

Some one-third to two-thirds of inpatient paediatric patients have to cope with psychological issues (Stocking *et al.* 1972; Burket & Hodgkin 1993). Existing data on psychological morbidity is difficult to compare as the studies utilize different measurement tools, represent small sample sizes and use a combination of patient, parent and paediatrician reports to assess emotional distress (Shugart 1991). Nevertheless, it is difficult to imagine hospitalization in which some stress and challenges to coping are not a factor for the child and family.

Lewis & Vitulano (1988) estimated that about 12% of outpatient children with chronic illnesses had DSM-IV diagnoses and 8–10% of paediatric outpatients had psychosomatic symptoms. Using screening tools, such as the Paediatric Symptom Checklist (Jellinek *et al.* 1999), in routine (well) outpatient clinics suggests that the proportions of psychologically symptomatic children range from a high of 34% in lower socioeconomic status high-risk populations (Murphy & Jellinek 1988) to a low of 8% in more affluent communities with approximately 20% of children with chronic illness noted to be symptomatic (Jellinek *et al.* 1988).

Paediatricians and child psychiatrists: collaboration and conflict

In spite of recognizing high levels of psychological distress in their hospitalized patients, paediatricians often do not refer to the child psychiatry consultants. In one study, paediatricians identified 64% of their inpatients as having emotional issues warranting psychiatric consultation, yet referred only 11% of these children (Stocking *et al.* 1972). Paediatricians often prefer to look to their paediatric colleagues for consultation on difficult cases rather than consulting child psychiatrists. They see their paediatric colleagues as uniquely equipped to understand the demands of paediatric practice and thus able to provide more relevant practical advice. Paediatricians who sought child psychiatry consultations during their house staff training years are much more likely to continue to seek consultation compared to colleagues who had not had this experience during their training years, suggesting that approaches to patient care are best developed early (Bergman & Fritz 1985). It is essential that child psychiatry consultants be integrated into paediatric training programmes in order to facilitate appropriate long-term utilization, a goal very dependent on financial support.

Key to paediatrician satisfaction with psychiatric consultation is quality timely communication. Paediatricians' perceptions of child psychiatrists are overwhelmingly positive, but tensions do exist. Dissatisfaction with consultations is linked to a perception that the child psychiatrist was not available quickly enough, did not communicate findings, or that findings were not tailored to the needs and realities of the referring paediatrician (Burkit & Hodgkin 1993).

Child psychiatrists complain that paediatricians often consult too late in the course of the hospital stay, presenting the consultant as a last resort instead of seeking the psychiatric assessment as an integral part of the routine work-up and introducing the psychiatrist at the outset as a member of the treatment team (Fritz *et al.* 1987). This is especially problematic when coupled with completion of diagnostic tests that have not produced a definitive diagnosis or when routine treatment has not been effective. The timing may suggest to the patient and family that the medical team has completed their evaluation, possibly failed, and now are deferring to the child mental health consultant to define a purely psychological origin of the symptoms or treatment failure.

Barriers to requesting consultation

There are several common barriers to child mental health consultation. The consulting paediatrician may be uncomfortable talking to the patient and family about psychiatric consultation. Frequently, senior paediatricians and house officers worry that consulting a psychiatrist will be experienced as an insult by the patient or family. They may think that the family will assume the paediatrician thinks the child or parent is 'crazy' or does not believe the child's symptom is legitimate. By reviewing least threatening ways to introduce consultations to families such as, 'Dr X is the psychiatrist on our team and we like to have her see all our patients' either 'with diagnosis Y' or 'hospitalized for X days' or 'Y times', the consultant can help alleviate some of the paediatrician's anxiety or perceived stigma. When paediatricians wait until the end of the diagnostic period to invite the consultation, they maximize the likelihood of getting a negative response from the patient and family.

In some settings, child mental health consultants are not available at all or not in a timely fashion, a critical issue with decreasing length of hospital stay. There may be only a day or two in which to accomplish multiple goals for the admission. Short stays may push paediatricians to focus on essential, sometimes high-technology procedures and defer attention to psychological issues. When patients come to the hospital from distant locations, it may be the staff's perception that psychological issues other than of a life-and-death nature can be taken up by the primary care providers in the child's own community. Unfortunately, the child may be returning to a setting in which psychiatric support is not available or the clinicians in the community may be uncomfortable in addressing emotional issues.

In the USA, the type of insurance a patient uses may present a barrier to consultation, as some insurers 'carve out' mental health care. Patients and families may be eligible for reimbursement for medical care at a given institution, but not care from mental health providers at the same institution. Insurers will sometimes make an exception to their exclusionary practice, if time-consuming appeals are made by the consultant. If the patient stays in the hospital long enough for an appeal to be completed, the demand on the consultants' time of lengthy

phone contacts and extra paperwork becomes a barrier to providing care.

Consultation models

Consultation services are organized to meet the demands created by the size of the patient population, specific higher risk treatment populations, and the availability of different child mental health consultants (child psychiatrists, child psychologists, psychiatric nurse clinicians, social workers). The service will develop in response to the perceived need of the paediatricians and patterns of consultation. Child mental health consultants, particularly child psychiatrists and child psychologists, are often available only for a limited number of hours. When this is the case, the paediatricians and child mental health consultants must work together to establish a set of practice priorities. These may include using some of the consultant time to supervise nurse clinicians and social workers, who do more of the direct service, and some consultant time to see the most challenging cases. In many paediatric settings, child psychologists are the primary child mental health consultants, with child psychiatrists acting as paediatric psychopharmacologists. Child psychologists, and child psychiatrists with limited paediatric training, will need to educate themselves in the medical disease process to maximize their effectiveness as consultants. Child psychiatrists are often less well trained in behavioural interventions, such as desensitization, hypnotherapy and behaviour modification, and will need to complement their training if behaviourally trained child psychologists are not available.

Consultations can be initiated on a case-by-case basis or by protocol. In the case-by-case model, the paediatrician requests a consultation after assessing an individual patient. Consultation by protocol systematizes psychiatric consultation for children with certain diagnoses or risk factors. Common examples are cancer, inflammatory bowel disease, overdoses, eating disorders, recurrent abdominal pain, severe asthma or organ transplantation. Protocols recognize the conditions under which a psychiatric assessment is an essential part of routine good quality care. In the setting of short hospital stays, protocols for high-risk diagnoses facilitate early identification and minimize wasted time. Protocols can also specify routine consultation for any child who is hospitalized for more than 2 weeks or in an intensive care unit (ICU), has more than two hospitalizations in a year or has more than three subspecialists consulting to the paediatrician. These protocols acknowledge the emotional impact of extended or repeated hospital stays on children, and the additional stress on the family and the treatment team when multiple specialists are involved. If possible, the same consultant should follow a child over multiple hospitalizations or from inpatient to an outpatient specialty clinic.

The child mental health consultant's role will vary depending on the parameters established by the consultation service as well as by the demands of an individual patient and family. The consultant may carry out a complete assessment of the child and

family or may assess the ill child while a social worker assesses the family. A child psychologist may undertake psychological assessment and the child psychiatrist may assess whether psychotropic drugs are indicated. Often the child psychiatrist will have a leadership role in the multidisciplinary team, facilitating discussions of strategies for improving communication and compliance, or allowing staff to voice frustrations or sadness. This latter function is sometimes referred to as liaison and it may be the sole purpose of the consultation or be in conjunction with direct service.

One study of several hundred consultations ascribed one-third of the consultation requests to staff-related conflict (Hengeveld & Rooyman 1983). Not surprisingly, some would argue that no consultation on an inpatient can be performed effectively without the integral 'liaison' piece of understanding the child's condition in the context of the concerns arising from the members of the treatment team (Tarnow & Gutstein 1982; Hengeveld & Rooyman 1983).

Working in a paediatric setting necessitates understanding not only the disease process, but also the care delivered by a complex medical team. It is key to respect the roles of each member of the multidisciplinary treatment team and to understand how the chain of command works within each discipline. The child psychiatrist is likely to work with a wide range of hospital workers, spanning surgeons, social workers, nurse specialists and occupational therapists.

Part of respecting differing professional roles is understanding the value of each member's contribution to care, as well as being sensitized to particular challenges inherent in each discipline's treatment demands. For example, the paediatric house officer in the ICU may feel most stressed by decision-making, whereas the nurses at the bedside may feel most stressed by observing suffering (Jellinek *et al.* 1996).

Work with medically ill children is enormously rewarding but it can also arouse powerful feelings of sadness, frustration and helplessness. When these shared painful feelings are addressed in the setting of a multidisciplinary team, it can help provide the staff support necessary to care for the ill child and emotionally recharge staff members so they can continue to reinvest in new patients and not act on hostile feelings at work or at home.

Some team members will inevitably face personal or professional challenges that interfere with their ability to provide quality care and will come to the psychiatric consultant for assistance. The consultant may have a key role in facilitating referral to psychiatric treatment for troubled team members seeking help. The consultant should not personally provide psychotherapy treatment to a team member as this would be crossing an essential boundary in a long-term working relationship. Concerned colleagues may approach the consultant for direction on how to help a troubling member of the team who seems unaware of the problem themselves. The consultant will encourage the concerned colleague to share observations with the appropriate supervisor of the impaired individual and may meet separately with the supervisor or director to share observations of his or her own. Behaviours that put patients at risk may

be mandated to be reported to the appropriate overseeing body, such as the chief of service or hospital-based board. Concern for the mental health and vulnerable state of an impaired colleague while recognizing the responsibility to protect patient care stirs up powerful feelings in the reporter, including feeling punitive, having betrayed a friend, or feeling vulnerable to being targeted him or herself.

Approach to consultation requests

The first task for the consultant is to understand what concerns have led to the consultation request. He or she must speak with the consulting paediatrician or staff member, listening to the expressed concerns and asking for elaboration about concerns that seem to be lurking beneath the surface. It is helpful to work together to establish realistic goals for the initial consultation, with a plan to set additional goals after the initial meetings with the child and parents. The consultant should seek any supporting information that is available from other members of the treatment team and from the hospital chart. It is useful to gather the observations from several individuals as the child may be behaving differently in different settings, or may have established warmer relationships with some team members than with others.

Although the consultant will gather data from many sources, a basic tenet of consultation work is being clear about the person receiving the consultation. Ultimately, the goal is to facilitate the child receiving optimum care, but the consultant may be serving the primary paediatrician, a subspecialist, or a subspecialty team. Usually what serves the child best is helpful to many team members and to the family, but there can be conflicts. For example, the consultant to the paediatrician may recommend that an aggressively interventionist gastroenterologist chosen by the family may not be the best choice for a somatizing child with recurrent abdominal pain, or a consultant to a lung transplant team may recommend outpatient psychotherapy and a more rigorous exercise programme as a way of assessing an adolescent with questionable pretransplant compliance before accepting the paediatric pulmonologist's patient into the transplant programme.

In order for a child to be seen, a parent must give permission. In the specific situation of an older adolescent who is living or functioning independently from parents, it may be possible to consult without parental permission. It is best if the paediatrician or subspecialist, with whom the family already has a relationship, informs them of the decision to obtain a psychiatric consultation. When the paediatrician tells the family that psychiatric consultation is routine, as it is when consultation is part of the diagnostic protocol, parents are usually receptive to this additional helpful input. A psychiatric consultation can be presented as a way to help the team understand how the child is feeling and to help the child cope with the difficult circumstance of hospitalization. Some parents and children will be uncomfortable with the idea of psychiatric consultation, but will warm up

to the intervention upon finding the child mental health consultant respectful, knowledgeable and attuned to the needs of the child and family. Other parents will be resistant, but reluctantly agree under some pressure from the referring paediatrician. A small number of parents will adamantly refuse consultation under any circumstance. In this uncommon group who refuse all consultation, the consultant may meet with the team in a liaison capacity and assist the team without directly interviewing the child. In the other situations, the child mental health consultant will meet with the child and the parent(s) after receiving permission from the parents to do so.

Depending on the child's age and circumstances, the consultant will decide whether to meet with the parents first, the child first or both together. It is usually helpful to have a chance at some point to meet older children without a parent present. Even young children will often not want to say some things in front of parents. However, many children under 6 will be more comfortable meeting the consultant with a parent. As the goal is to facilitate the child being most forthcoming in talk and play, it is important to respond to the child's preferences for the initial interview.

The parents of young children are likely to want time alone with the consultant to share observations and concerns that are not appropriate to share in the child's presence. Similarly, many parents of older children will find it easier to be candid about their worries in the absence of the child. Older children may be uncomfortable knowing that parents are talking to the consultant without knowing what is being said. Nevertheless, it remains key to the initial assessment to provide an interview setting that facilitates child and parent independently being able to express feelings freely.

Assessing the child

Premorbid functioning of the child and family

When assessing a hospitalized or ill child, the consultant is seeing only 'a snapshot' of a stressful moment in the child's life. Some families will be confronting a new diagnosis or change in the prognosis, whereas others may have had time to develop an ongoing coping strategy in the face of a chronic illness or a lengthy treatment protocol. It is often startling to see how well a child and family cope, once the shock of the bad news passes and a treatment plan is underway.

A biopsychosocial model may help. Under the 'bio' heading, the consultant will want to understand the particular challenges presented by the child's medical condition and interplay of medications. Under the 'psych' heading, the consultant will want to learn about depression and anxiety preceding the medical condition as well as psychological strengths and resiliency. What successful coping strategies have the child and the family drawn upon in the past that may serve them well in the adjustment to the medical condition and current hospital stay? What are the stressors the family is experiencing, parents and siblings,

related to and unrelated to the child's medical illness? For example, the child's illness may be occurring as a parent has just lost his or her job, or the maternal grandmother's recent death. In the 'social' arena, the consultant wants to know about the child's relationship with peers and his or her functioning at school. It is easier for children with good friends and solid academic skills to continue in their pre-illness activities in spite of the disruptions caused by hospitalizations and medical treatments.

To gather this information, consultants will want to look to many sources—including the referring physician, the primary paediatrician and multiple members of the treatment team. They will want to read the current hospital chart, and records on past admissions when available. With permission from the parents or guardian, the consultant will want to speak with the outpatient psychotherapist, school professionals or members of other involved social agencies, or the court system.

Developmental perspective

Development is the lens through which a childhood medical illness can best be seen. The challenges of living with leukaemia are different for a 1 year old and his or her family than for a 16 year old and his or her family and friends. A full review of the interplay of development and medical illness is well beyond the scope of this chapter, but a few key developmental points will be highlighted to illustrate common issues.

Infants and toddlers cannot understand the gravity of a given diagnosis. They live in the moment, experiencing the medical condition and treatment according to the physical limitations and discomforts imposed. Infants rely on key caregivers to hold and soothe them and to make the hospital environment feel safe. It is important for the hospital staff to support the infant–parent attachment, and not allow treatments and technologies to interfere with this key emotional milestone. The paediatric unit can provide a milieu that supports breastfeeding mothers, and allows rooming by parents. A parent who wants to be present during procedures, and can play a soothing part in supporting the infant, should be allowed to do so. Parents may be encouraged to be physically close, touching the infant or toddler if the procedure permits, but restraining a fighting older infant or toddler is usually upsetting to both parent and child and is frequently inadequate for safety during procedures.

Preschool-aged children (3–6 year olds) are egocentric: they understand all events as occurring in relation to them. They have associative logic, which means that for them any two unrelated things can be understood as if one is causing or explaining the other. The combination of egocentricity and associative logic leads to magical thinking. Magical thinking is the weaving together of fantasy and logic to explain how the preschool-age child caused something to happen. In the medical setting, it is frequently the preschool-age child's misconception that having a 'bad illness' means he or she did something wrong and the disease is punishment. It is helpful to get young children (and older children as well) to elaborate their understanding of the aeti-

ology of their medical conditions to uncover self-blaming misconceptions and correct them. When preschool-age children have a life-threatening illness, parents often wonder if the child is worrying about dying. Preschool-age children do not yet have the cognitive capacity to comprehend forever and envision death as a reversible event. The preschool-age child is likely to demonstrate the most affect around separations, such as having anxiety about going to sleep at night in his or her own bed, or wanting a parent to promise to be there when he or she wakes up from surgery.

Furthermore, preschool-age children cannot localize a medical condition to a specific body part, so they feel particularly physically vulnerable when ill. Faced with needle sticks, intravenous medication and surgical procedures, they are like little knights without any armour. They rely on parents and medical staff to prepare them for procedures, so they are not on high alert anticipating surprise medical attacks at any moment.

Children aged 7 to 12 can understand simple functional explanations of medical conditions. Many will pride themselves on mastering the names of medicines, illness-related terminology and how to use hospital paraphernalia just as they pride themselves on learning words at school and mastering ball-handling on the sports field. Children of this age look for simple cause and effect aetiologies for illnesses. They can understand viral illnesses being caused by 'germs', but are perplexed when there is no clear cause and effect explanation, e.g. why they have cancer without having smoked cigarettes. It is important to explain illness and treatment to the school-age child. In the context of understanding why a treatment plan is being initiated, the medical staff should seek the child's assent to procedures and treatments. In this age group, 'rules rule' and it is troubling to the child that so often medical illness does not follow the rules; the child does all his or her treatments and the cancer relapses or he or she avoids asthma triggers and has an asthmatic attack anyway. One of the challenges of working with younger children is to capitalize on their pride in trying hard and their wish for competency, while keeping them from becoming too disappointed by setbacks that occur in spite of their own best efforts.

Adolescents have abstract thinking, and thus are able to understand the chance luck of having an uncommon life-threatening or chronic illness with the same cognitive complexity of an adult. Education is a prerequisite for behavioural change, but on its own is not sufficient. Commonly, teenagers do not have the maturity to incorporate the consistently health-promoting behaviours they know they should engage in into appropriate changes in lifestyle. Turning cognitive understanding into behavioural change is the common battleground of adolescent and authority figure—parent or physician. Assent for medical treatments is sought from the younger child, whereas consent is sought from adolescents who have the cognitive ability to comprehend the purpose of treatment and the ramifications of refusing treatment (British Medical Association 2001). Although some physicians may view seeking consent from an adolescent for treatments and procedures as time-consuming and burdensome while knowing that parents must give legal

consent to proceed, these discussions foster trust and build a valuable alliance between patient and clinician.

Adolescence is a self-conscious time, with the emergence of sexual interests and heightened reliance on peer group norms for style and status. Medical illnesses or treatments that affect appearance are particularly difficult, such as becoming cushingoid on steroids, bald with chemotherapy or remaining very short with renal failure. The medical staff is challenged to find ways to respect the teenager's appropriate wish to be more independent in the face of illness that so often increases dependency.

As children with chronic illnesses live into adulthood, the transition to young adulthood and understanding of associated issues becomes relevant. Young adults are negotiating intimate relationships, career decisions, independence from parents, and sometimes relocation or parenthood. One issue is whether to transfer care from a paediatric into an adult setting, with a new treatment team. Some patients, e.g. with cystic fibrosis or congenital heart disease, may prefer to be on an adult ward or in a waiting room with other adults, but yet find it difficult to leave lifelong caregivers behind.

Specific challenges associated with a given medical condition

Each medical condition carries its own specific challenges. When the consultant is familiar with common frustrations or limitations imposed by a particular illness, this can provide credibility in the process of acquiring the family's trust as they relate what is hardest for them. Routine consultation to the same paediatric unit enables the consultant to become familiar with technology, treatment protocols and terminology, so making it easier for the family to feel understood. Many families describe how tiring it is to try to explain the medical experience to friends who are medically naive or therapists who are so saddened by the illness that they seem unable to get to the key nuances of the child's or family's experiences. The combination of psychological and medical knowledge is key to the consultant's expertise.

Mental status examination

Hospitalized children have many reasons to have an altered mental status, including delirium, central nervous system changes secondary to medical conditions, effects of medications, and trauma. A formal mental status examination should be part of the medical record, including observations of appearance, gross and fine motor function, speech, mood, affect, thought, suicidal ideation, memory and cognition. Many consultants have had the experience of carrying out a mental status assessment only to discover significant mental impairment that has gone undetected despite multiple specialists seeing the child.

It is common for medically ill children to be developmentally delayed and sometimes emotionally immature. Coping is a function of cognitive capacity and complex defence mechanisms

that may result in temporary or long-term regression in some developmentally appropriate behaviours and adaptation in others (Freud 1969). It is helpful for the consultant to integrate the information from the mental status examination and pre-morbid school and developmental information to assist the medical team in understanding the child's ability to comprehend medical information. For example, a child may be 11 years old, have the cognitive skills of a 7 year old, and behave like a preschool-age child faced with the anxiety of a painful procedure. On the other hand, there are teenagers who appear several years younger than their chronological age and feel patronized by medical staff who forget their actual ages and capacities because of their appearance and interact with them as if they are much younger.

The family

No child can be understood independently of his or her family. In the initial evaluation, it is key to assess the family's level of functioning and their ability to support the child through the anticipated treatment and outcome. Every hospitalization is a family crisis. During hospitalization, parents are coping with new and anxiety-provoking information, sometimes hourly. Frequently, it is conflicting information presented by multiple caregivers. Seemingly small inconsistencies in the presentation of information—one person being more optimistic, another more pessimistic, one person emphasizing a particular laboratory value and another devaluing its importance—can leave the parents feeling they are on an emotional roller coaster riding up or down in response to each new piece of information. There is little or no privacy for the family to regroup after hearing upsetting news. Many parents identify the continuous uncertainty as the hardest aspect of adapting to the child's illness. Some parents will derive support from other parents on the paediatric unit while others will report feeling further traumatized by witnessing other families in crisis. Parental anxiety negatively impacts on the child's capacity to cope (Awad & Pozanski 1975; Kashani *et al.* 1994; Wright 1994), yet it is hard to imagine how parents could be other than anxious.

Asking parents to share the history of the current illness, from the first symptoms through to the present hospital stay, allows the consultant to form an impression of the extent to which parents felt responded to or ignored in the process of diagnosis and treatment. For example, did the parent have to tell the primary care doctor repeatedly that something was wrong before the concerns were taken seriously or did the first physician act immediately? Do they trust the medical professionals as a group, or are they generally mistrustful except for faith in one particular caregiver? Do one or both parents feel guilty about the illness or condition or about not getting the child to care fast enough? Sometimes parents feel guilty because of a genetically transmitted illness for which one or both parents are carriers, or for an injury that occurred while the child was in the parent's care. Even when there is no apparent reason, parents may still feel profoundly guilty about having been unable to protect the child

from the pain and uncertainty of illness. Commonly, parents will voice the wish that they could switch places with their child, and be the sick one in the child's stead. Other times, a child's illness will fuel parental discord and even divorce.

Parental guilt sometimes occurs in the context of depression. An assessment of the family should include history-taking about present and past psychiatric history (including use of substances) to determine whether certain family members are particularly vulnerable. It is helpful to ask questions about neurovegetative symptoms for each parent and the siblings. In especially stressful circumstances, parents may increase their own risk-taking behaviour including use of alcohol, driving with less care, etc. Many parents who do not meet criteria for depression will benefit from being reminded of the importance of eating and sleeping so that they do not compromise their own health during what may be a long period in which the sick child will need additional care.

The family's experience is affected by past experiences with illness, and loss. The consultant wants to know if any other family members have had the same or similar illnesses, what the experience was of their care and the outcome. For example, a mother of a 3-year-old girl with cystic fibrosis whose brother died of cystic fibrosis in his teens may indulge her daughter as if she is about to die instead of likely to live well into adulthood. Helping the parent differentiate the current medical situation from past experiences helps the parent be more attuned to the child's actual needs.

Siblings are often the forgotten sufferers (Spinetta *et al.* 1999). The sick child is usually the object of everyone's attention and recipient of a multitude of gifts, whereas the siblings at home are coping with an absent parent(s), sometimes depressed parents, and a disrupted schedule. If the siblings voice feelings of envy or resentment toward the ill child, parents may become angry at their insensitivity to the ill child's situation. The consultant and social worker can model important empathy for the plight of the siblings, by talking about the ways the sick child is lucky and the ways he or she is unlucky; the sick child is lucky to get so many stuffed animals and have special time with Mom, but unlucky to have so many blood tests, medicines to swallow and uncomfortable procedures.

Frequently, paediatric hospital staff have a harder time working with the family than with the designated patient. By understanding the parents' concerns and their experience of the hospital care, the consultant can help the team understand the family better and feel more empathy for difficult behaviours that may seem callous, unappreciative or interfere with care. Difficult parents often cannot bear the feelings of helplessness, and vent their anger and frustration on hospital staff by being critical and devaluing (Groves & Beresin 1999).

Understanding the experience of the treatment team

Together with different professional roles, treatment team members are likely to focus on different stresses associated with caring for sick children. The neonatal ICU (NICU), a high stress

environment, serves as a good illustration of this principle. Senior paediatricians in the NICU are most stressed by the long hours in the hospital and the conflict this creates with the demands of their personal lives (Oates & Oates 1995). Advanced trainees held in high regard by juniors for their technical skills must cope with their sense of helplessness when they are unable to live up to this image and cannot save the young lives in their care (Jellinek *et al.* 1993). Nurses in the NICU identify overcrowded units without privacy, doctor–nurse tensions, and inadequate pain relief for the neonates as their key concerns (Oates & Oates 1996).

Recommendations

After meeting the child and family for the initial assessment, the consultant will share observations and recommendations with the referring paediatrician and available team members and write a note on the hospital chart. The preliminary formulation and recommendations should avoid the use of psychiatric jargon. Clear practical recommendations to improve coping, address behavioural problems, treat primary psychiatric disorders and maintain safety are key. Hospital records are permanent documents and should not be used for private or informal communications between physicians. One should assume that patients and parents will read the record, as can hospital staff and insurers. No one should write pejorative comments about other clinicians, patients or families in the hospital record. The consultant should be thoughtful about including personal information about the patient or family members, avoiding what is not germane to the care of the patient, such as a past history of parental substance abuse, marital infidelity or sexual abuse.

When presenting recommendations, safety must be addressed first. For example, one-to-one observation will be necessary for an acutely suicidal teenager and behaviours that prevent a child from receiving urgent medical care must also be addressed immediately. Both in the initial contact with the referring paediatrician and in the presentation of recommendations, an understanding of the urgency and time frame in which the referring doctor needs assistance must be attended to by the consultant.

Sharing an understanding of motivations that may underlie maladaptive behaviours can increase empathy for the child and family, but the consultant must work with the team to come up with concrete suggestions that can be implemented. For example, the consultant could recommend that all procedures for a fearful child occur in a treatment room, so that over time the child will come to feel safer in his or her room and in the playroom. The primary nurse might resist this idea if he or she was responsible for getting a potentially thrashing child to the treatment room on his or her own. Perhaps premedicating the child with an antianxiety medication, and getting the paediatric house officer and the parents to walk the child to the treatment room will help the nurse feel respected and able to endorse the plan. Similarly, a paediatric team would need specific recommendations to help them deal with angry demanding parents. Regular

meeting times with the senior paediatrician in which the important information of the day is communicated may help decrease the parents' anxiety and therefore their anger, but a regular check-in time with the paediatrician may be hard for him or her to achieve in person. Perhaps the consultant could commit to a regular time for a phone contact, during which he or she could tell the parents approximately when he or she would be on the unit that day.

Emergency consultations

The most common emergency consultations relate to the suicidal or self-abusive child admitted after an overdose or other act leading to self-harm, such as jumping off a high place or lacerations from wrist-slashing. The consultant's first recommendations focus on the child's immediate safety in the hospital setting. Hospital units are not designed with the safety of a self-injurious child in mind. There is potentially dangerous medical equipment throughout the unit, including sharp objects and flammable substances (oxygen). It is therefore necessary to assess carefully the child's risk for self-harm in the hospital. After having made an impulsive suicide attempt or gesture that is serious enough to require medical hospitalization, many children are frightened, regret their actions, feel supported by their families and may be assessed as being at low risk to hurt themselves while hospitalized on the medical unit. Others only regret that the suicide attempt was unsuccessful, or are uncommunicative, and leave the consultant unsure of their mental state. When unsure, one must err on the side of safety, providing one-to-one observation of these children on the paediatric unit. Once safety has been assured, the consultant will assess the precipitants for the acts of self-harm and recommend an appropriate treatment for the hospital and disposition.

Another common urgent consultation is for behaviour that disrupts essential medical treatment. This behaviour is sometimes driven by extreme anxiety, as in the frightened preschool-age child who kicks, screams and bites when approached; at other times it is agitation in the setting of delirium; disinhibition following head injury; or angry threatening behaviour in a child with a clear sensorium, but who views the essential medical treatment as an unnecessary assault. Medical treatment of the cause of delirium, reassessment of medications affecting the central nervous system, antianxiety medication, antipsychotic medication, behavioural treatment plans, and sensitive education may be appropriate interventions depending on the aetiology of the difficult behaviour.

Parental behaviour may be the reason for an urgent consultation. Parents may be refusing essential medical treatment for the child or acting bizarrely. The reason for the parental actions may be unclear or may represent cultural beliefs at odds with standard medical practice, mistrust of the hospital staff, psychiatric illness in the parent, or extreme anxiety. Hostile parents making physical or litigious threats may interfere with critical care by frightening the medical staff. Paediatric staff often underesti-

mate the danger of an angry teenager or parent and the consultant's sensitivity may facilitate the appropriate use of hospital security personnel.

The consultant may be asked to interact directly with the parent to help the referring physician work with the family or to recommend further assessment, including social services or court interventions. Often parents who are obstructing essential care for their child are doing so because they are themselves overwhelmed with helplessness and are trying to control what they see as uncontrollable. They mistakenly choose a counterproductive stance to achieve the feeling of being a powerful agent in the treatment decisions for the child. By helping the parent to feel that he or she is an essential member of the decision-making process and thus has some control in productive ways, many parents will step out of a combative stance and into a more collaborative one. There are specific legal interventions that are implemented when parents prevent a life-sustaining treatment, such as a blood transfusion for a child with life-threatening blood loss. These interventions include emergency assessment of guardianship by a judge to determine what is in the best interest of the child, and may lead to custody shifting to the hospital acutely, followed by temporary and permanent custody decisions occurring after the emergency medical situation is resolved or stabilized.

Primary psychiatric illnesses

Depression

Depression is common in the hospitalized child. It may be a secondary response to the stress of acute or chronic illness, or it may be primarily presenting as psychosomatic illness or behavioural problems including self-harm. Recognition of depression in childhood is a relatively recent phenomenon and the treatment of depression with psychotropic drugs is still viewed as controversial by some clinicians. One barrier to the appropriate treatment of depression in hospitalized children is the misconception that depressed mood and neurovegetative symptoms are an appropriate response to serious illness and thus should not be identified as depression nor treated. Individual and family therapy, play therapy, behavioural therapy and medication are useful modalities in the hospital setting. Our clinical experience supports the use of antidepressants in the depressed ill school-aged child or adolescent. Selective serotonin reuptake inhibitors (SSRIs) have become the antidepressant of choice as they are generally well tolerated, have limited interactions with other medications, and present a lower risk of intentional or accidental overdose (see Harrington, Chapter 29).

Anxiety

Anxiety can be secondary to the stresses of the medical condition and treatment or pre-existing. Children with pre-existing generalized anxiety or specific fear of doctors, needles and injections

are likely to have more difficulty adjusting to medical assessment and treatment. In addition to the obvious discomfort severe anxiety causes the child and parents, anxiety can interfere with procedures and complicate history-taking and symptom assessment.

Age-appropriate explanation of medical interventions for older children, and medical play with explanation for younger children, can decrease anxiety. Children from around 6 years of age can learn a variety of coping techniques to help them with anxiety-provoking procedures. Many children will respond to distraction, breathing exercises, visualization or hypnotherapy (Jay *et al.* 1983, 1985; Kuttner 1987; Kuttner *et al.*, 1988).

Clinicians must pay attention to minimizing pain for every child (Schechter *et al.* 1993). The use of anaesthetic creams before procedures, reducing the number of times bloods are drawn, and treating chronic and acute pain with analgesics should be standard practice. For young children, all painful procedures should occur in a treatment room and not in the child's bed nor in the playroom. Protecting the child's bed and the playroom as safe havens will eventually help the young child relax in these settings.

With quality pain management, relaxation techniques and preparation for procedures, some children will continue to be too anxious to comply with treatment and may suffer sleepless nights, be nauseated, or frantic during the hospital stay or in anticipation of visits to the hospital. Benzodiazepines may be helpful adjuncts to lessen debilitating anxiety. In young children, one must be aware of the potential for benzodiazepines to disinhibit children and thus worsen coping difficulties.

Anorexia nervosa

Anorexia nervosa is characterized by significant weight loss or the absence of appropriate weight gain for age and height in the setting of distorted body image and fear of gaining weight (see Steinhausen, Chapter 34). Paediatric hospitalization usually occurs when there has been rapid or profound weight loss, cardiovascular abnormalities, electrolyte imbalance and hypothermia. The goal of paediatric hospitalization is medical stabilization with nutritional assessment and treatment, psychological assessment of the child and family, and recommendation for level of psychiatric intervention after medical stabilization (Andersen *et al.* 1997). If the anorexic patient has been in outpatient psychotherapy, it will be key to seek input from the outpatient therapist. Medical hospitalization may represent a failure of outpatient psychotherapy.

It is often helpful to institute a detailed anorexia protocol, because the care of the anorexic teenager differs from the care of younger medically ill children. The protocol begins with very restricted activity, including bed rest, observation during and directly after meal times, bathroom privileges only after weight gain has begun, and limited phone contact and visitation with family. As the child demonstrates that he or she is able to meet nutritional goals, privileges are added.

Once the child is medically stable, recommendations about disposition can be initiated. The consultant will consider:

- 1 the anorexic patient's motivation to change;
- 2 inpatient eating behaviour;
- 3 the family's commitment to psychotherapy;
- 4 their ability to put the child's health as a top priority;
- 5 the input from the outpatient psychotherapist and primary paediatrician.

The child may need to be transferred to an inpatient psychiatric hospital or may return home with outpatient psychotherapy, and weights and vital signs monitored by the paediatrician.

Paediatric and nursing staff often feel frustrated and angry at anorexia patients, whom they see as making themselves ill. This is in stark contrast to other children on the paediatric unit who are viewed as struggling to overcome 'real' illnesses. Some staff members engage in frustrating arguments with the anorexic patient believing that a logical interchange should convince him or her that he or she is not fat. Many anorexic patients will present as sweet and compliant, but a few days into the hospital stay be discovered in secretive behaviours such as hiding food, or faking weight gain by water loading. When these behaviours are revealed, staff may feel manipulated and deceived. Team meetings provide an opportunity for staff members to voice the feelings engendered by the patient, to ensure that the protocol is being instituted consistently, and that the team is unified in providing high-quality compassionate care.

Psychosomatic illness

Some children will be admitted to paediatric departments with intense persistent somatic complaints, such as headaches, abdominal pains, bowel complaints, neurological symptoms or fatigue. Paediatricians may suspect that the intensity of the symptoms or the combination of complaints exceeds what would be explained by a medical condition and reflects underlying emotional factors and thus may seek a consultation. The paediatrician's assessment that psychological factors are influencing the somatic presentation is at odds with the child and parents' understanding of the aetiology of the condition. In psychosomatic illness, the somatic complaints are an unconscious expression of emotional issues. Additionally, some families are overly invested in an exhaustive medical work-up to prove a purely medical aetiology. Although this may appropriately arouse paediatric concern, the family believe that the child is seriously ill and therefore do not view the medical tests as unnecessary or risky. Typically, psychiatric consultation is resisted, treating the recommendation for assessment as an insult, and evidence that the medical team either does not believe the symptoms or medical condition to be 'real' or is unwilling to investigate fully all the medical possibilities.

The term 'psychosomatic illness' spans a range of illnesses, conditions and presentations that include not only symptoms with no clear medical aetiology, but also those that have a medical basis, such as chronic pancreatitis or kidney disease with chronic stone production, in which the child's somatic

complaints may reflect a flare of the baseline illness or may be an expression of emotional distress, or a combination of both factors. Also encompassed under the term 'psychosomatic' are medical conditions that generate debate in the medical community, such as chronic fatigue syndrome (ME) and Lyme disease, in which a family may find substantially different responses to the child's condition in different treatment centres, reflecting the differing opinions of medical specialists. In the absence of clear medical knowledge or consensus about an illness, the potential for conflict between family and medical staff is heightened.

It is common for the family to seek multiple medical opinions about the child's somatic complaints, and sometimes to choose the most aggressive specialists, e.g. those who do the most diagnostic testing or prescribe the most medications. All too often the child is maintained on multiple medications in spite of little or no improvement in symptoms. The same diagnostic tests may be repeated to satisfy parental demands for action or in an attempt to decrease persistent patient and parental anxiety about undetected serious illness. In some cases, the parents may cling to insignificant positive findings from the diagnostic work-ups to vindicate their belief that a yet undiscovered medical aetiology exists. For these families, the relentless pursuit of a medical explanation overshadows their concern about the morbidity associated with invasive tests.

The best approach to treatment is a joint medical and psychiatric one. The psychiatric consultant must be willing to listen to the somatic symptoms and associated medical hypotheses in order to establish an alliance with the patient and family. Presenting the consultant's role as one of helping the child cope with chronic symptoms that are interfering with school, peer activities or family life is less threatening to the family than suggesting that the consultant has been sought because the symptom intensity reflects psychological issues. The child and family must be reassured that the presence of the child mental health consultant will not be associated with reduced access to the medical team, but is truly an adjunct to ongoing medical care. The paediatrician has the important role of re-examining the child regularly, reassuring the patient and family that no worrying new findings exist and not acquiescing to unnecessary testing.

The medical team may recommend a graded re-entry plan to work toward getting the child back to age-appropriate activities. The child and the parents are often very anxious about the child's return to normal activities and a stepwise re-entry plan addresses some of this anxiety. The child may benefit from a face-saving explanation for his or her physical symptoms that includes reasons why he or she is now able to work toward successful reengagement in normal activities. The parents will need support to endorse the child bearing some amount of anxiety and discomfort during this time. If the parent insists on withdrawing the child from any activity at the onset of somatic complaints, the child is unlikely to be motivated to cope with his or her symptoms or to find another medium for expression of emotional distress.

Initially, the consultant is likely to hear that everything was

going well for the child and family until the onset of the somatic symptoms, but over several meetings the pre-existing emotional issues may begin to surface. The consultant might discover, for example, a learning disability that interferes with school adjustment, parental discord, depression or the recent death of an important family member.

Commonly, the child's somatic symptom stabilizes the family system, which is organized around the illness being the designated family problem. The symptom becomes a solution to avoid more provocative and difficult feelings. Family therapy or parent guidance therapy will often be required to address the issues that the illness has served to mask, while the child's individual therapy will address underlying psychiatric illness as well as communication skills that allow the child to express feelings with words instead of somatic symptoms, and thus help improve self-esteem.

Non-compliance

Non-compliance with medical treatment is estimated at 50%. It varies according to illness and in some illnesses may be as high as 88%. Surprisingly, confidence in the efficacy and importance of the treatment does not necessarily translate into improved compliance rates (Van Sciver *et al.* 1995). Indeed, illness-related compliance rates are likely to reflect a complex array of factors including the convenience of treatment, impact on age-appropriate activities, effect on appearance, chronicity of treatment demands, discomfort caused by illness exacerbation, and degree of correlation between single acts of non-compliance and negative consequences. The impact of non-compliance ranges from essentially harmless, in the case of a child with otitis media who misses a single dose of antibiotic, to life-threatening for a brittle diabetic who ignores his or her insulin needs and precipitates an episode of ketoacidosis. When consultation is sought for non-compliance, usually it is because of risk to the child's health, escalating conflict in the family, or frustration with inappropriate use of medical resources, as with the asthmatic who does not take maintenance medication and therefore is seen repeatedly in the emergency room.

Medical non-compliance is multidetermined, associated with medical education, active vs. passive coping style, pride vs. embarrassment with respect to self-care, impulsivity, family support, peer support, relationship with medical providers and underlying psychiatric disorder.

The consultant's task is to understand why the child is non-compliant and to work with the team to modify aspects of treatments that trouble the child where possible, while working to help the child and family adopt strategies that support clinically important treatments. If there are treatable psychiatric disorders, such as attention deficit hyperactivity disorder, these need to be identified and addressed. Treatment promoting supports, including disease-specific support groups, more frequent meetings with clinicians and psychoeducation groups, can be helpful.

Child abuse

Possible physical abuse, neglect (see Emery & Laumann Billings, Chapter 20) and sexual abuse (see Glaser, Chapter 21) may need to be considered. Without educated suspicion, abuse will often go undetected. Injuries to body surfaces that do not commonly bear the brunt of an accidental fall, multiple broken bones or bruises in various stages of healing, bruises that resemble finger marks, belts or cords are highly suspicious. Implausible or inconsistent stories from caregivers, and inappropriate delay in bringing a child for medical care should raise suspicion, as should caregivers who ascribe the injury to siblings or self-inflicted injuries.

Suspicion of abuse must be reported to the appropriate social agency. When abuse is suspected, the child should be fully examined for other physical signs. It is important to notify authorities of other children known to be in a potentially unsafe home. The paediatric unit may serve as a safe haven for a child while allegations are being investigated.

Sexual abuse is believed to be seriously underreported. The prevalence has been estimated at around 15% for boys and as high as 38% for girls under the age of 18 (Crewdson 1988). Three common presentations of sexual abuse on a paediatric unit are:

- 1 a child with traumatic injury to genitalia or a sexually transmitted infection;
- 2 a child who reveals that sexual abuse has occurred without physical evidence; and
- 3 a child who has physical symptoms suggestive of sexual abuse, but who has not disclosed any abuse or a perpetrator (Sugarman 1990).

Münchhausen by proxy

Münchhausen by proxy syndrome is a form of child abuse that is particular to the paediatric setting (see Emery & Laumann Billings, Chapter 20). A parent, usually a mother, consciously distorts or fabricates medical symptoms attributed to her child, including acting to create symptoms of medical illness in the child, and then seeks paediatric hospitalization and interventions for the child. The understanding of the aetiology of this syndrome consists of a character-disordered parent who finds the support of the hospital staff and/or the drama of the child's purported illness so personally gratifying that the morbidity associated with unnecessary tests and even the death of her child becomes secondary to her need to keep the child in the sick role. These parents may ultimately kill their children, e.g. by injecting faeces into an intravenous line to cause sepsis, or suffocating a child in an attempt to create a documented cardiac or pulmonary arrest. They may use their own blood to add to a child's urine sample or vomitus in order to maintain the heightened concern of the medical team.

There is no exact profile of a Münchhausen by proxy parent, but some perpetrators have worked in medical settings. The parent is unlikely to disclose her own psychiatric history, but many

have documented psychiatric illness, including suicide attempts, in the past (Souid *et al.* 1998). Usually the mother stays at the bedside with her child, typically an infant or very young child, but at times an older socially isolated child with his or her own reasons to maintain the sick role imposed by the parent.

The mother is often seen as nurturant toward her child and ingratiating with the nursing staff, until it is suggested that the child is well or the medical findings seem spurious. At this juncture, the mother usually becomes irate and threatens to or does take the child out of the hospital unless the medical team supports her demands for continued medical interventions. The parent rarely has had long-term relationships with medical caregivers and often the child has had multiple paediatricians, multiple subspecialists and hospital stays in different facilities, each ending with the same angry response to withdrawal of acute care (Schreier & Libow 1993).

This is a difficult diagnosis to prove unless the parent is observed hurting her child, or diagnostic work demonstrates the parent's role such as typing the blood in the child's urine and having it match the mother's blood type, not the child's own. The risk of morbidity and mortality is high (Samuels & Southall 1992) forcing paediatric providers to be aware of the potential for this form of abuse. Suspicion should be aroused when the medical condition does not follow an expected course, the symptoms are inconsistent and puzzling to seasoned clinicians, the symptoms are only observed by the mother or can be traced to an intentional aetiological agent. When suspected, the caregivers should notify the hospital legal team for assistance. All caregivers should be particularly vigilant observing the parent's behaviour, especially when she is unaware. In some settings, the parent has been videotaped thus revealing the abusive actions.

It should also be noted here that, occasionally, when a child has a difficult to diagnose illness or a persistent less likable parent, a member of the medical team will raise the spectre of Münchhausen by proxy as an expression of frustration. Just as it is a form of abuse that should not be regarded as trivial, it is also important not to ascribe uncertainty of diagnosis and parental anxiety to this serious form of abuse. Once suspicion of this diagnosis is written in the permanent hospital record, the parent will be viewed with suspicion by every provider to follow.

Coping with chronic illness

Chronically ill children demonstrate the enormous resiliency of childhood. These children are not defined by their illnesses: there is no typical diabetic or classic asthmatic. To the contrary, chronically ill children have the same range of personalities and coping styles seen in healthy children, and are engaged in mastering the developmental milestones and challenges they share with their peers (Perrin & Thyen 1999).

Estimates of psychological morbidity associated with chronic illnesses in childhood range from 10 to 30% (Bauman *et al.* 1997), which is only slightly higher than the general paediatric population. Greater morbidity is associated with multiple hos-

pitalizations admissions (Geist 1977). Other documented risk factors for adaptation to chronic illness include physical disability and brain dysfunction, pain frequency, younger age, poverty, single-parent family, and increased psychological symptoms in the parents (Knapp & Harris 1998).

Specific illnesses may present particular challenges (Horner *et al.* 2000), such as the dietary restrictions in diabetes or the decreased exercise endurance in advancing cystic fibrosis. Many factors influence how problematic a disease-specific challenge is for an individual child. It is the consultant's job to understand the unique meaning of the illness to the child and family, and to assist in the process of adaptation.

The consultant will need to ask many questions to elucidate the child's subjective experience of the illness. What is the hardest aspect of the illness or treatment from the child's perspective? How does it affect the child's image of him or herself now, and has it changed? Does the child have worries about the future? How do the illness and treatment impact on peer interactions, and favourite activities? When and how does the child tell others about the illness and why? Are there areas of conflict between the child and parent or the child and physician in relation to the illness? What is the child's perception of the parents' worries? Variations of the same questions can be asked of the parents and the siblings.

Chronic illness requires adjustment on the part of the child, the family, and perhaps the school, friends and organizers of activities. The extent to which the child is able to continue with age-appropriate activities and special interests is central to good adaptation. Children with personal strengths, whether in academics, sports, music or interpersonal skills, are likely to have an easier time accommodating to the limits of their illness and treatment because they can rely on their strengths to maintain self-esteem and build important relationships. Temperament is also a factor, with more flexible and outgoing children likely to adapt more easily to the uncertainty and limitations imposed on their lifestyles. Parental support, warmth and attitude toward the illness and the child's adaptive style is key. Parental anxiety, anger, sadness, guilt or blame can impede adjustment.

A number of chronic illnesses have been the focus of particular interest. Strategies are being sought to understand the disease-specific challenges and to illuminate common areas of stress, models for improving compliance, and recommendations for improving quality of life. In addition, improved coping may result in reduced medical costs for emergency visits and potentially unnecessary admissions.

Asthma

Asthma is a common illness of childhood with a paediatric population prevalence of 5–10% and a mortality rate of 1–2% among severe asthmatics (Godding *et al.* 1997; see also Mrazek, Chapter 48). Although overall mortality rates are noted to be declining, the mortality rates among adolescents and young adults are unchanged as is the morbidity of the disease (Conway

1998). Recent studies have sought to understand the factors that affect adherence and compliance, delineate common psychosocial stresses that may act as triggers for asthma attacks, and devise psychoeducational programmes, combined medical and psychological treatment strategies, and teach stress management skills to improve compliance and decrease morbidity (Sadler 1982; Perrin *et al.* 1992; Godding *et al.* 1997; Conway 1998; Rutishauser *et al.* 1998; Randolph & Fraser 1999). Educational programmes should offer clear guidelines on when to call the paediatrician for appropriate timely guidance, while seeking input from the family to ascertain whether there are barriers to these contacts. The impact of triggers in the home should be addressed realistically and empathically. Common triggers, such as smoking and pets, require a major commitment from the family to alter. School-related issues need to be explored from the perspective of the child and the school, such as access to inhalers in the classroom or embarrassment about going to the school nurse. Strategies to improve parent and child anxiety, and to address parent–child conflicts around compliance are valuable.

Diabetes

Adaptation to insulin-dependent diabetes presents special challenges associated with the need for tight control of blood sugar, the intimate relationship between the primary role of food as a source of nurturance and soothing, the meaning of a child's relationship with eating and the parent's role of providing or limiting access to desirable foods, and the mode of monitoring blood sugars and delivering insulin involving needle sticks and thus pain (see Mrazek, Chapter 48). The acute consequences of blood sugar abnormalities include symptomatic hypoglycaemia, hyperglycaemia and ketoacidosis, and the long-term sequelae include effects on vision, renal function and neuropathy. Symptoms associated with hypoglycaemia are often difficult for parents to differentiate from common irritability in young children or for older children to recognize as different from anxiety in themselves. This leads either to more frequent blood testing or a tendency to keep the blood sugars at a higher level than the physician would recommend. Some children will have considerable anxiety about hypoglycaemia, either in response to an actual episode or arising independently. It is key to treat anxiety disorders and concurrent eating disorders in order to improve compliance (Jacobson 1996; Strauss 1996; Burroughs *et al.* 1997).

Parents of children with diabetes may benefit from the support of the child mental health consultant as well as parent support groups to help achieve a healthy family attitude toward eating. Concrete ways to minimize the child's experience of being deprived of age-appropriate food treats, such as having sugar-free desserts at school and at home, altering insulin to accommodate special events, and supporting the child's understanding of how insulin helps him or her grow bigger and stronger are useful.

When patterns of conflict arise between parent and child

around non-compliance, such as lying about foods eaten, hiding sweets and refusing blood monitoring, psychotherapeutic input should be initiated early. Children who enter adolescence with pre-existing parent-child conflict around health maintenance can be expected to have greater difficulty during their teenage years. Non-compliance in insulin-dependent diabetes can be life-threatening, so the full range of psychotherapeutic, educational and family supports should be utilized.

Cancer

Childhood cancer presents numerous challenges to adaptation and development, but does not lead to serious psychopathology in adulthood (Roberts *et al.* 1998). There are predictable high stress points in the course of the illness including diagnosis, onset of treatment, treatment completion, and sometimes recurrence, renewed treatment and end of life care. Psychological support for the child and parents is particularly beneficial at these critical points (see Mrazek, Chapter 48). The siblings too will benefit from support at the transitions in the course of the illness (Murray 1999; Spinetta *et al.* 1999). Diagnosis of a life-threatening illness is understandably frightening to parents and older children, creating a family crisis. Although not commonly the case, some children and parents may respond to diagnosis and aspects of treatment with symptoms seen in post-traumatic stress syndrome (Stuber *et al.* 1998).

Although cancer is rare in children, it is a common medical condition in older adults. Frequently, children and families will face the child's cancer diagnosis with past experiences of cancer in a family member or close friend colouring their understanding of what lies ahead for their child (Hoekstra-Weebers *et al.* 1999). Exploring the child's understanding of cancer with attention to the role of development, as well as the understanding of the parents and the other siblings, is important and offers an opportunity to differentiate the child's situation from that of others, while potentially uncovering misconceptions about the illness.

Challenges to psychological adaptation include persistent pain whether as a result of the cancer or of the procedures (Ljungman *et al.* 1999), persistent debilitating side-effects of treatment such as nausea, alteration in body image, school disruptions, compromised peer relationships, interference with ability to engage in favourite activities, and conflicts in the family. Adolescents may worry about future health status, sexual function and reproductive capacities, and future career choices (Kasak & Meadows 1989; Roberts *et al.* 1998).

During the course of cancer treatment, many children develop strong positive relationships with members of the medical team, experience a special closeness with supportive parents, and maintain key pre-existing peer friendships while acquiring new friends in the hospital. Many children will report feeling a special sense of purpose for living as a result of the cancer diagnosis and most will be treated with special status as a result of the illness. Resiliency and positive life change are also part of the cancer experience (Woodgate 1999).

Organ transplantation

Liver, kidney and lung transplantation are current realities for the paediatric population. Transplantation centres in the USA are required to include psychological assessment as part of the work-up in order to receive accreditation. Data on criteria for approval of candidacy for transplant are vague. The serious disease process leading up to transplantation, the risks of surgery, the long-term medical management of organ rejection post-transplantation, the threat to survival, and the vast array of medical personnel involved should place these children in the highest of high-risk populations. It is noteworthy therefore that the data on adjustment to liver transplantation suggests that overall these children view themselves as healthy and competent (Mastroiannopoulou *et al.* 1998; Tornquist *et al.* 1999). Not surprisingly, some children and parents are vulnerable to anxiety, and there is broad acceptance in transplant centres of the role of emotional support (Ullrich *et al.* 1997; Walker *et al.* 1999).

Dying in the hospital

The death of a child is an enormous tragedy that affects every member of the child's family. There is no way to protect a child or family from the unique pain of the loss of a child but sensitive care at this difficult time may serve to lessen regrets and support the impending process of bereavement. Careful attention to the child's quality of life in these last days or hours is essential. Attending to pain, anxiety and privacy/dignity needs is key. Adapting the medical setting to allow parents to nurture the dying child within the limitations of the setting, or facilitating a child's return home to die, can play a significant part in the family's experience of the death and the subsequent bereavement (American Academy of Pediatrics 2000).

The emotional impact on the medical team also requires careful attention in order to best preserve each team member's ability to continue to deliver quality care into the future. The medical staff need recognition of their grieving process. Some units will have staff meetings including the child mental health consultant or other facilitator after every death or after those deaths that are most troubling to staff members, such as favourite patients, trauma-related deaths or unanticipated deaths.

A common misconception is that a family's attachment to a child increases with age, thus making the death of an infant less difficult. Many of the hospital-based paediatric deaths occur in NICUs or during infancy. The death of an infant is both the loss of the unique child, whom the family is coming to know, and the loss of possibilities for who he or she could have become. Key to supporting the family of a dying infant is respecting the infant's full status as a loved child. This may include facilitating religious ceremonies such as a naming or christening, creating mementoes such as photographs, footprints or a lock of hair, and creating the most loving situation possible for the moment of dying such as providing a private room and allowing a parent to hold the infant at the time life support is disconnected.

From age 3 years onwards, the child's personal experience of impending death should be considered. The child should be offered developmentally appropriate opportunities to express thoughts and fears associated with dying either with words, drawings or through play. It is not uncommon for even 2 and 3-year-olds to verbalize explicit thoughts of joining dead grandparents and seeing angels, but it is also common for dying children to focus only on wanting parents with them at all times, and exhibiting a shift in behaviour with more resistance to medical treatment, loss of interest in activities and food, but without any explicit verbalization of an awareness of dying.

Children of all ages, but especially younger children, are likely to take their cues about whether explicit discussion of death is permissible from parents and caregivers. When parents invite this dialogue it is common for it to occur. When parents signal that such discussion would be unbearable, the child is likely either not to speak about dying or to talk with a medical staff member when the parent is not present.

Child mental health consultants may help prepare parents for discussions with their dying child. Asking the parents for observations about shifts in the child's behaviour may help the parents recognize that they would not be introducing a new scary idea to the child in talking about death, but would rather be accompanying the child in the thoughts that he or she is already engaged in. Asking open-ended questions about worries, enquiring whether the child has questions that he or she is afraid to say aloud, or asking if he or she thinks about peers from the hospital who have died, may serve as invitations to begin the dialogue. Reminding children that articulating worries does not make them happen may free some children who are worrying silently to speak. Many parents will feel more comfortable embarking on end of life conversations with a child if they are told that they can welcome the child's questions warmly without having specific answers. 'I am interested in your ideas', 'What got you wondering about that?', 'Your good questions deserve good answers', 'I want to think about that or talk to our minister or the doctor' are examples of reasonable responses to a child's existential or medical questions. In the role of child mental health consultant, one of the most useful comments in response to questions about death is to tell a child 'I don't know what it is like to be dead, because I have never been dead. But, I am always interested to hear children's ideas about it.'

Children from age 7 onward may talk about the life experiences that they will not get to enjoy. These discussions challenge a parent's or professional's ability to bear the sadness of facing an untimely death. The child may talk about not getting to attend the next school year, never being able to drive a car, not having the chance to ride on the biggest roller coaster at the amusement park or not growing up to be a doctor or a teacher. It is often the specificity of the opportunities lost in the words of a child that is so evocative. There is a sense of privilege that one experiences in listening to children as they face the end of their lives that is as special as it is sad.

Often children will talk about being tired of the fight against the disease and will look to parents for permission to give up.

When the surviving family members can support each other in the painful process of letting go of the beloved child, believing that everything that could be done was done, and that further treatment would be unfair to the child, the final phase of dying seems more peaceful. In the setting of a long battle against an illness, it is easier to get to this difficult emotional state. In the setting of an acute event with little time for adjustment, or when parental discord interferes with the parents' ability to grieve together, such peace is harder to achieve.

The consultant should encourage subspecialists to follow up parents 6 months to 1 year after the death of a child. These calls can assess the parents' grieving and need for referral as well as help the subspecialist grieve and come to closure.

Conclusions

Child mental health consultants must stay attuned to the changes in the field of paediatrics. Advances in pharmacology, genomics and technology offer new hope and new challenges to psychosocial adaptation. Patterns of access to consultation will need to reflect shorter hospital stays and utilization of outpatient venues. New technology, such as telemedicine, may offer novel access to consultative expertise. Research in compliance outcomes, efficacy and quality of life become increasingly important as the financial pressures of modern medicine force the consultant to justify the value of the work.

However, many of the key features of quality consultation will remain unchanged. The consultant will continue to bring to the multidisciplinary medical team the combined expertise of psychodynamic understanding, psychopharmacology, a developmental perspective on the meaning of illness, adaptation to trauma, knowledge of psychiatric conditions, behavioural interventions, and central nervous system influences in medical illness and as a result of medical treatment. The goal will remain to answer the consultation request in a thoughtful timely fashion that respects the needs of the child, the family and the treatment team and facilitates quality of care and quality of life.

Local Specialist Child and Adolescent Mental Health Services

Peter Hill

Introduction

The term 'mental health' refers to a broad concept. Correspondingly, a concept of 'child and adolescent mental health problems' covers a wider range than does 'child and adolescent psychiatric disorders'. It includes problems and difficulties in emotions, behaviours, relationships and development that may not be captured by orthodox psychiatric classification systems and which may be equally well or better addressed by non-psychiatrists. A service for mental health problems therefore implies a multi-professional approach, including non-psychiatric specialists in child and adolescent mental health such as psychologists, social workers and behavioural paediatricians.

Whenever child and adolescent mental health professionals see a child for assessment and treatment they are offering a professional service to that child. In one sense therefore the concept of a child and adolescent mental health service is a personal one. In many countries, provision for mental health assessment and treatment is organized so that one can talk about services in a more civic sense; planned and organized for local groups of people. Such services may be funded by individual families directly, or through health insurance schemes which may be funded privately, or through employers of family breadwinners. Alternatively, there may be provision funded by the state and available free or at reduced cost to a local population when they use it. Not uncommonly, there is a mix of various mechanisms. The thrust of this chapter is to raise issues that are predominantly to do with specialist mental health services that are planned and organized for a local population of children and adolescents, irrespective of the source of funding.

Concept of health gain

Children (a term used here to include school-age teenagers) can experience or manifest a range of problematic emotions, behaviours, developmental asynchronies and personal relationships. These can be conceptualized as mental health needs in that they merit alleviation. Such alleviation is a goal for mental health services and can be referred to as one instance of health gain. The need for such services depends upon how much the population they serve can benefit in terms of the health gain that results from their activity. How health gain is understood will vary somewhat according to what the purpose of a service is.

One view of the objectives of a health service is that it is there

to solve problems. Children present or are presented to it with a mental health problem, which is then addressed and resolved. By and large such a service will be reactive, except to the extent that it takes steps to educate potential referrers to it. In order to describe how well it works in terms of health gain, it would refer to a classification of mental health problems such as a list of diagnoses and the extent to which children seen as patients have these diagnoses and recover from them as a result of treatment.

Alternatively, a service may be seen as promoting mental health in which case it will do more than assess and treat those referred to it. It will include a proactive component and include preventive measures. It would refer to an informing principle, such as social participation or a notion of ideal mental health, as well as a list of diagnoses. This is necessarily a broader approach so that health gain in such a context includes the population's capacity to benefit from prevention and rehabilitation as well as from improvement in symptoms or impairments as a result of treatment.

It is not self-evident that one approach is superior to the other. A service funded predominantly by private health insurance will tend to favour a problem-solving approach because the costing is more straightforward when a child can be considered to have or not have a condition that requires or has benefited from treatment. Social funding is a little more likely to be sympathetic to a mental health promotion approach because most child mental health promotion schemes have been rooted in local populations at risk rather than individuals (see Offord and Bennett, Chapter 52) or because insurance companies often exclude cover for chronic conditions even though these might benefit from tertiary prevention or rehabilitation approaches.

The distinction between each approach has implications for the definition of disorder. Some well-recognized diagnoses, such as attention deficit hyperactivity disorder (ADHD), are essentially defined in the language that parents and teachers use to complain about the child. Similarly, conduct disorder is recognized in terms of the problems an affected child causes other people. A tendency is evident for the condition to be recognized simply by the fact that it is a problem rather than referring to a fundamental explanatory biological or psychological dysfunction.

On the other hand, notions of ideal mental health that underpin a broader approach to child mental health services can promote medicalization of deviance or underperformance if this is responsive to professional intervention. For example, some

Table 63.1 Definition of child and adolescent mental health according to Hill (1995).

Mental health in children and adolescents is indicated by:

- a capacity to enter into and sustain mutually satisfying personal relationships
- continuing progression of development
- an ability to play and learn so that attainments are appropriate for age and intellectual level
- a developing moral sense of right and wrong
- the degree of psychological distress and maladaptive behaviour being within normal limits for the child's age and context

children who do not have the ADHD condition will nevertheless improve their concentration when given stimulants (Rapoport *et al.* 1978) and psychiatrists may therefore be asked to prescribe stimulants for them so that they can improve their school grades.

What becomes apparent is that health gain is a slippery concept. In part this reflects the fact that health is a complex concept, itself susceptible to social influence. Earlier definitions of mental health in childhood and adolescence derived from the World Health Organization's approach (Table 63.1) which promotes an idealistic view, more specifically a model of ideal psychosocial development without referring to how that development might progress.

An alternative approach is to consider mental health as a commodity; something which one has enough of in order to master particular challenges. This is pragmatic rather than ideal and allies mental health conceptually with coping and mastery. This suggests that mental health is something that can be increased by preventive interventions that tutor coping strategies. Impaired functioning becomes a matter of insufficient or poorly selected coping strategies.

There is a third approach to health which neither of the above cover, and that is the issue of the child who contains the seeds of future morbidity or mortality. By physical analogy we would regard someone as unhealthy if within their body there were an as yet undetected carcinoma, even if their ability to develop or cope was impeccable. As our understanding of genetic causation progresses, such a model of health will become more important and it will be necessary to include it in any notion of health gain or health need.

With this in mind, it may be preferable to split our understanding of health into three dimensions that could be measured.

Health 1: the absence of symptoms or signs of a recognized psychiatric disorder.

Health 2: adequate functioning so that challenges can be mastered.

Health 3: the absence of vulnerabilities to future disorder.

It is against such measures that the need for, and the performance of, a mental health service for children can potentially be assessed.

Ascertaining mental health needs

Epidemiological studies have generally confirmed quite high prevalence rates for children's psychiatric disorders: 20% or more for phenomenologically defined syndromes, about 10% if impairment is also included as a necessary condition for diagnosis (Simonoff *et al.* 1997; Meltzer *et al.* 2000). Impairment is not a single threshold but varies and can be quantified, as in the levels of personal psychological functioning described for instance in the Children's Global Assessment Scale (C-GAS) (Shaffer *et al.* 1983) or the Global Assessment of Psychosocial Disability, which is Axis VI of the multiaxial classification of child and adolescent disorders in ICD-10 (World Health Organization 1996). The degree of impairment does not covary precisely with the severity of the psychiatric disorder: in the population study by Harrington's group some children with only a few symptoms of depression were more handicapped than others with numerous symptoms (Harrington & Clark 1998).

Impairment is known to be a key variable in determining referral to specialist services (Garralda & Bailey 1988; Goodman 1999). Furthermore, many children are impaired by their psychological difficulties without these being sufficiently severe to be classified as disorders—as many as half of all children attending clinics in the Great Smoky Mountains study (Angold *et al.* 1999). In the latter study, the fact of a child's problem being below threshold for DSM-IV caseness did not stop physicians treating it.

Most children with identifiable mental health needs according to diagnosis will not be seen in specialist child mental health services (for recent studies in the UK, the USA and France see Gasquet *et al.* 1999; Laitinen-Krispijn *et al.* 1999; Wu *et al.* 1999; Meltzer *et al.* 2000). Clearly, factors other than diagnosis operate in determining who is seen.

In the group of children that might be defined as having sufficient impairment to be regarded as cases according to major classification systems, the actual diagnosis has some effect in determining whether they are referred and how they are treated, although different studies provide different estimates of its power and some find a negligible effect (John *et al.* 1995). The power of diagnosis in determining clinical engagement probably varies with what is provided within a range of services. For instance, diagnostic category had less impact in predicting admission to hospital at the well-provisioned demonstration site in the Fort Bragg study than in the comparison site (Bickman *et al.* 1996). Clinical diagnosis alone is a poor indicator of level of service needed (Harrington *et al.* 1999), as is level of intellectual disability for children with general learning disability (Haveman *et al.* 1997).

A third variable to be considered in predicting whether a child will be referred to a mental health service is the burden their problem places upon their family. It is usually the case that the agents of a child's referral to a health service are the parents so it is not surprising that in studies of service utilization, burden emerges as a key element in determining referral to specialist services (Angold *et al.* 1998; Wu *et al.* 1999; Rawlinson & Williams

Table 63.2 Proxies for estimating local child and adolescent mental health need.

Perinatal mortality rate
Infant mortality rate
Under-16 pregnancy rate
Proportion of lone-parent families
Number of children in temporary housing
Number of children on the child protection register
Number of children looked after by the local authority
Number of children with a statement of special educational needs
Number of children on the disability register
Number of children accommodated with private fostering agencies
Number of children absent from school without authority
Number of children excluded from school
Number of young carers
Number of refugee children
Number of young people involved with the police

2000). This relates interactively with service provision, so that stress among caregivers for emotionally disordered children increased with poor co-ordination of services (Yatchmenoff *et al.* 1998).

In order to measure the extent of mental health need in a population, a direct epidemiological approach would assess all children (for instance in a particular school) or a sample of such children in one or more stages. Even the latter may be prohibitively expensive if the population is large. With this in mind, a number of proxy measures or indicators have been suggested, using particularly statistics that have been collected for other means (see Table 63.2).

Such attempts to quantify need do not predict absolute levels of required health care; rather, they indicate how resources might be allocated relatively within a population.

Targeting and focusing

Given the common nature of child mental health problems, it is unlikely that any society would ever be able to allocate specialist child and adolescent mental health care to all affected children. Nor would this necessarily be appropriate. Mental health problems are likely to coexist with social privations, physical health problems, educational difficulties and wider family or peer group relationship problems. Some of these are primary in terms of a chain of causal factors and the mental health complications will resolve when the primary conditions are addressed in their own right.

Furthermore, some childhood mental health problems are milder than others. Some authorities have used different descriptive categories for different levels of severity (Health Committee 1997) and imply a hierarchy. Thus, sleep-settling problems or breath-holding episodes in preschool-age children,

enuresis in middle childhood and private hypochondriacal anxieties in teenagers are generally mild and may be termed *mental health problems*. Persisting and severe extremes of emotion or behaviour which are significantly impairing and associated with considerable suffering are *psychiatric disorders* and are listed in formal psychiatric classification systems as diagnoses. Among these, children's disorders that are similar in form to serious adult disorders, such as bipolar disorder or schizophrenia, are *mental illnesses*.

There is a terminological problem with such an approach because the term for the milder conditions ('problem') is also that commonly used to encompass all psychological morbidity. Nevertheless, there is value in drawing attention to an apparent hierarchy of severity, particularly when detection is considered, because some adult inventories predominantly pick up the relatively less common cases of mental illness whereas these may well be missed by some epidemiological screening instruments for child psychiatric disorder. However, this framework of terms cannot consistently predict which diagnoses belong to which group and breaks down when conditions classified within a list of psychiatric disorders can be mild or severe yet true to type in form. Unipolar depression, Tourette syndrome and obsessive-compulsive disorder can all present at varying degrees of severity: from that associated with the terminology of mental health problem at one extreme to devastating and crippling severity at the other. Nor does such an approach work well with developmental disorders, such as autism, for similar reasons. As it covers the whole field and allows a multiprofessional and multi-agency approach, it is worth retaining for service planning reasons but no more.

Mild psychological problems can usually be dealt with by health professionals who are not specialists in child mental health, so long as they have had some training. Advice and information for parents and teachers of young children, and for teenagers in their own right, straightforward advisory or simple behaviour programmes can be implemented without the need for specialist input.

Some professionals concerned with children, such as paediatricians, educational psychologists, therapists or teachers, have a significant yet not encompassing knowledge of child mental health. Without being specialists in child mental health they can make a significant contribution to assessment and treatment, especially of mild and moderate problems. Indeed, in many settings they see more disturbed and disturbing children than mental health services do (Kurtz *et al.* 1994).

Child mental health specialists will see a number of children while working solo and this will overlap with the activities of this group although extend the range of problems that can be managed. The work may be directly with children and their families or be consultative to other agencies or parts of a service.

More complex cases, those with severe, entrenched and comorbid patterns or with multiagency involvement, will need a team approach, traditionally from a multidisciplinary group operating in an outpatient or day patient setting. Cases that cannot be assessed or managed at this level will require highly special-

ized services such as day units, inpatient units or highly specialized outpatient clinics.

This differentiated approach represents a spectrum of resource that attempts to correlate resource or spend with clinical severity and complexity (extent of mental health need). It also makes the best use of rare or costly specialist expertise while acknowledging the contribution that less specialized professionals or services make to child mental health work. It assumes a gradient of severity and complexity rather than a single threshold of caseness. In the UK, it is referred to as a tiered service model and attempts have been made to link it across agencies to form a matrix but, although it is a recommended pattern for child mental health services, it has not yet been either fully developed or evaluated. The approximate equivalent in the USA is the continuum of care approach, evaluated, for instance, in the Fort Bragg experiment (Bickman *et al.* 1996).

Community and hospital services

In a number of countries there has been a parallel evolution of child mental health services in the community on one hand (child guidance clinics/child and family consultation centres, etc.) and the hospital or university clinic on the other. The community care approach, fashionable in general adult psychiatry, is often extended in an unthinking way to child and adolescent mental health so that hospital-based clinics, which are nevertheless community-focused, may be seen as undesirable on ideological grounds. Coupled with this is the relatively low demand by child mental health for hospital services such as inpatient beds, investigative imaging or chemical pathology. This, together with the expense of hospital premises, has provided further impetus for child mental health activity often to be situated away from hospitals.

Where this has happened there seems to have been greater separation from paediatrics and sometimes from adult psychiatric practice although this can be obviated by establishing community polyclinics. The opportunity to move mental health services to where the children predominantly are (schools) has not usually been taken, although there are arguments that this would be logical (Kestenbaum 2000) and there have been valiant efforts to provide this, especially in the USA (Adelson 1999).

The risk of community-based practice is that of professional isolation from colleagues, libraries and regular academic meetings. Cross-cover, so that colleagues can attend distant academic and professional meetings, is harder to obtain than in a hospital setting. There are other potential impediments to the development of a service. Innovations are apparently adopted more slowly if there is no colleague of the same profession with whom to discuss methods. Training posts are harder to establish if there is a relative lack of academic support. Community clinics sited in small buildings are harder to expand physically.

Nor is it the case that community-based provision is necessarily cheaper. Harrington *et al.* (2000) found no significant dif-

ferences in cost or outcome to service or family when hospital-based outpatient and community clinic services for young children with behaviour problems were compared. Ideology seems a poor basis for blanket service provision and there are options for adopting a flexible approach, especially when interface with primary care systems is the focus. For instance, the use of non-specialist community-based health visitor services, supported by mental health training and supervision, can be shown to be effective (Davis & Spurr 1998).

The above remarks are relevant for developed countries with established systems for child and adolescent mental health promotion and care. Models more feasible for developing countries might need to be based on existing primary mental health care systems (Nikapota 1991; De Jong 1996; Khoja & Adlaim 1997; Rahman *et al.* 2000).

Generalist or specialist?

As a general rule in medicine, specialist centres achieve better results than generic services. This has to be offset against expense and inconvenience to patients who have to travel further. A point of balance needs to be established for a specialty that is predominantly community-orientated and outpatient in nature. A truly generalist service will have to make compromises. Premises suitable for preschool-age children are not necessarily judged favourably by middle or late teenagers. Inpatient units that admit teenagers with conduct disorders as well as those with anorexia nervosa are not viewed favourably by parents (Health Committee 1997). Staff with expertise in managing self-injurious behaviour in a child with general learning disability are not necessarily able to cope with borderline personality disorder. Heroin dependency and epilepsy have different nursing needs.

On the other hand, specialized services make exclusions, by definition. A well-planned service that provides broad coverage can allow for this but, even so, comorbidity can result in some children being hard to place, e.g. a 17 year old with both brittle diabetes and self-harming behaviour.

It is sometimes assumed that specialized services are for rare conditions, e.g. gender identity disorders. On the other hand, common conditions such as ADHD may best be managed in a clinic devoted to it (Taylor & Hemsley 1995). The arguments in favour include the use of routines for procedures such as questionnaire completion, the availability of electrocardiography (ECG) services, the presence of particular professionals or provision of parents' groups on a specified day, and a setting that allows informal educational contact between concerned professionals on one hand and between affected families on the other.

In achieving some sort of balance, a common trend has been to separate some features of services for children and for adolescents. In Finland, for instance, these are two separate mental health services (Piha & Almqvist 1999). In many countries, inpatient services for these two developmental epochs are differ-

entiated, not uncommonly with a tendency for children's units to be close to paediatric nursing resources and adolescents to be near adult psychiatric facilities.

Contextual issues

A child mental health service rarely exists in isolation because children with mental health problems often have other exceptional needs to be met: educational, physical, forensic, etc. Children who can no longer be looked after by their families and who enter some form of charitable or public residential or substitute family care are known to have a high rate of mental health problems (McCann *et al.* 1996; Dimigen *et al.* 1999), as do recidivist young offenders (Kurtz *et al.* 1998), the homeless (Vostanis *et al.* 1998) and children with chronic physical conditions (Eiser 1990). In each case there will be non-mental health care professionals involved in the management of such children who can potentially contribute to their mental health and assist in the resolution of mental health problems. Their ability to do this will be assisted by consultation arrangements with local child mental health services, and although it has been hard to evaluate the contribution of such input there is little doubt that it is well received (see Nicol, Chapter 64).

If the resource spectrum (tiered service) which can be established within a health service is expanded to social, educational or criminal justice systems, a matrix can be drawn that resembles a pyramid (Williams & Richardson 1995). A relatively small number of children or teenagers will be known to several agencies and is likely to consume a considerable slice of their budgets. Such an arrangement is an obviously sensible move where agencies duplicate each other's service inputs, yet interagency communication is notoriously ineffective (Health Committee 1997). Establishing a matrix of concern and provision for child and adolescent mental health enables a contextual approach and sharing rather than duplication of resources.

Coverage

There are common uncertainties about the boundaries of a child and adolescent mental health service. Part of the reason for this is the tendency for some children to be clients of several social agencies because of their general distortion of social or psychological maturation. However, there are further administrative confusions that are shared by other areas of children's medicine, especially the single-organ specialties.

One is the upper age limit. In most countries, paediatrics is preoccupied numerically with babies and preschool-age children. Adolescents with physical disorders are often seen by adult physicians and surgeons. Child and adolescent psychiatry cannot reliably take its cue from other aspects of children's medicine in such circumstances. Other social guidelines do not help. There is no clear-cut boundary between childhood and adolescence and a variety of age thresholds separate the two. Bound-

aries defined by biological, social, or educational considerations rarely coincide.

Not surprisingly therefore different countries and different services set different upper age limits for the age range served by a child and adolescent mental health service. This would not matter particularly if there was consistent dialogue between adult and child services but this cannot be guaranteed. Children with ADHD, conduct disorder or specific developmental disorders who have been managed by the health services as adolescents can easily find no adult service willing to take them on. The mental health needs of the children of adult psychiatric patients are often, it is said, overlooked by the psychiatrist who is seeing the parent (Poole 1996).

Children with a measure of general learning disability are at increased risk for psychiatric disorder yet may, in some countries, also be excluded from mainstream child mental health services. Their needs may be addressed by developmental paediatrics or by all-age mental handicap services instead.

Access to mainstream child mental health services may also be difficult for children who do not have a conventional family and are looked after by charitable or statutory agencies, for refugee children whose families have other priorities or do not understand the system, and for ethnic and linguistic minorities (Vostanis *et al.* 1998).

Duplication

There has been a recurring problem of duplicated and competing child and adolescent mental health provision, particularly between clinical psychology, child and adolescent psychiatry, and community paediatrics. A child with recurrent enuresis, for instance, might be seen in any service. To an extent this has been reduced in some places by the adoption of a tiered service structure but there persists a relative failure to differentiate what might best be treated by medical specialists, what by psychologists, and what by combinations of both. Child psychiatrists prefer, it would seem, to work in teams, but to what extent this is efficient is untested. Their medical responsibilities to examine bodies and mental states, to prescribe and to seek the application of special laws are universal but it seems to be the case that many would welcome a wider brief.

Components of a child and adolescent mental health service

The coverage of a specialist child and adolescent mental health service can only be decided by referring to its context and the contributions (or deficiencies) of other adjacent services, such as education or social care. Doubtless, the roots of a service will be in primary health care of some sort (see Garralda, Chapter 65) where the greatest number of children would be seen by any health service. Specialist services might be directly accessible for families but are more likely to be referred to by some form of

gatekeeper within the health service (family doctor or paediatrician) or from an adjacent service (such as a special educational needs teacher). It would be rational to anticipate that initial contact with a referred child would be provided by only one or two professionals in order to use resources efficiently. Most children's problems might be dealt with at that level but some will require more detailed assessment by a specialist outpatient clinic, multidisciplinary team, or local day unit. Relatively few children require inpatient management so that an inpatient psychiatric unit appropriate to their age might be more remote if there is an insufficient number of children needing admission in a particular locality. A service would need access to such a unit but it might not be a managed part of the local service.

In order to facilitate other agencies, there needs to be liaison arrangements with, for instance, paediatrics, special education resources, and social care or voluntary agencies.

A generally replicated finding that low-income families are relatively high users of child mental health services (see, for example, the Ontario Child Health Study; John *et al.* 1995) has led a number of authors to suggest that the design of such services should make them accessible to the poor.

The structure of a service needs consideration yet is not necessarily a key feature in producing health gain, as was demonstrated in the Fort Bragg experiment in which an ambitious programme of continuum-of-care at one US army base could not be shown to yield better mental health outcomes than more traditional service models at two comparison bases (Bickman *et al.* 1995, 2000). The content of what is provided in terms of clinical skills and knowledge is more important. Although the scientific evidence base for child and adolescent mental health practice is rather limited and there is still considerable reliance on expert testimony and open trials (Graham 2000), remarkable consensus is emerging as to what skills are required for a comprehensive service. Systematic reviews, practice parameters and official guidelines exist for most child mental health problems encountered and there is good agreement between them.

All child and adolescent services need easy access to a psychiatric contribution, not just because of the occasional need for mental state and physical examination, medical diagnostic skill or medication prescription, but because of the advocacy potential of senior medical figures within health systems.

Although not restricted to psychological practitioners in many countries, the skills of formal psychometric and neuropsychological assessment are best developed by psychologists. It is also the case that cognitive-behavioural approaches are usually delivered by them.

Dynamic psychotherapies, individual, group and family, may be offered by any trained professional and there seems little a priori reason for assuming them to be restricted to any particular health professional.

The care of children and adolescents within residential treatment settings is generally in the hands of nurses but focused training for them seems rather unusual. Rather similarly, the contributions of occupational therapists, speech and language therapists (speech pathologists) and creative therapists do not

often stem from a body of professional knowledge and skills specifically tailored to child and adolescent mental health. Commonly, they derive on an individual basis from paediatric or adult mental health practice. An exception is the tradition of pedagogy in some European countries in which therapeutic education, particularly for children with learning disabilities, has been established for decades.

The evidence base is strongest for medication and cognitive-behaviour therapy (CBT), less so for family and multisystemic therapies, and weak for individual and group dynamic therapies (Kazdin & Weisz 1998; Graham 2000). Indeed, recent trials of individual psychotherapy in real-life settings have indicated that it is usually ineffective compared with placebo (Weiss *et al.* 1999) or shows no dose-effect relationship (Salzer *et al.* 1999). Nevertheless, dynamic approaches have informed much thinking about developmental deviance and distorted family functioning and have informed therapeutic interviewing and nursing care so that they are still remarkably influential in the child and adolescent mental health systems of most developed countries (Remschmidt & van Engeland 1999).

It is no longer possible to assume that one form of therapy or conceptual framework will provide demonstrable effectiveness for all cases and all modern systems have adopted a more or less differentiated approach on eclectic lines: the preferred treatment for a particular child being based on rational assessment and available evidence. The place of consumer choice within this is less clear, especially when it is unclear who the consumer might be.

The last point merits some consideration. In some countries, referrals to a child mental health service may be made or prompted by a variety of people: parents, teenagers themselves, paediatricians, GPs, teachers, social workers and so on. A child with a mental health problem is likely to be known to several of these and they may have differing ideas of what constitutes improvement. They may also have differing explanatory models for the child's problem or condition. Essentially, medical approaches of diagnosis and treatment 'are of secondary importance for the benefit of other missions, such as educational, protectional, and/or legal' (Matot *et al.* 1999). Indeed, there may be competition between different frameworks, with misconceptions about a reputedly reductionist 'medical model' and difficulties arising from perceived stigmatization. This can have secondary difficulties for the language used to describe children's difficulties. Although the major classification systems are widely used by psychiatrists internationally, non-medical staff in a service are sometimes less ready to do so or are even openly hostile, which makes for problems in documentation and communication.

Contact with a specialist child and adolescent mental health service

It is apparent that there is some uncertainty as to what constitutes an appropriate referral to a specialist service. On the basis

of a study of referral pathways, Leff & Bennett (1998) argued for written guidelines for potential referrers. In a large national UK study (Audit Commission 1999), 25% of referrals to specialist outpatient/community child mental health services were from non-medical sources.

Given the historical recency of much child and adolescent mental health service provision, it is not surprising that in a number of countries there are waiting lists for specialist opinion. It is recognized that this is an important factor in determining whether a referred child will be brought to the service, long waiting times correlating with higher non-attendance rates for first appointments (Rawlinson & Williams 2000). This is a perversity in that wasted first appointment times further increase waiting times so that pressure on specialist services increases even without an increase in demand. It has proved impossible to identify any single factor predicting non-attendance and attempts to alleviate the problem by preliminary telephone contact have met with varying results (contrast Mathai & Markantonakis 1990 with Burgoyne *et al.* 1983). What may be better is to reduce the amount of clinical resource devoted to first contact in order to limit waste and place first-contact evaluation at a point in a spectrum of resources or tiered structure.

Priorities within a service

There are huge variations among countries in psychiatric provision for children. Within Europe, Remschmidt & van Engeland (1999) were able to show that the ratio of senior specialists in child and adolescent psychiatry to child population (age < 20 years) varied from 1:5300 (Switzerland) to 1:45000 (Hungary). The figures for the UK and Ireland were intermediate, 1:27500 and 1:31500, respectively. It is not surprising that a number of countries have services with long waiting lists for first appointments. This sharpens the need for prioritization and various indices of priority have been developed by local services. These are often complex and difficult to ‘sell’ to referring agencies who, it is said anecdotally, will find ways round them in order to gain preference for their own referrals.

In such a setting, developing prevention strategies (see Offord & Bennett, Chapter 52) becomes politically difficult because it takes clinical resources away from reactive services that are already not coping with demand. Considerable courage is required to mount prevention programmes in such a setting and in spite of the logical claim for prevention, comparative costing does not always show benefit for primary prevention over later treatment (Harrington & Clark 1998). In an attempt to resolve this dilemma, concepts of early intervention have been promoted although their impact outside pilot programmes is largely untested.

Issues of health economics

As Knapp & Henderson (1999) pointed out, economics con-

tributes importantly to decisions about resource allocation and ‘is concerned with how resources can be transformed into improved outcomes for the users of services, their families and wider society’ and that ‘the underlying prompt for economics—scarcity—is as prevalent and constraining in [child and adolescent mental health] as it is elsewhere’. This applies both to the policymakers of publicly funded services and to health insurance companies who wish to operate managed care.

The cost to society of mental health problems in the young is not confined to a health service. Indeed, major costs, particularly of disruptive behaviour, can be charged to social services, special education and property in childhood as well as having secondary costs to parents (loss of earnings because of increased supervision and care requirements, etc.). Because these separate services or households have individual budgets, the cost saved by treatment in a health service goes unrecognized (Light & Bailey 1993). In a small study of the costs of conduct disorder in 10 children, Knapp *et al.* (1999) found that the average annual cost to the health service (£2457) was about half that to local education services (£4754) and the annual cost to social services (£991) nearly half that to the health service. Average direct and indirect costs to the family of a child with conduct disorder (loss of employment, additional home repairs, etc.) were estimated at £13 109 per annum. Attempting to derive cost-benefit figures simply from health service costs misses the point.

Nevertheless, there is value in applying microeconomic analyses to specific interventions or groups in order to illustrate or compare. The extraordinary expense of the Lovaas programme for young children with autism demonstrated by Gresham & Macmillan (1998) is an instance of illustration. Comparison of two alternative approaches to dealing with adolescent deliberate self-harm: routine care and routine care plus four sessions of home-based family intervention (Byford *et al.* 1999; Harrington *et al.* 1998) found, surprisingly, no difference in cost or outcome between the two but greater parental satisfaction for the intervention that included home-based sessions. This suggests greater benefit from the latter at no increased cost.

Quality assurance

The performance of a service requires relevant information to be collected and, for instance, the degree of adherence to particular administrative and clinical procedures to be ascertained by this. It has become popular to use peer audit to examine the performance of clinical services and a number of strategies have been developed for child mental health services (Hardman & Joughin 1998). However, the final stage of the audit cycle, closing the loop, may cost extra resources and these have not always been forthcoming. Audit is a useful tool for improving clinicians’ adherence to care or administrative procedures but cannot of itself improve clinical outcome unless there is sound evidence for

effectiveness of a procedure or, better, direct measurement of outcome.

Outcome evaluation

Outcome measures for research studies do not easily transfer across to services. Research studies usually aim for homogeneous populations and select their patients, excluding comorbidity, standardizing treatments, and admitting only consenting volunteers. Services, however, deal with heterogeneous groups of children with problems of varying severity and complexity and operate in a wider context of non-health agencies whose own contribution may or may not be helpful. In order to measure the outcome of processes within a child mental health service, allowance has to be made for all this.

Several parameters have been suggested (adapted from British Psychological Society 1993):

- clinical symptom/sign improvement;
- achievement of mutually agreed goals for change;
- acquisition of new skills
- improved functioning;
- reduced duration of inpatient stay/school exclusion, etc.; and
- improved self-management of ill-health/disability.

To these may be added:

- improved quality of life;
- improved mental health; and
- improved social participation.

Rather similarly, Hoagwood *et al.* (1996) and Jensen *et al.* (1996) suggested five outcome domains to be considered in their SFCES model.

- Symptoms/diagnoses
- Functioning
- Consumer perspectives
- Environmental contexts
- Systems.

The common denominator is thus a recognition that optimal outcome measurement is complex, perhaps too complex for routine evaluation in the field. Even in research studies, hardly any work is sufficiently comprehensive as to tap all criteria; Jensen *et al.* (1996) found only two studies assessing all domains of the SFCES model. There seem to be three major areas in which more usable frameworks are being developed. Symptomatic improvement is generally popular in research studies but many symptom scales are intended primarily for epidemiology. The Health of the Nation Outcome Scales for Children and Adolescent Mental Health (HONOSCA) have been developed in the UK with the intention of being acceptable to a wide range of professionals, only requiring a few minutes to complete and being sufficiently sensitive. Initial experience in field trials (Gowers *et al.* 1999) and a large national survey (Audit Commission 1999) has been promising.

A second area is to evaluate functioning rather than clinical change, as instanced by the SumOne for Kids system (Beck *et al.* 1998). Thirdly, a rather more cumbersome but arguably relev-

ant method of identifying agreed outcomes as a result of negotiation with key stakeholders or families and assessing criterion referenced change accordingly has been advocated by Berger *et al.* (1993) and Hernandez *et al.* (1998). This third approach has the advantage in bridging the poor agreement between clinicians' and families' views of a child's problems (Yates *et al.* 1999).

There is also the dimension of service performance that hinges upon activity indicators: number of cases seen, wait for first appointment, consumer or referrer satisfaction, etc. These are easier measures to obtain and can be taken as indices of service quality but are arguably less fundamental measures than clinical change.

It is clear that no single scale will tap all aspects of change thought to follow an intervention. To a certain extent, what is selected will depend upon what the goals of the service are in terms of health promotion or problem-solving (see above). One way through is to use the agreed goals approach coupled with Likert scaling (Berger *et al.* 1993). However, this depends upon goals negotiated by therapist, parent(s) and child which may not agree with goals that would have been set by other agencies. Ratings of clinical outcome in an unpublished pilot of such an approach (Spender, Byrne & Hill, unpublished data) showed good agreement between parent and therapist but poor correlations with school and GP opinion. The matter might be improved by adding one of the various scales of functioning, such as the C-GAS (Shaffer *et al.* 1983), but even so there will be aspects of service provision such as expert report drafting, liaison consultation and child protection intervention which would not be well served by such an approach.

It is also the case that attempts to offer treatment are thwarted by poor attendance, failure to complete homework tasks or take medication and a judgement about compliance needs to be made by the treating clinician. Similarly, the extent to which schools, housing, poverty, peer group and so forth support or hinder treatments must be made explicit. Once again, the context in which a child mental health service, a child psychiatry or psychology service, or an individual clinic operates has to be considered.

Looking ahead

Two contrasting forces currently operate in developed societies. On the one hand, the impact of evidence-based practice means that children are being treated better than ever before. Differentiated practice with an eclectic basis and a focus on specified treatment goals is now widely accepted. The days of protracted psychotherapy for (nearly) all and lengthy inpatient stays have gone. On the other hand, economic pressures can mean less state or insurance funding available for child mental health with adverse consequences for clinical practice. The advent of managed care in the USA has, it is argued, led to a disruption of 'attaching, trusting and caring' and a diffusion of the full benefit of the skills of child and adolescent psychiatrists because psychiatrists have

found their role narrowed to 'using structured questionnaires, conducting symptom-based interviewing, and prescribing medication all in an hour or less' (Jellinek 1999). Similar statements could be made about specialist practice in state-funded health care when finances become scarce.

Constrained resources, funding by separate agencies, and political pressures to reduce waiting times seem likely to encourage a focus on symptom relief where this can be demonstrated. In terms of the earlier definitions of health gain this supports a focus on Health 1 approaches and a tendency to concentrate on episodes of care rather than a longer view. Because it is cheaper and faster in producing symptom relief, psychopharmacology might thus be favoured by a reimbursing or funding body over, say, CBT in the treatment of obsessive-compulsive disorder, because the latter takes longer to produce benefit and requires more clinician time. Yet, given the rate of relapse following discontinuation of medication it would appear that, in this example, medication functions as water-wings compared with the swimming lessons of CBT. The longer view could therefore indicate different economic benefits when the two treatment approaches are compared although, in order to demonstrate this, research findings are required. There is then the comparable problem of how to obtain research funding for longer term evaluation, rather than the short project with definable goals. In parallel with this there is often a need for breadth in interdisciplinary or inter-agency study so that the effect of specialist treatment can be assessed across a variety of social and personal domains. Fortunately, there are signs that this is beginning to happen.

Introduction

Child and adolescent mental health services led the way in developing multidisciplinary work in the early part of the last century. Even at that time, the boundary between medical and non-medical settings seemed arbitrary. Many clinics were sited outside mainstream medical settings and referral policies were designed to offer services directly to social service and educational departments as well as health services. Attempts to channel all referrals through health agencies alone have occurred from time to time, usually in order to limit access to overloaded services or to satisfy some bureaucratic dogma. Such an arrangement simply results in a perception of the service as remote and inefficient.

Most clinicians work in non-medical settings as part of their duties; indeed, many of the other chapters of this book refer to such a role, if only implicitly. In the previous edition a list of eight advantages offered by this flexible approach were listed (Nicol 1994). These included:

- 1 the reluctance of many families to attend a formal clinic;
- 2 the possibility of rapid response to straightforward problems;
- 3 avoidance of the administrative complexities of referral;
- 4 encouragement of interagency collaboration as a result of a mental health service presence in the community;
- 5 taking the treatment to the environment where the problem is manifest, as a way of dealing with situational influences; and
- 6 opportunities for primary and secondary prevention.

Relevant non-medical settings and the children's problems they contain

A brief review of non-medical settings illustrates the relevance of practice outside the clinic and hospital.

The mainstream school

There are a variety of political views about the aims and priorities of schooling but few deny that good quality schooling is an experience from which all children learn more than the formal curriculum, e.g. how to cope with a wide variety of human relationships including competition, co-operation, coping with authority, friendships, enemies and love relationships. Children's psychopathology will also be evident in the school setting. Influences at school can modify the behaviour of the students (Maughan 1994; Mortimore 1995).

Young people's prisons

The aim of this setting may be punishment and rehabilitation but this does not alter the fact that mental health problems among young prisoners are extremely common. Maden *et al.*'s (1995) study of British remand prisoners (with 206 male young offenders) showed an overall prevalence of 'psychiatric disorder' of 19% (including a few with psychosis). In the USA, Yates *et al.* (1983) assessed 339 young offenders aged 18–19 who were remanded in a secure facility. Three had schizophrenia and two an organic disorder; the overall rate of psychiatric disorder was extremely high.

Suicide and attempted suicide in prison constitutes a substantial problem (Liebling 1992). This includes a few instances in children between the ages of 15 and 16 (Garfield 1998, personal communication), although the rate is higher in older teenagers and young adults. Use of alcohol and drugs in the populations of young offender institutions is a persistent and growing problem. A survey by McMurren (1989) of 100 sentenced British young offenders revealed that 43% were heavy drinkers, consuming over 50 units per week. In Maden *et al.*'s study of remand prisoners, nearly one-quarter of male remand prisoners used drugs of dependence. Obviously, the young people who end up in prison bring their emotional and behavioural problems with them, but the contrast between behaviour in prison and in well-run (but much more expensive and non-punitive) facilities with similar populations suggests that the setting is a crucial influence.

Children's homes

In recent years there has been great concern in the UK about the state of children's homes. With a recognition, some 20–30 years ago, that even quite small group homes did not offer a satisfactory long-term alternative to family life, there has been a major movement towards fostering of children in public care (see Rushton & Minnis, Chapter 22). Group homes have therefore changed in an attempt to accommodate those whose behaviour is so difficult that fostering is not an option. The provision of children's home accommodation has shrunk and now stands at around 10 500 places in England, accommodating some 7000, mostly adolescents (Utting 1997); around 400 of these offer secure provision. Much is known about the qualities of effective children's homes. These include a clear statement of purpose and orientation; a degree of self-determination, as opposed to an

extension of local authority bureaucracy; manageable size; and agreement among the staff about how the establishment should be run. The negative reputation that children's homes have suffered needs to be balanced by the fact that, in a recent survey, local authority homes for adolescents were seen by the residents as more helpful than among a comparable group in young people's prisons (Nicol *et al.* 2000).

A survey of the mental health of young people in the children's homes and foster care of one local authority showed that nearly all manifested some form of psychopathology (McCann *et al.* 1996). Disorders involving major depression, anxiety or conduct disturbance were particularly common. Berridge & Brodie (1998) found that there was little or no contact or other link between health service provision of mental health services and the child care sector or social services departments. Nicol *et al.* (2000) found that in both care and penal settings there were gross shortages of mental health services.

As with prisons, children in children's homes bring many problems with them. With recent problems of widespread child abuse in such institutions, it is more than ever clear that the experience in the setting itself can add to their difficulties.

Foster care

A higher proportion of children in public care are now in foster placements than used to be the case, although the absolute number has changed little over the last 30 or so years. Foster care includes so-called shared care, used particularly with disabled children, and also emergency or short-term placements. The therapeutic potential of foster care is recognized in many pioneering schemes (Hazel 1981) and has led to specialist foster care programmes for children with particularly severe emotional and behavioural problems.

Among the homeless

This is the ultimate failure of all the social settings mentioned above and is common among young people leaving care. British census figures in 1991 showed that of the 2650 people sleeping rough only 35 were under 18. On the other hand, the best UK study, where a representative sample of young London homeless were interviewed, suggested that the majority of older teenagers actually started their street career when they were under 18 (Craig *et al.* 1996). Of this sample, 85% had their first episode of homelessness before the age of 18, and the same proportion had run away from home before the age of 16.

The reason for the homelessness in this sample was also important. Disagreements with parents was the major cause, including a substantial minority where violence had been involved. Leaving care or prison together made up 17% of the group. Material poverty, housing or occupational reasons were given as the cause in only 9% of the sample. These figures tell a story of social and relationship problems being the leading cause of the vast majority of homelessness at the outset and the homeless group scored higher than a comparison group on all

measures of social adversity, including physical and sexual abuse. Conduct disorder from an early age, and attempted suicide at any age, was much more common in the homeless group; substance dependency/abuse was also common. Many had contact with the homeless primary care service, although not with family doctors. The authors argued that the provision of a specific psychiatric service would make a substantial difference to their care.

Similar studies in other countries, e.g. Shaffer & Caron (1984) in New York and Reilly *et al.* (1994) in Australia, have revealed a similar picture.

Intervention in non-medical settings

The mainstream school

Dewey (1916) traced the school as arising from apprenticeship situations where skills were commonly passed down the family. According to this interpretation of history, the child's development was originally given over entirely to the local family and community. As society became more complex with industrialization, this was no longer possible. The school environment is one where the child spends a large proportion of his or her waking life and where he or she has to learn to cope with many challenges, not only in the sphere of learning but also of coping with relationship issues such as co-operation and sharing, competition and authority—all challenges and growth points for the child and opportunities for the perceptive teacher. The learning situation is full of challenges: the management of students' anxiety, rebelliousness, discouragement and unhappiness are essential to good teaching (Galloway 1985).

The influence of schooling on pupil behaviour, attendance and attainment has been examined in a range of studies using the same basic strategy designed to differentiate between outcome differences caused only by variations in the characteristics of children at the time of school entry and differences that derive from school influences on the children (Rutter 1983; Maughan 1994; Mortimore 1995). Intake variations are assessed through measures of children's behaviour, educational attainments, and social background prior to starting at the schools to be studied. Longitudinal data are then used to determine the same features after some years at those schools, or at school leaving. The test is provided by determining whether pupil outcomes vary among schools, after taking into account schools' intake characteristics, and whether the outcome variation is a function of measured school characteristics. There has been a consistent finding of large differences among schools that cannot simply be put down to the characteristics of the children, and which are systematically associated with variations in school qualities (Rutter 1983). Positive leadership from the head teacher is associated with better adjustment and progress of pupils. This leadership style involves staff in decision-making, provides active curriculum planning and staff training, and includes effective monitoring of pupils' progress. This was associated with a staff

consensus on key values, low staff turnover, and good communication among teachers taking the same class. At the class level, a degree of lesson structure, together with a teaching pace and style that challenged the children intellectually is associated with good pupil progress. A work-centred environment that concentrated on one or two themes at a time, even if at different levels for different children, seemed to be the key to success. High levels of communication in the shape of good teacher record-keeping and links with children and parents are key ingredients. What results is an accent on rewards and praise, and an atmosphere of direction and orderliness that makes the school a comfortable and facilitating place to be. Most of the studies have used a rather limited set of measures to assess pupil outcomes, but those studies that have considered a wider range of indicators of quality have, on the whole, showed a reasonable degree of correlation among them (Mortimore *et al.* 1989).

Clinical implications

Sensitive visitors quickly recognize the well-run school. However, greater expertise is needed to recognize the particular qualities that matter at school and classroom levels and in the individual interactions of staff and pupils. Collaboration with educational psychologists and school advisors are needed to help teachers bring about change in the classroom. Does the influence of being in a particular social environment, such as the school, affect subsequent adjustment? A follow-up of children attending 12 schools in London suggests some interesting possibilities. The schools showed quite wide variation in truancy and behaviour (Rutter *et al.* 1979) but also variation in post-school adjustment (Gray *et al.* 1981). The latter seemed to be caused entirely by the fact that children in the less successful schools dropped out earlier and failed to attend school consistently. This illustrates the importance of indirect chain effects in developmental processes: a depriving experience in one period of life, be it difficult circumstances in the early years, poor school experiences or an early pregnancy, may put the child at a disadvantage at subsequent life stages, not because of direct effects on personality structure but because it sets in motion a chain of risk experiences (see also Rutter, Chapter 19). The clinician with a perspective that extends beyond the clinic has many opportunities to observe the unfolding of transactional processes.

Interventions that use the environment: the example of bullying

An example of marshalling the resources of the non-medical setting for intervention is provided by the case of bullying.

Bullying has always occurred but over recent decades its extent and destructiveness has become apparent as a result of some well-publicized suicides by children and of some seminal research (Olweus 1993, 1994; Rigby & Slee 1993; Smith & Sharp 1994). There is also an issue concerning the right of all children to feel free and comfortable in environments and activities that

they have to attend by law. Studies show that as many as 15% of children are involved in any one school either as bullies or as victims (Olweus 1993). A special helpline that was set up in the UK in 1990 was besieged by several thousand calls in 3 months (La Fontaine 1991). Bullying does not come readily to the attention of the school staff and, when it does, it is all too easy to deny its importance and gravity—or even side with the bully. Because it is so closely linked to the school setting, it can only be handled within the school with the active co-operation of the school staff.

Many studies have attempted to characterize the bully and the victim. The most important studies have been by the Scandinavian psychologist, Dan Olweus, and this account is heavily dependent on his findings. His main method of investigation has been survey techniques using the anonymous questionnaire developed by him.

Olweus defined bullying as negative actions directed at one individual and repeated over time. Bullying may be direct with unprovoked attacks, or indirect with schemes to undermine the self-confidence of the victim using social isolation, humiliation, malicious rumours and name-calling. Indirect methods are just as destructive but are more difficult to detect and deal with. Olweus found the problem to be just as grave in small village schools in Norway as in large city schools but was more prevalent in junior schools than secondary schools.

Typically, the bully emerges as relatively socially competent and confident, from a background where discipline and child-rearing is inconsistent and chaotic, aggression is condoned and interactions are along a power-assertive dimension and, in some 40% of cases, with other seriously antisocial and offending behaviour. Most bullies are boys. Girl bullies have not been studied in such depth but seem more likely to use indirect bullying methods.

The victim is more likely to be shy, anxious and socially isolated. Apart from being physically weaker than bullies, victims are commonly younger. Characteristics of the victim's family are also sharply different from those of the bully. Family relationships are close, particularly with the mother and the family atmosphere is non-violent. All these aspects of the relationship mean that the bully can attack with little fear of retaliation. Victims have not been found, as some have suggested, to have an excess of physical stigmata. The effects of the bullying were described in the UK study of Smith & Sharp (1994) as sleeplessness, severe loss of self-esteem, social withdrawal and depression. These symptoms can long outlive the experience of bullying at school.

According to Olweus, the bully quickly identifies a potential victim. It is not difficult for him or her to recruit a few assistants to perpetrate the torment that then gets underway. The bullies (characteristically two or three in number) can then justify their behaviour by isolating the victim in the class and the school by humiliation and ridicule. In this way, the confidence of the initially insecure and shy youngster is further undermined, thus encouraging further attacks.

The group dynamics within the school are of great impor-

tance in understanding bullying. Olweus found that most bullying happens in the school grounds, not, as some have suggested, on the way to and from school. Poorly supervised breaks and lunch times are a fertile breeding ground for bullying, as is a culture of staff detachment from the social life of the children. The culture of group identity possible in school offers a tempting environment for the bully and his or her lieutenants, offering a weakening of inhibitions to misbehaviour, social support for misbehaviour and reduction of the probability of being caught.

Treatment of bullying should start with a study of the size of the problem in the particular school involved (using anonymous questionnaires). Comparison of the findings with those of other studies gives a firm starting point from which to tackle the problem with school staff, governors, parents and students. The intervention itself can best be understood at three levels:

- 1 the whole school level;
- 2 the classroom; and
- 3 the individual child.

Whole school level

There should be an explicit policy that bullying is unacceptable and must not be allowed to happen. This should be accepted by all staff, governors, parents and pupils, using the regular consulting structure of the school to ensure that this happens. Students must be included because the target of the whole school component of the programme is the entire student body, not just those children who are suspected of being involved in bully/victim problems. Pupil opinions should be canvassed at an early stage of planning.

Bullying flourishes in isolated and unsupervised changing rooms and corridors, out of the sight of supervising staff; this needs to be borne in mind in building design and alterations. Secluded paths and bus stops in the vicinity of the school offer other vulnerable points. However, the key considerations concern the attitudes of staff and their willingness to take part in the antibullying programme, which may impinge on their relaxation time over lunch and coffee breaks. It is at these times that vulnerable areas should be supervised. If a staff member detects suspicious group activity, intervention should be immediate and questioning assertive. Better to be overvigilant, writes Olweus, than allow bullies to benefit or be seen to get away with their behaviour. In Smith & Sharp's (1994) British study, a whole school approach of this kind was encouraged and monitored. There was a moderate correlation between school commitment, and the intensity of the school's intervention, and a good outcome.

Attention to the ethos of the school is crucial to the management of bullying. There should be an atmosphere of autonomy in the context of support, with an overall sense of the school as a community where each is responsible for the self and others. Students need to be told that they have the right to attend school without fear of being bullied.

All these issues point up the central importance of staff morale in the management of bullying. A contented and dedicated staff group means punctuality, good supervision, a well-structured

curriculum and attention to the children's needs. Cases of bullying identified early can be quickly discouraged; conversely, neglect of warning signs can be taken as permission to continue by the potential bully. Pastoral staff or heads of house can identify and so support isolated children who are likely to be vulnerable. A special group of interested staff can be appointed to take the question of bullying in the school forward and develop an antibullying plan. It may be possible to involve more senior and mature children to offer support in the form of peer counselling.

Classroom level

A similar clear and explicit set of principles is needed at the classroom level. Olweus (1993) recommends the following three rules as a starting point:

- 1 not to bully other students;
- 2 try to help other students who are being bullied; and
- 3 make a point of including students who become easily left out.

It is very important to describe what types of behaviour constitute bullying (including indirect bullying). Techniques to increase student empathy with victims of bullying include the use of story material, and role-play in the classroom, followed by classroom discussion. It is particularly important to address the issue of the passive onlooker or follower. Such students are in a very good position to blow the whistle on bullying. Students should be praised when improved behaviour is shown — not just to the passive student who has taken on a more active role, but to a potential aggressive bully who has shown evidence of restraint, respect for agreed rules, and victim empathy. Progress can be formally checked in regular class, year or tutorial group meetings.

Individual level

Bullying requires sanctions on occasions. These may consist of confronting bullies with regard to their behaviour and depriving them of privileges when appropriate. As in all such cases, it is important that the sanction does not put the staff member to more inconvenience than the culprit! Care must be taken to avoid an overpunitive stance that will simply model yet again the vindictive attitude that led to the problem in the first place. The young bully is likely to have serious problems of his or her own in the shape of a developing antisocial tendency. Mentoring and supervision may be needed and parental co-operation should be sought as well as attempts to guide the student towards prosocial behaviours.

Not everything can be achieved by ameliorating the school environment. Bullying is a serious, secretive and malignant process and must ultimately be met head-on and dealt with without delay (Rigby & Slee 1993; Smith & Sharp 1994). For this to happen, the bullies must be confronted and interviewed to make crystal clear that their behaviour will not be tolerated. Equally, the victim must be interviewed and counselled. The immediate task here is to offer protection against further attacks by the bul-

lies. Any protective move should be done with the knowledge and preferably the consent of the victim. Victims will often pressurize their parents not to take steps to stop the persecution. Beyond this, steps can be taken to assist in the building of the self-confidence of the child by building on latent abilities and encouraging mixing with appropriate peers.

Effectiveness

A major evaluation of a nationwide campaign against bullying which involved the whole school system has been carried out in Norway and included training for both teachers and parents. The research design was to measure change between two time points: before and after the introduction of the programme. While this is a relatively weak research design, the results showed a spectacular 50% reduction in bullying problems (Olweus 1993, 1994). The programme was particularly effective for direct attacks, and seemed to become more effective over the 2 years of the evaluation. It was not simply that the bullying shifted to other settings. There was no increase in bullying outside the school grounds. New bullying problems were also reduced. In a large study in Sheffield (Smith & Sharp 1994), encouraging results were also found, although the improvements were not quite as spectacular as in Norway.

The school as an environment to support treatment

Therapeutic success in one setting does not necessarily, or even often, extend to another environment because situational influences are important. The implications are well appreciated by researchers who have evaluated therapy in schools, e.g. behaviour modification programmes to encourage on-task behaviour (O'Leary & O'Leary 1976); special teaching/therapeutic sessions outside the classroom; social problem-solving training/social skills training; or crisis intervention (Maher & Zins 1987).

One particularly comprehensive study illustrates some of the key features. This controlled comparison of interventions with 7- and 11-year-old children gave pointers regarding the most effective approaches (Kolvin *et al.* 1981) and some tentative leads about the effects of the environment. The interventions for 7 year olds were parent counselling–teacher consultation, nurture work (a teacher aid support) and playgroup therapy, using the technique developed by Axline (1947). Compared with a no-treatment control group, the playgroup therapy had the greatest impact on the children's problems, followed by the nurture work. The consultation programme was only marginally effective. For the 11 year olds, the programmes were group counselling using a Rogerian technique (Rogers 1951), behaviour modification in the classroom and, again, a parent counselling–teacher consultation approach. The most effective interventions in this case were group therapy and behaviour modification. In short, direct intervention of skilled and

trained professionals with the children was associated with effective intervention. The theoretical framework underlying the treatment approach seemed less important.

Follow-up, at 18 months and 3 years, showed that the therapeutic effects of the study persisted, with continuing differences from the control group. Possibly, these reflected therapeutic qualities present in the school. There was also some evidence of generalization, in that the children who had the more successful interventions also showed changes in home-based measures.

Skills that can be used in non-medical settings

The skills needed in non-medical settings are similar to those used in health-service-based settings but there are some special considerations. Professional isolation could be a problem but it is easily overcome. In practice, working in high-risk community settings requires an awareness of possible street violence. A little 'street wisdom' is a valuable asset. In family homes, it is necessary to make clear that you have come to do a job of work rather than to visit as a guest. If the television is interfering, ask for it to be turned off; if there are neighbours in the home, politely ask that they be invited to leave.

A particularly successful example of work in non-medical settings is multisystemic therapy (Henggeler *et al.* 1998). This technique is governed by careful assessment of all the settings and relationships that make up the life of the young person. Great care is taken in developing a treatment hypothesis that governs the development of intervention across a number of environments. Perhaps the boldest innovations are the intensity of the therapy (the clients and their families are seen every day) and the commitment of the therapy team. Each family is taken on by one therapist whatever the intervention style—be it individual therapy, family work or school consultation. Some other principles of the work are an emphasis on positive behaviours, avoidance of an 'illness' model that absolves the client and family from responsibility for their actions, an emphasis on responsible behaviour, encouragement of appropriate discipline and sanctions (but not inappropriate or unenforceable discipline) and positive reinforcement for positive behaviours. What is striking is that none of these components of the programme are particularly new. It is probable that the degree of rigour, the intensity and the commitment in application contribute to the success of the project. Case loads of individual therapists are very low but the severity of the problem behaviour that is tackled by this team is correspondingly high.

This programme has been carefully evaluated since the outset in the late 1970s. Early modestly funded evaluations using quasi-experimental designs yielded promising results but, by the mid-1990s, results of larger designs using random allocation began to appear. These involved the treatment of chronic delinquency, sexual offences and substance misuse, with findings indicating useful improvement over a period of 1–2 years, as

compared with controls who had either routine management or a comparison treatment.

If this intervention can make inroads into the negative and expensive ‘revolving door’ treatment of the recidivist young offender, it could provide the beginning of a revolution in the management of serious and persistent offenders. The authors commented that it may be applied from a base in a variety of different agencies, including mental health agencies.

Roles for the general child mental health worker

Programmes like the ‘Help Starts Here’ project or Multisystemic Treatment for Antisocial Behaviour may ultimately contribute to more effective routine clinical practice but, at present, the intensity and focus required for these special programmes puts them outside the range of resources available in most services. One attempt to solve this problem has been through the concept of mental health consultation. In the USA, this became extremely popular in the 1960s and 1970s. In the UK, it has failed to achieve the same full-hearted support and training structures. However, as demands for the services of the child and adolescent services grow, it is surely time to re-examine these techniques in a much more professional way than has been carried out so far to assess their effectiveness.

Mental health consultation

This set of techniques consists of the mental health professional working collaboratively with another professional who is in regular contact with the client but who lacks the skills in the assessment and management of children or young people with mental health problems. This could be the staff of the organizations described above: schools, children’s homes, prisons, foster carers or the staff of shelters for the homeless. The approach originates from a psychoanalytic tradition associated with Caplan (1970).

Varieties of consultation

There are now a variety of theoretical underpinnings of consultation, including:

- 1 traditional consultation from the medical tradition;
- 2 Caplan-style mental health consultation;
- 3 behavioural consultation; and
- 4 social systems consultation.

The traditional approach

This is traditional in the sense that consultants use their expertise to carry out their own assessment of the child, the family and their problems (Mattison 2000). After this, they may join with other staff to develop further assessment or treatment. The prac-

tice is common but is seen by some as conservative, paternalistic and likely to promote dependency. On the other hand, many of the problems seen in non-medical situations today are extremely complex and need the most skilled evaluation available. It is not helpful to sustain a false image that the consultees are more expert than they actually are and can undertake specialized diagnoses and treatment that is beyond their experience and training. However, it may be entirely appropriate for the staff of an institution to take on the treatment or management of a problem, once questions about diagnosis and treatment recommendations have been clarified. Alternatively, a member of staff at a residential setting may work collaboratively with a consultant. This can be the essence of a good creative partnership.

Caplan-style mental health consultation

Caplan (1970) has had an enormous influence on the field of consultation, and his book remains required reading for anyone wanting to enter the field, even if some of his ideas now seem questionable. One of the central ideas is that the difficulties encountered in relationships between consultees and their clients arises from distortions in perception related to stereotypes held by consultees related to their own cultural traditions and childhood or other experiences. Caplan saw this as the most common reason for misunderstandings of client’s behaviour and certainly the most important. He strongly emphasized that his method of consultation was not a form of therapy for the consultee. He was also strong in his belief that responsibility for the conduct of the relationship between consultee and client should remain with the consultee and that to take this over both emasculated the consultee and encouraged dependency. The consultant’s responsibility, wrote Caplan, should be to the mental health of the children in general in the institution or the district. It is difficult to see how this position could be sustained today in many of the settings where there have been major problems of abuse. Another of Caplan’s recommendations which remains fresh today is the care with which the arrangements for consultation should be developed, including with the institution itself and with the administrative or local government bodies responsible. Some of his ideas have been incorporated in the section below on setting up consultation.

Behavioural approach to consultation

Many attempts have been made to develop a behavioural approach to consultation, the best developed being that of Bergan & Kratochwill (1990), which centres on the principle of operant conditioning, and that of Brown *et al.* (1998), which centres on social learning theory. The behavioural principles have tended to follow those of other applications (see Herbert, Chapter 53).

The principles and precision of behaviour modification programmes are their strength and an aid to clarity at all levels. Nevertheless, the detail and the relatively structured approach does add to the demands placed on busy consultees, who may have a

misleadingly simplified idea that all that is necessary is the giving of gold stars and sweets. For this reason, the groundwork may have to be carried out with considerable rigour. Considerable training in the basic approach is needed which may raise doubt about whether the true spirit of consultation as the specialist assisting the non-specialist is being followed. Maybe the non-specialist has simply had to become a specialist!

In addition, the ethical issues have to be discussed. Some people's first reaction may be to suspect bribery or dehumanization of the client. Studies of consultation sessions in school psychology have shown that, in fact, consultation in school environments are far from 'an equal collaborative partnership' and that consultees judge consultants who adopt a leadership role to be more effective than those who remain more tentative (Erchul & Martens 1997). Behavioural consultation, in schools at least, does not seem to be very popular. Erchul & Martens (1997) reported a study showing that consultation was considered one of the most complicated and least effective ways of responding to children's learning difficulties and behaviour problems. Ysseldyke *et al.* (1983) reported that consultation came low in the list of priorities about what to do for school problems. Happé (1982) reported that only half the plans that consultees agreed to implement may be actually completed. Erchul and Martens (1997) emphasized that, apart from problem-solving, two other components must be present if behavioural consultation is to be successful. The first is social influence within the school; the authors discussed several mechanisms by which this could be achieved. Although the claim is that the techniques that might be used are not coercive, the impression is that the consultant would have to move quite a long way from Caplan's (1970) original principle that the advice of the consultant is something that the consultee can take or leave. The second added component is psychological and material support. This can consist of any way in which the consultant can put the teacher in touch with services that may be of help in their work. Instruction in class craft or other aspects of skill development could be included and modelling or coaching of a variety of skills. The same principle is true of residential care. Consultation will always be an adjunct to training in managing groups and individuals in residential situations, group work and counselling, planning programmes and activities associated with regular routines and administrative issues. It will have to be very useful if it is to win friends among potential consultees. It is important to note that behavioural approaches have been used primarily for secondary prevention and for study problems rather than major psychopathology.

Social systems approaches

School differences research suggests that benefits could come from modifying the social systems in schools. Efforts have been made in this direction but mostly to improve academic achievement. Silence surrounds any results from recent policies of appointing 'superheads', 'naming and shaming' of schools or privatization. More serious attempts to help schools in a general

way have proved difficult, although the successful attempts to reduce bullying show that, given a clear focus, much can be achieved.

General points

A number of principles are relevant to all types of consultation. In the problem-solving process, workers do not wait for professional guidance before starting to problem-solve; they attempt their own solutions before thinking of consulting a professional outsider. This has been confirmed in the school work of Ysseldyke *et al.* (1983). In many cases their own attempts succeed and no more is heard about the matter. It is essential that the consultant find out about, and show respect for, these preconsultation methods. This dimension is taken into account in Bergan and Kratochwill's system under the heading of 'plan' (planning of treatment package).

Setting up consultation

The consultant must be aware that an approach to an institution is likely to be treated with suspicion rather than unalloyed enthusiasm. Approaches must be carefully planned to negotiate with the leaders and to tap usefully into the communication network of the institution. Some may feel that the consultant is usurping their role. This requires sensitive clarification and negotiation. Staff may harbour negative feelings about a newcomer driven by previous experiences or the general reputation of mental health professionals. Genuine and non-patronizing respect for the difficult work carried out by the staff, courtesy, consideration and humour are essential. A lecture seminar at which the consultant exposes his or her skills and a non-threatening approach may be a help. It is the consultant's responsibility to understand the language of the consultee's profession and of the consultee institution. The ground rules of how the consultant can help and how he or she can be approached have to be established and essential aspects of the institution understood.

It is essential to gain the support of higher levels of management in the agency that employs the potential consultees and of the consultant's own agency. This should preferably be in the form of a written contract.

Is the climate right for consultation?

It is particularly important at an early stage for the consultant to decide whether the organization is suitable for consultation. Relevant questions might include how the consultant is handled by the organization, e.g. how do referrals come forward? Are they really not problems at all but success stories to reassure the consultant that all is well? Is time allocated for the consultation process? Does the director of the organization really see the point of consultation or is he or she merely going along with something that has been imposed?

Worrying signs include inadequate line management, minimal

direct management contact with children and staff, unsatisfactory or absent placement policies and processes, inadequate recruitment processes and staff training, reluctance to use secure provision and more specialized alternative services, inadequate or no external expert advice and the presence of a ‘macho’ or bullying culture. Unusual and untested ‘therapy’, or the taking over of the running or control of the home by a group of senior boys who are imposing a reign of terror on younger and weaker children, should set alarm bells ringing (Berridge & Brodie 1998).

Relationship building and intervention

Having dealt with the organizational issues, we must now turn to the practical matter of consultant–consultee interaction. The starting point must be the problem that is troubling the consultee about the client. With this in mind, the consultant must encourage the consultee to tell the story. Often this will start with something like, ‘What do you do with a child who shouts “knickers” in class all the time?’ or, ‘What do you do with children who keep running away?’ or, ‘What do you do with a mother who threatens to beat up the headmaster?’ These are the openings of professionals who on the one hand may be feeling a bit worried and defensive, and on the other want to test the mettle of the consultant. Gentle encouragement to move towards describing concrete examples is the best response at this stage. Once this is achieved, the consultant should become quite active, asking for details about the setting, others typically present when the behaviour occurs, and more details about the child and family. A good start is to ask the consultee to describe a typical day.

Where? It is helpful to ask about the setting in which the behaviour manifests. Is it in one place or several? If more than one, what do they have in common? Is it to do with an audience? Is it a setting, such as a classroom, where the child may feel unable to cope?

What else has happened? How does the behaviour relate to possibly significant life events? For example, a home visit or the admission of a new child to the class or foster placement?

Towards or against whom? One of the stressful aspects of front line work in non-clinical settings is the intensity with which children develop feelings about members of staff which relate to their experience of parenting and family life (called transference feelings in individual therapy; see Jacobs, Chapter 58). A common example is the child who behaves particularly badly towards a foster carer or house parent, in place of their own mother. These relationships can also have all the agonizing ambivalence of any disturbed relationship. Examples are children who test limits to the extent that they elicit the rejection that they most fear, or children who seem to develop a relationship of being ‘too good’ but at the same time show their underlying rage by stealing from the foster family.

What is the pace and intensity? Behaviour can be diverted into more adaptive channels if these take account of the level of intensity. It is no good asking a hyperactive child to sit quietly reading a book but an opportunity to let off steam in a more constructive way is more likely to help.

Executive skills. It is essential not only that the consultant be active but also that they have clinical skills and techniques relevant to the problem under discussion. The details will differ according to the theoretical orientation of the consultant and the trick is to select areas from one’s own experience that may be relevant and simple enough to be applied by someone whose skills are less specialized. As in all clinical work, it is important, according to orientation, to arrive at a behavioural hypothesis or dynamic formulation (see Herbert, Chapter 53; Rutter & Taylor, Chapter 2). This can be shared in simple jargon-free language with the consultee. In the normal way, it should inform further work. It is very important to be optimistic. In behavioural terms, the consultant’s main contribution can often be as a reinforcer of the consultee’s efforts, which are often not acknowledged by authoritarian and bureaucratic management structures. A common put-down for the enthusiastic consultant is ‘it’s been tried before’—it is essential not to be put off by this. A final word of warning: some professionals take on the consultation mode of practice as an exclusive way of working, abandoning face-to-face clinical work almost entirely. This is a mistake. The consultant should be respected as having high-level skills in direct clinical work.

Other aspects of practice in non-medical settings

The enthusiastic clinician, keen to move out of the clinic to where the action is, may be bewildered and discouraged when, instead of an equally enthusiastic response, he or she meets polite resistance and even sabotage of carefully prepared ideas. These road-blocks can be negotiated and two themes come to mind: communication difficulties and legitimacy.

Communication

Community workers may be categorized into those who have almost continuous contact with the child, such as foster parents; those who have long periods of contact, such as teachers, nursing staff and care workers; and those with relatively fleeting contact, such as a field social worker. All these professionals will meet with a lot of child disturbance, although it is not their sole or even main concern.

Psychiatric terminology may have little currency outside clinic confines. The move from the clinic can be experienced as a liberation, but it has its frightening aspects. Models of behaviour based on descriptive psychiatry are unlikely to be received with sympathy. Although systems, behavioural or psychodynamic theories may provide points of contact, there may be dif-

ferences in terminology, perception and level of training that can become very apparent in community settings. However, there may be other explanatory models, more or less well formulated and explicit, that form the basis for the management of problems. In the search for points of contact it is vital to try to detect the frame of reference of the other professionals in the field, a process that can only be achieved by listening, by asking tactful questions and by an attitude of humility.

There are several reasons why subtle detective work may be needed. The community worker may not be fully aware, and therefore may not easily be able to report their own set of assumptions. The clinician may be part of the assumptive system, viewed in a less than complimentary light. For example, the mental health worker may be seen as an unwelcome agent of social control on the part of the 'powers that be'. The worker may be reluctant to reveal a working model that they fear may be criticized or ridiculed by the mental health worker. Crucially, the mental health worker may find it difficult to cope with the assumptions of others because of different underlying political assumptions or because the assumptions of the other worker seem to cast him or her in an unfair light. Similarly, the mental health worker may be dismissive of the model and belief systems of others and unable to accept that they may have usefulness and validity.

Practice in non-clinic settings is a collaborative exercise. Not to accept the need for this detective work is to run the high risk of blocks in communication that are certain to derail co-operation. For this reason, it is worth citing some of the concepts that are commonly found among community workers in child care and education. Differences and disagreements about assumptions are best resolved around clinical case work. What the child or parents say is always the important first step to a solution to practical problems.

Labelling theory

The idea here is that each child is an individual, and that the application of labels (such as those contained in ICD-10) is damaging as it tends to depersonalize, to rob individual children of responsibility for their actions and to push them into a deviant role. Few would deny the importance of all these considerations but empirical evidence for labelling is much more limited than the claims of some professionals would suggest (Rutter & Giller 1983). Two areas provide examples. First, there are the effects of court appearance on delinquent boys. In a major longitudinal study, Farrington (1977) compared boys who appeared before the court with a group who had similar self-report delinquency scores but no court appearance. In the years after the court appearance, the self-report scores of the convicted boys increased whereas those of the non-convicted controls decreased. On the other hand, these differences were not sustained at further follow-up.

The second example comes from research in the classroom. A great deal of research has been carried out about the effect of teachers' preconceptions of children's abilities on academic

progress (for a brief review see Rutter & Madge 1976). Some studies have used an experimental approach, giving teachers false information and assessing the effect on the progress of children in their classes. This approach has yielded mixed results, possibly because the attempt to prejudice teachers was unsuccessful (teachers make up their own minds). The second strategy has been to find naturalistic differences in teachers' attitudes. For example, teachers' assessments of ability can be compared with those gained from objective tests, or children whose older siblings are known to the teachers can be compared according to whether those siblings were high or low achievers. These studies have been more consistent in showing that teacher expectations can, in some circumstances, have effects on pupil progress (Pilling & Kelmer Pringle 1978). With some children, in some situations, labelling effects can be important.

Although this is true, to fail to analyse and classify also leads to problems in that without a common language of diagnosis and management, which to some would mean labelling, co-operative progress becomes extremely difficult. A wide variety of ideologically driven practices will be found in non-clinic settings. These may impinge on the work of the psychiatrist in many ways. For example, it is not uncommon for institutions to be operating a total ban on the use of psychotropic drugs, on the grounds that they imply an illness label. To avoid stigmatization is a sensible principle, but should not be a pretext to avoid effective treatment.

Challenging behaviour

'Challenging behaviour' is a common modern but somewhat ambiguous term used in practical situations. It may reflect the fact that the individual child's challenging behaviour disrupts the well-ordered setting of the school or youth club, or it may be that the child's behaviour is a challenge to the professional skills of those who care for him or her. It is perhaps typical of a number of such terms in that its usage seems to implicitly reject a deeper understanding of behaviour, including any notion of diagnosis or interpretation. It is a further indication of the deep distrust abroad of any suspicion of labelling or categorization of children. That it is behaviour and emotional problems that need to be categorized is not in dispute; the children should be valued as unique people.

Single-problem agencies

There are currently many agencies that have a central focus on one type of problem. For example, rape crisis centres are geared towards the victims of rape and the National Society for the Prevention of Cruelty to Children is directed principally at that aim. It would be extremely unfair to say that such organizations cannot have a broader focus, but collaboration with a mental health service may be both mutually beneficial and serve the needs of children by offering a broad choice of frameworks and approaches.

Panic behaviour

A panic response can occur. This often takes the form of an assumption that there is a 'cut-off' point where troublesome problems are seen to change in quality by community workers and become a 'mental illness' that they are incompetent to handle. This assumption may be linked to perplexity in the face of disturbed behaviour, to ingrained attitudes in the leadership or to relationship problems in the establishment concerned. The result is a helpless call for 'experts', a belief that drug therapy is needed and that the current environment is unsuitable for the child's needs. Often an undercurrent of hostility hampers collaboration. The clinician who is comfortable in work outside medical settings can at least detect this phenomenon, even if, at this stage, a helpful response is often difficult. Mental illnesses such as schizophrenia certainly present in non-medical settings, particularly in work related to the youth justice system, but the same attitude of partnership and collaboration is needed as with other problems, although the details of management will be different from the variety of other problems that may be encountered.

Legitimacy

Recent years has seen a massive extension of managerial control over the delivery of services. This trend is not limited to medical services; indeed, line management is far more evident in other major agencies. This means that informal working relationships on the ground are increasingly hard to sustain unless supported by senior management. Resistance to obvious need may be because of the fact that contractual arrangements have not been negotiated at a higher level of management. It is not possible for fieldworkers on the ground to respond unless this homework has been carried out.

Networking

Enormous numbers of professional workers can become involved in situations of family difficulty. In a recent study of a random sample of teenagers with severe learning difficulties, and who did not necessarily have special behavioural difficulties, Dossetor & Nicol (1991) found an average of six professionals visiting any given family, and this was in a district without lavish resources! Co-ordination of effort is needed if criminal waste of scarce resources is to be avoided. A variety of devices can be useful. These include:

- 1 the case conference;
- 2 regular network meetings;
- 3 information gathering;
- 4 parent organizations; and
- 5 knowledge of community agencies.

The case conference

This has been the main vehicle for co-ordination of effort in net-

work situations. It was developed in a major way in relation to work in child abuse, where co-ordination is of vital importance. It is also the cornerstone of work with other client groups. A new edition of the guide *Working Together to Safeguard Children* was published in 1999 by the Home Office and Departments of Health and Education (1999). This is compulsory reading for the mental health professional in non-medical settings.

Regular network meetings

The fact that professionals serving the same child population are employed in different agencies and management structures does not mean that they cannot collaborate closely. Regular meetings to discuss individual problems can be of great benefit.

Information gathering

This includes telephone calls, letters and case notes reviews. Collection of information from as many sources as possible can put assessment work on a different basis. The present author, together with most clinicians, can remember situations where co-ordination and simple review of voluminous notes from a variety of agencies could have prevented a disaster.

The life table

This technique was developed by Adolf Meyer in relation to life events and illness to plot the relationship between the two. It can be of great help in organizing and making sense of historical information where time relationships are complex. The process is very simple. A large sheet of paper is taken and a series of columns are drawn up. Each column is designed to chart the progress of a particular problem area for the child and family. For example, one column could be times the father was out of work and another could be a record of the child's change of school. The development of such a chart from old and not very legible records is extremely laborious but it does clarify the course of events and can pay big dividends in terms of understanding.

Life story book (Ryan & Walker 1985)

A somewhat similar technique can be used diagnostically and therapeutically involving the child or young person. A good quality scrapbook or album is used as a life story book. Information from the notes can be gathered, old photographs can be brought into play, and memories evoked to recall people and places which have figured in the child's life. Places which have a key emotional meaning or which are important in the development of the child's identity can be visited. Access to the case notes is now within the child's rights and this also can play a part. This work can be undertaken by the child's key worker with back-up consultation. Such consultation can be important in helping the key worker to use the opportunities which such an

exercise affords for counselling and also in identifying points at which the material is likely to put the child under stress.

Geneograms

The geneogram (Leiberman 1979) is another technique that can be very useful in helping a child to make sense of their experience.

Review and follow-up

The need to follow-up and review difficult situations is also a crucial part of the process of networking. A common finding in the tragedy of child abuse cases that have come before the courts and judicial inquiries is that follow-up has been sloppy and inadequate.

Parent and family organizations

Recent decades has seen the growth of a large number of organizations for different sorts of problems in children: examples in the mental health field are Mencap, for people with learning difficulties, the Autistic Society and the Schizophrenia Fellowship. It would be difficult to overestimate the importance of these organizations as a source of mutual support and in the struggle for adequate resources for children with difficulties. Compared to families of children with disabilities of physical origin, such organizations are relatively sparse in the field of mental health and there can be little doubt that further development in this area would be a powerful force against stigma and in favour of a voice for children with emotional difficulties and their families — never forget parent power.

Knowledge of community agencies

The vast panoply of statutory and voluntary agencies that now exist and the fact that they are of potential help to children and families in difficulties is evidence of the health, vigour and altruism of modern society. It is important that the clinician knows of their existence in the relevant area.

There are several other techniques that are common in network situations. It is important that the clinician has some knowledge of them.

Organization of a service in non-medical settings

The organization of services varies from country to country. However, when clinicians are attached to a clinic that is capable of providing a wide range of services to the local community, sometimes in medical and sometimes in non-medical settings, several basic principles apply.

First, there needs to be an agreement that, as part of the clinic's operational policy, work in non-medical settings is important. It

is best if the service as a whole has a statement of aims. This can include direct work in the clinic, in other medical settings such as the paediatric ward, special care baby unit or the child development centre, and in non-medical settings such as the special school and residential home. In addition, there should be agreement that consultation is important and appropriate. Teaching activity is another area that should be accepted as part of the clinic's task. A teaching commitment to non-medical professionals in the local community, either on courses developed by the clinic or as a visiting speaker or tutor, may be one of the most effective ways of helping them to help children.

What are the needs of the community? Calculations can be made from epidemiological findings that give some guidance but do not by themselves identify the wish for services by families and workers in primary care settings. Some attempts have been made to estimate need, e.g. in a recent large survey in England and Wales by Meltzer & Gatwood (2000). One of the problems is that need is likely to be much greater than the supply of expertise available from the clinic. The simple conclusion must be that the major problems of child unhappiness and maladjustment will not be helped by one profession or in one setting alone so collaboration with other agencies and professionals is essential. Providers of services are likely to be the only people who can identify gaps in the service and they have a duty to identify these and bring them to the attention of those responsible for funding.

One way to identify gaps is to draw up a 'district profile'. This can include all the settings where service should be being provided. Against this list of settings a second column can be filled in, stating whether the need in each setting is being met. In completing this second column it is important to consider other agencies that may be fulfilling the role. It could be that there are areas where collaboration could mean that relatively little input from the child psychiatry service can make a great difference.

Effectiveness of interventions

Child mental health services have been notoriously short on research into their effectiveness. Examples of evaluation have been given in relation to the treatment of maladjustment in schools (Kolvin *et al.* 1981); to the reduction of bullying in school (Olweus 1993; Smith & Sharp 1994); and to delinquency (Henggeler *et al.* 1998). The more general theme of consultation is a particularly difficult area because it contains so many components and variables. Nevertheless, beginnings have been made (Mannino & Shore 1975; Kenney 1986). Most of the work is on consultation within education, with a strong emphasis on school work rather than emotional and behaviour problems. Medway *et al.* conducted a meta-analysis of school-based consultation and reported evidence of effectiveness, particularly in behavioural methods (Medway & Updyke 1985). Apart from the area of school consultation, where there is some evidence of effectiveness, these have mainly been small-scale studies lacking power to demonstrate useful changes on

outcome. However, in the large-scale Newcastle study, a programme of teacher consultation and parent supportive counselling came out with a disappointing result when compared with more direct approaches to treatment, such as playgroups and behaviour modification (Kolvin *et al.* 1981). The verdict therefore has to be 'not proven'.

The simple question 'Is consultation effective?' is, as with so many other similar questions, not likely to be productive. What is needed is to define the context much more carefully. It seems likely that consultation in mainstream schools has more in common with other school effectiveness research than it does with, say, consultation with disturbed delinquent adolescents in residential care. Consultation in this area may be a useful adjunct to the multisystemic approaches to young delinquents which is currently showing such promise (Henggeler *et al.* 1998) and could, where conditions such as a very scattered population suggest it, be included in such a programme. New legislation in the UK criminal justice system gives rise to multidisciplinary teams (youth offender teams) that will have resources to offer a variety of management programmes. This gives ample opportunity for mental health consultation if the will, energy and initiative can be found among mental health workers to respond. The development of court diversion schemes offer opportunities to develop assessment and treatment programmes without the complex administration and time taken for a special referral to mental health clinics.

Introduction

Contact with primary health care—also called general practice or family doctor service—is a common experience in childhood. Over the course of 1 year most parents take their children to primary care health services, and work with children has been estimated to occupy about one-quarter of the doctor's time. There are age trends reflecting the differential experience of illness, with young preschool-age children being seen more often than older children. Thus, over 90% of preschool-age children but about two-thirds of 5–14 year olds will consult at least once a year, and the average annual number of consultations—over four a year—is also higher in preschool-age children (OPCS 1995).

The majority of children's consultations are for physical health problems but a small proportion are for psychological or developmental problems, and responding to psychological and social issues is one of the tasks of the primary care practitioner.

Families often trust general practitioners (GPs) as providers of information, support and advice. Regular contact with children and adolescents with psychiatric disorders provides primary care doctors with a potential opportunity for early identification and treatment of disorder. Primary care interventions have the advantage that GPs often have knowledge of families' circumstances over time, that general practice is less stigmatizing than psychiatric services, and patients tend to prefer this option.

This chapter reviews the organization of primary care services and research on the contribution of psychiatric disorder to primary care work. Specific issues that are addressed include the following. How much does psychiatric disorder feature amongst children attending general practice clinics? How much of it presents somatically? To what extent is it recognized? What happens after recognition? What determines referral of children by GPs to child psychiatrists?

Consideration is given to working models for psychiatric and primary care liaison, and to attempts that have been made at evaluating professional interventions in this setting. Work aimed at improving detection of psychiatric cases, the provision of psychiatric management within primary care, the public health education role of primary care and simple interventions for high-risk groups are outlined. Future directions for clinical practice and research are discussed.

Primary care services

Primary care services are delivered to children through three main avenues: first, through GPs, family practitioners or general paediatricians; second, by child health clinics, which often have a preschool as well as school medical service component; and, third, through hospital casualty departments, particularly in big cities.

The organization of services varies from country to country. Continuity of care is not universal and in some countries primary care doctors work in restricted settings such as emergency departments. Graham (1982) reviewed variations as they apply to paediatric services in European countries. These variations involve:

- 1 the degree to which primary services are delivered by family doctors and GPs rather than primary care paediatricians;
- 2 the extent to which preventive work is linked to general practice illness services;
- 3 the proportion of services which is delivered privately, on an insurance basis, or as part of centrally organized and funded national or regional health service;
- 4 the level of surveillance service provided; and
- 5 the degree of compulsion or inducement attached to preventive services.

In the UK, GPs provide primary care services for the whole population. Their services are free; they are family services in that they attend to both children and adults; they are involved in assessment and in treatment and also in the prevention of ill health, including mental health. A GP will attend to the needs of about 2000 patients in the local general population but some doctors work together with other doctors in health practices with correspondingly larger populations and with more opportunities for providing a number of primary care services, including the appointment of paramedical staff. Many general practices have nurses attached with a special commitment to supervise the development and health of under 5 year olds (paediatric nurses or health visitors). Some practices also employ psychiatric nurses, counsellors or psychologists.

Primary care doctors are the major referring source to many secondary or hospital medical services, including child psychiatric clinics. In the UK, about 10% of attendances for all types of medical consultation will result in a referral (OPCS 1995). Some children with emotional or behavioural problems are referred by family doctors to community or hospital paediatric services

who will often investigate possible associated somatic problems and then refer on to child psychiatry. However, in countries where there is no such sharp differentiation between primary and secondary paediatric care, many paediatricians provide both. This review, although primarily emphasizing primary care work, will also consider the psychiatric problems of children who present to general paediatric clinics.

Child psychiatric morbidity in primary care

Behavioural and emotional problems are the main reason for consultation in many children presenting to general paediatric and hospital outpatient paediatric clinics but, in addition to this, they also constitute an associated problem in a considerably larger proportion of children presenting with somatic symptoms.

Presentation to primary care with emotional or behaviour problems

A number of surveys in various countries have documented that some 2–5% of children and adolescents who attend primary care or general paediatric clinics present with psychological problems (e.g. anxiety, behavioural problems, overactivity) (Goldberg *et al.* 1979, 1984; Jacobson *et al.* 1980; Starfield *et al.* 1980; Garralda & Bailey 1986a,b, 1989; Kramer & Garralda 1998). Educational and social problems also feature as reasons for consultation.

Frequency of associated child and adolescent psychiatric disorders amongst attenders

There is evidence that psychiatric disorders are present in a considerably higher number of children attending primary care than may be supposed from the overt presenting complaint. Independent psychiatric research interviews carried out with children and their parents following primary care contact have found psychiatric disorders in about one-tenth to one-quarter of children across different countries (Giel *et al.* 1981; Garralda & Bailey 1986b; Costello *et al.* 1988; Gureje *et al.* 1994). The rates are probably higher in adolescents attending primary care (over 30%; Kramer & Garralda 1998) and amongst schoolchildren attending general hospital outpatient paediatric services (28%; Garralda & Bailey 1989).

Most children with psychiatric disorders present at the surgery with somatic symptoms. Do the high levels of psychopathology simply reflect general population rates? Are they relevant to the somatic presentations? Although there is no unequivocal answer to these questions, there are some indications that child and adolescent psychiatric disorder may contribute to consultations by increasing the likelihood of attendance for somatic symptoms. This is suggested:

1 by the comparatively high rates of disturbance among con-

sulting children in relation to general population prevalence (Garralda & Bailey 1986a,b; Kramer & Garralda 1998);

2 by the associations found amongst preschool-age children between behavioural/emotional symptoms and increased primary care use (Lavigne *et al.* 1998);

3 by the particularly high levels of psychopathology amongst frequent surgery attenders (Bowman & Garralda 1993); and

4 by findings from general population studies of high levels of medical service use by children and adolescents with psychiatric disorders (Richman *et al.* 1982; Offord *et al.* 1987; Monck *et al.* 1994).

Interestingly, there is tentative evidence that children with psychiatric disorders may be comparatively more likely to attend primary care with somatic symptoms and less likely to attend mental health services in areas with low levels of psychosocial disadvantage (Garralda & Bailey 1986a).

Are there specific associations between psychiatric disorders and physical presentations or symptoms amongst primary care attenders?

This is a pertinent question, because most children with psychiatric disorders present in primary care with somatic symptoms, but in older children and in adolescents there seems to be little specificity in the range of physical symptoms presented at consultation by children with psychiatric disorders (Garralda & Bailey 1986a,b; Kramer & Garralda 1998).

A more indirect link between physical symptoms and psychopathology is suggested by findings that mothers of primary care frequent attenders — when compared with mothers of other frequent attenders without psychiatric disorder — are more likely to view their children as lethargic, in poorer general health and more handicapped by their symptoms (Garralda *et al.* 1999). In a study of children attending general paediatric clinics, parents of those who were found to have psychiatric disorders were particularly likely to report tiredness and lethargy in the child (8/36 or 22% vs. 2/90 or 2% of non-disordered attenders); this meant that 8/10 attenders reported as tired and lethargic had an associated psychiatric disorder (Garralda & Bailey 1989). In adolescents attending primary care, psychiatric disorders have been found to be associated with high levels and intensity of, and more impairment from, physical symptoms (Kramer & Garralda 1998). These findings suggest poorer general physical well-being in attenders with psychiatric disorders in spite of the lack of specificity in the presenting symptomatology.

The nature of psychopathology amongst primary care attenders

There may be more specificity in the type of psychiatric problems identified in children attending medical settings. Although the range of common psychiatric disorders is seen, in contrast with general population findings, surveys of schoolchildren and adolescents in primary care tend to find more emotional than

conduct disorders (Garralda & Bailey 1986b, 1989; Costello *et al.* 1988; Kramer & Garralda 1998). This suggests that enquiry about the presence of and expertise in the management of associated emotional symptoms is specially appropriate if primary care is to have an enhanced role in the identification and management of child psychiatric disorders.

Family stress and the consultations of children with psychopathology

It has long been recognized that family stress and maternal neurotic problems are related to both an increased tendency to consult for children's physical symptoms (Roghmann & Haggerty 1972; Woodward *et al.* 1988) and to childhood psychiatric disorder. On both accounts it seems highly likely that family stresses will contribute to the consultations of children with psychiatric disorders.

Bailey & Garralda (1987) documented an excess of recent (in the previous 3 months) undesirable life events—including family arguments and changes in parental financial and work status—in schoolchildren with psychiatric disorders attending primary care when compared with attenders without disorder. Mothers of schoolchildren with psychiatric disorders who are frequent general practice attenders report reduced maternal well-being, an increase in marital problems and maternal health attitudes characterized by overemphasis on the ill-health implications of symptoms and a tendency to affective inhibition from negative feelings (Garralda *et al.* 1999). Children are usually taken to health services by their mothers, and maternal stress and health attitudes may contribute to disordered children consultations by undermining their mothers' sense of confidence in parenting in relation to both the somatic and behavioural problems.

Psychosomatic problems

The presence of psychiatric disorder—defined as handicapping abnormalities of emotions, behaviour or relationships—is not sufficient to explain the range of problems presenting to GPs and paediatricians where psychosocial factors have a significant part to play. A useful complementary concept is that of psychosomatic presentations. These can be defined in either a broad or narrow sense.

The *narrow definition* implies that certain somatic symptoms (e.g. abdominal pains, headaches) are often an expression of the somatization of distress. Starfield *et al.* (1980) found psychosomatic problems so defined (e.g. children presenting with insomnia, headache, asthma, abdominal pain or other abdominal symptoms) in 8–10% of children attending various primary care facilities in the USA. Campo *et al.* (1999) reported aches and pains with no organic diagnosis in 2% of 11–15-year-old paediatric primary care attenders. There is suggestive evidence that these presentations are found in excess at psychosocial transitional periods: during the early elementary school years (particularly in boys) and in early adolescence (especially in

girls), perhaps reflecting the stress of early learning performance for boys and of puberty in girls (Schor 1986), and the possibility that some of these symptoms represent a response to life stresses.

Defined in a broad way, psychosomatic problems would apply to any physical presentations where the doctor makes a clinical judgement that psychological or social factors are contributing in significant way, e.g. aggravating the symptom. This broad definition is in keeping with the commonly held view amongst medical practitioners which assumes that psychological events can be relevant in the aetiology or in the maintenance of virtually any physical condition.

When doctors are asked to note any physical presentations with associated or contributing psychological factors, e.g. asthma exacerbated by stress, such presentations are recorded for about one-fifth of schoolchildren attending primary care and for as many as half in outpatient paediatric clinics, indicating a high degree of sensitivity and vigilance by many clinicians to these issues (Bailey *et al.* 1978; Garralda & Bailey 1987, 1990). Presenting symptoms in these cases tend to be those regarded traditionally as having psychosomatic components (e.g. aches and pains, incontinence, asthma and blackouts) but virtually any physical complaint is featured. These children do have an excess of emotional and behavioural symptoms, with mood changes and relationship problems. However, most do not suffer from psychiatric disorders. A special stress by mothers over parenting and concerns over schooling have particularly been noted in primary care settings, suggesting the relevance of high academic and behavioural expectations.

Addressing the psychosocial concerns of families with children with psychosomatic presentations may have substantial consequences for medical service use. These children come from families with a high tendency to focus on health issues, as shown by the fact that they are high users of primary care and that the children themselves are given more hospital appointments, more referrals to specialist clinics and more follow-up appointments at the surgery than children with purely physical presentations (Garralda & Bailey 1987; Campo *et al.* 1999).

Recognition of psychiatric disorders and psychosomatic problems in primary care

The recognition of child psychiatric disorders by physicians is obviously a prerequisite if primary care and paediatric services are to become fully involved in attending to the mental health of children and adolescents, but the evidence indicates that recognition is often quite limited. The adult literature shows that while between one-quarter and one-half of primary care patients have psychiatric morbidity, doctor recognition is only 40–50% of the actual rates (Upton *et al.* 1999). Doctor recognition of child and adolescent psychiatric disturbance in primary care settings is similarly reduced (Garralda & Bailey 1986a; Chang *et al.* 1988; Kramer & Garralda 1998). Although doctors identify psychological problems associated with somatic presentations in a considerable percentage of children, this cannot

be equated with recognition of psychiatric disorder because the majority of these children fail to show psychiatric disturbance from research interviews, and conversely many disturbed children are not identified as such by doctors.

As in adult studies there is wide variation between doctors, with some not identifying any disturbed children at all. Doctors' assessments tend to be highly specific but only moderately sensitive: they identify few non-disturbed children and adolescents as disturbed but they miss a considerable percentage of disturbed children. Recognition is higher when children have severe, as opposed to milder, problems and accordingly the more severely affected children are more likely to be referred to psychiatric services (Costello & Edelbrock 1985; Kramer & Garralda 1998). As well as severity, recognition may partly be linked to the child's age (more 7–14 year olds), social circumstances and stresses (being on welfare, broken homes) and to presenting symptoms (chronic conditions, digestive problems and ill-defined problems) (Goldberg *et al.* 1979; Kramer & Garralda 1998).

Interventions by primary care doctors for child mental health problems

What sort of interventions are provided by the primary care doctors and teams once child psychiatric disorders have been identified? Goldberg *et al.* (1984) asked primary care paediatricians in the USA to indicate the treatment provided by them to 7–14 year olds attending with diagnoses of mental health problems. Doctors reported providing some treatment for the majority of detected disturbed children and for nearly one-third this was the only known source of care for the problem. Most frequently provided by paediatricians were supportive therapy or counselling (81%) and suggestions for environmental change (half of the presentations).

There is very little knowledge on the exact nature of the supportive and psychotherapeutic interventions provided by doctors in primary care. The relative importance given by them to reflective or behavioural approaches has not been systematically scrutinized, nor have the benefits in terms of parent satisfaction of symptom reduction. However, there is some evidence that the style of the intervention affects parent satisfaction. Work with young mothers in health clinics has documented the superiority of statements by doctors reflecting empathy and encouragement over the simple expression of support (Wasserman *et al.* 1984).

In the survey by Goldberg *et al.* (1984), of children attending primary care with mental health problems, drugs were prescribed for 11% of affected children (amphetamines in 4%). However, there are indications that drug prescribing for behavioural and emotional problems in primary care has increased since this study was carried out. A diagnosis of attention deficit disorder in some primary care clinics in the USA virtually predicted the use of methylphenidate and the lack of use of other treatment forms a decade ago (Wolraich *et al.* 1990). There is

now alarm at the trend for a marked increase in the use and range of psychotropic medication in ambulatory care organizations, even for preschool-age children (Zito *et al.* 2000).

Referrals to child psychiatry by primary care workers and paediatricians

Referral to child psychiatry remains the most frequent interface between primary care and child psychiatrists. A significant proportion of children seen in psychiatric clinics are referred by GPs (Garralda *et al.* 2000). However, each GP refers few children and the factors that determine referrals are not well understood. Whilst doctors' recognition of disturbance is obviously important, so are parental and doctor attitudes. Length of time the patient is known to the doctor is probably relevant (Goldberg *et al.* 1979) as is a maternal request for referral in many cases (Bailey & Garralda 1989), the GP's role in the process being often rather passive. This may be accounted for by differences in GPs' and parental perceptions of problems such as hyperactivity. GPs appear more unsure than parents whether hyperactivity is a medical disorder warranting a diagnosis and specific treatment, more often seeing it as a passing phase related to family stresses (Klasen & Goodman 2000).

Once children are referred to child psychiatry clinics by GPs, the majority are found to be disturbed, whether from research interviews, GPs' estimates, or both (Garralda & Bailey 1988; Bailey & Garralda 1989; Garralda *et al.* 2000). The factors associated with referral by GPs in this age group are comparable to those that determine referral for the majority of children attending clinics and are therefore probably not specific. A study sought to clarify this by comparing *non-referred* children with psychiatric disorders attending primary care with disordered children who were *referred* by GPs to psychiatric clinics. Referred children had higher severity levels of disturbance, more appreciation by parents of the child's disturbance, more male sex, antisocial symptoms and psychosocial disadvantage (Garralda & Bailey 1988). Higher severity and male sex are consistently found in other surveys (Laclave & Campbell 1986; Lavigne *et al.* 1998).

An interesting minority of children referred by GPs to child psychiatry clinics is found not to be sufficiently disturbed to be considered as having psychiatric disorders. When compared with non-referred non-disordered children attending general practice, parents of referred children, contrary to expectations, do not regard their children as disturbed more frequently, nor is the referral a 'ticket' for help with psychiatric morbidity in the parents. It seems likely from this work that, quite specifically, for a number of parents the difficulty they experience in controlling and coping with exuberant activity in somewhat rebellious children in the context of difficult economic and housing circumstances and perhaps a family history of serious antisocial behaviour contributes to help-seeking (Garralda & Bailey 1988). However, the fact that all these features are common in the general population, and that referrals of non-disordered

children are few, indicates that additional unknown factors must determine referrals.

On the basis of the little audit work which has been carried out in this area, most parents appear to be satisfied with the part played by the primary care doctor in the referral process (Bailey & Garralda 1989). However, this only applies to children who have been referred, and there may be many non-referred children whose parents' attitudes toward GPs' helpfulness are more jaundiced.

Child psychiatry and primary care liaison

Adult psychiatrists have been actively involved in primary care liaison work for several decades and the models proposed by them provide useful guidance for the little documented area of liaison schemes between child psychiatric and primary care teams.

Gask *et al.* (1997) summarized the purpose of the common current consultation-liaison approach as:

- to help GPs identify psychiatric morbidity in the practice;
- to assist them to deal directly with cases within their competence and skill;
- to help define the best time for specialist referral;
- for the specialist to take on the assessment and to initiate the joint care of referral patients and their relatives; and
- to share with the primary care team the continuing burden of chronically sick patients, to explore the limits both of the doctor–family relationship and that of GP and specialist in the setting of general practice.

The history of these developments in adult psychiatry was comprehensively outlined by Mitchell (1985). Balint pioneered the field through GP seminars focused on the relationship between the doctor and the patient using a psychodynamic perspective as the primary diagnostic and management tool. By the 1980s one in five British psychiatric consultants surveyed indicated that they or their junior staff spent more time in a general practice setting (Strathdee & Williams 1984) and other members of the psychiatric team have similarly reported attachment liaison schemes in general practice. Subotsky & Brown (1990) described a child psychiatric clinic in general practice.

A number of different ways of working together were discussed by Mitchell (1985) within the attachment-liaison style.

- 1 Regular and co-ordinated home visits.
- 2 Shift of psychiatric clinics to health centres or surgeries.
- 3 Visits to health centres or surgeries by psychiatrists to see selected patients.
- 4 Regular group discussions at the health centre or surgery.
- 5 Conjoint consultations in the health care centre or surgery to be used with highly selected prepared patients.

In child psychiatry this would involve members of the psychiatric and the general practice multidisciplinary teams, including health visitors, community child psychiatric nurses and psychologists or counsellors.

The different options within the attachment-liaison model are not exclusive and have several elements in common which may be important for its success. They include regular and readily available face-to-face contacts between professions, time for the growth of understanding of what each wants from the other, a common and acceptable meeting ground, and openness of communication based on mutual respect and trust. In addition, an important way to promote liaison between child psychiatrists and primary care doctors is the participation of child psychiatrists in the postgraduate training of GPs, in order that basic information on assessment, handling and counselling skills can be taught.

Currently, there is active interest in the UK in the development of primary care child and adolescent mental health workers to help take on some of these attachment-liaison tasks. As in adult psychiatry, however, practical considerations limit the value of liaison schemes. The ratio of child psychiatric teams to primary care units is low, and only a minority of GPs in a health district could be involved and benefit. Moreover, child psychiatric teams also consult with other services, such as education and social services. In any case, consultation-liaison interventions must be closely monitored and evaluated to help determine provision, and different professionals from both services should be involved. These schemes will be shown to be worth carrying out if more children with psychiatric disorders are identified and successfully helped in the general practice setting and if it results in more efficient referrals to specialist clinics. They should be shown to have an impact on referral patterns, changes in the primary care workers' ability to detect and manage cases that are not referred, and be cost-effective (Gask *et al.* 1997).

Improving the detection of cases for specialist treatment in primary care

The prospects of receiving treatment for actual psychiatric disturbance are currently limited by low rates of detection within primary care. Simple, quick, easy-to-complete questionnaires have been developed or adapted to screen children and young people with behaviour problems, depression and parent–teenager conflict in primary care and paediatric settings (Jellinek *et al.* 1986; Campo *et al.* 1999). They have proved efficient but the impersonal nature of questionnaires begs the question of how useful they will turn out to be for face-to-face interventions in paediatric consultations. It seems probable that the use of open questions during the consultation about existing emotional or behavioural problems in the children will similarly prove useful as an aid in the identification of psychiatric disorders (Costello *et al.* 1988). Exploration of the actual rather than the ostensible reason for seeking paediatric attention may also reveal family stresses, possibly related to child psychopathology (Bass & Cohen 1982).

Training primary care workers in the identification of child psychiatric disorders

The World Health Organization has sponsored interesting initiatives to explore the potential of primary care to respond to mental health problems in children. Giel *et al.* (1988) showed that, with the use of a small set of simple questions, it was possible to identify probably disturbed children and to increase awareness on the part of family care workers in various developing countries. Brief training sessions led to improved identification by the carers of severe psychiatric problems (e.g. emergencies such as suicidal behaviour, depression or psychosis), neuropsychiatric problems (epilepsy and mental retardation) and in improved attitudes by them towards the management of cases.

Bernard *et al.* (1999) developed a training package on child and adolescent mental health problems for primary doctors in training. This included preparatory reading (Hughes *et al.* 1995) and teaching sessions with problem exercises, role-play and video-vignettes. Evaluation demonstrated enhanced detection of child and psychiatric disorder as well as improved self-perceived competence and knowledge amongst GP trainees. My colleagues and I (Gledhill *et al.*, unpublished) developed and tested a package to train GPs in the identification and management of adolescent depression opportunistically during routine consultations for any kind of presentation. Its use resulted in improved detection of adolescent depression by GPs and in positive feedback by doctors and adolescents.

The screening role is far from exclusive to doctors working in primary care. The contribution of nurses is particularly important for young preschool-age children, and the appointment of counsellors, psychologists and psychiatrically trained nurses offers the opportunity to develop dedicated screening clinics. The motivation of clinicians to recognize psychiatric problems will be enhanced by the existence of appropriate and effective therapeutic strategies in primary care and in paediatric clinics.

Interventions for children with psychiatric disorders

Studies within adult mental health have shown that primary care interventions are feasible and can be effective, but comparatively little is known about the treatment available for psychiatrically disturbed children in primary care or paediatric settings. Controlled studies of interventions are methodologically difficult to implement but there is growing interest in this area.

Bower *et al.* (2001) carried out a systematic review of interventions for child and adolescent mental health problems in primary care. Studies can be divided into those describing treatments carried out by the primary health care team, management delivered by specialist mental health professionals, and consultation-liaison models. Most work on children and adolescents with actual psychiatric disorders falls within the first category

and involves treatment in primary care by mental health specialists. Most interventions described are brief (6–12 sessions) but they include a variety of techniques from behaviour-cognitive to family therapy, non-directive counselling, dynamic therapy, psychiatric evaluation and guidance, parent education and counselling, group work and child education. Study designs tend to consist of simple before-and-after studies without control groups and there are often important gaps in the description of details of the process of treatment delivery. Problems in the statistical analysis include lack of power analysis, the treatment of losses to follow-up and the presentation of differences between groups. Results can therefore only be regarded as tentative and pointing the way to further work. Examples will be considered here briefly.

Earlier attempts at screening children for psychological problems as part of a paediatric evaluation and at providing interventions in this setting resulted in poor uptake (Metz *et al.* 1976). Subsequently, Finney *et al.* (1991) showed that it was possible for mental health professionals to offer short interventions (one to six visits) in primary care to parents of children and adolescents with behavioural and mental health problems. Individualized treatments were offered, guided by problem-specific protocols. Parent outcome and behaviour checklist ratings showed improvement or resolution in 74% of cases with high satisfaction. Use of medical services in the following year, especially primary care visits, showed a decrease when compared with a matched control group having routine care. Finney *et al.* (1989) also described a psychological intervention for children with recurrent abdominal pains referred to a primary-care-based paediatric psychology service. The treatment involved a self-monitoring of pain, limiting the attention given to the symptom, use of relaxation and dietary fibre supplementation and encouraging the child to participate in routine activities. The results indicated improvements in pain symptoms and reduced school absences. More complex approaches have been implemented and monitored. In an example of a 'shifted outpatient clinic', family therapy clinics based on systemic ideas within a large group general practice in London were found helpful by many families (Graham *et al.* 1992).

Child psychiatrists have successfully developed and piloted short interventions, which may be adapted for use by primary care workers. Coverly *et al.* (1995) provided a protocol-guided single psychiatric consultation in primary care to mothers of frequently attending schoolchildren found from psychiatric interviews to be psychiatrically disturbed. The intervention aimed to boost parental confidence in dealing with difficult behaviour through clarification of the problems, empathic and encouraging remarks, and succinct advice on management. Most mothers attended for the intervention of which two-thirds reported it had been markedly helpful at short-term (3-month) and longer-term (18–24 month) follow-up. Westman & Garralda (1996) piloted a brief psychotherapeutic intervention (four to six sessions) for adolescents with depressive and anxiety disorders attending a health promotion clinic in primary care. Less than half the adolescents offered the intervention attended, but

the majority of these attenders felt subjectively improved. It was noted that most youngsters with mood disorders had attended their GP in the previous year and that more of these youngsters could be reached if the intervention was provided by the GPs themselves.

My colleagues and I (Gledhill *et al.*, unpublished) therefore developed a treatment package incorporating cognitive and interpersonal behavioural principles, suitable for delivery by GPs opportunistically during adolescent consultations. The study showed the feasibility of training GPs in its use because most GPs applied the therapy techniques in the majority of youngsters identified by them as depressed. Their intervention was associated with reductions in depression-related functional impairment. The key question is how much it is possible to generalize these interventions and how to document any possible benefits rigorously.

Primary care as a resource for public child mental health education and simple intervention for high-risk groups

The virtually universal attendance of young children at primary care and child health paediatric clinics is an opportunity to provide parents and children with general information aimed at promoting child and adolescent mental health. This is an extension of the well-recognized role by primary care paediatric services in the dissemination of information about health, child development and behaviour.

Mothers of young children value and make use of general health advice provided during general practice consultations to manage health problems in their children (Cunningham-Burley & Irvine 1987). They also rely on health care professions for advice about child-rearing and psychosocial issues (McCune *et al.* 1984). However, different professionals (e.g. GPs, clinical medical officers and community paediatricians) can give conflicting advice (Jewel & Bain 1985), probably reflecting insufficient emphasis in training. It seems important therefore that serious attention is given to education in this area for primary care workers.

Some reports have documented the effects of educative/supportive interventions in primary care for parents of young children. In an early controlled study, Gutelius *et al.* (1977) described an intensive child health supervision programme started by a project nurse during pregnancy and continued by the nurse and by a paediatrician at well-being clinics over several years. The emphasis was on counselling and anticipatory guidance for mothers of normal first-born black infants from low-income families and on group sessions where mothers were given direct advice about their personal life. When compared with a control group there were behavioural benefits during the first 6 years of life, with positive effects also found in diet and eating habits, toilet training and in child-rearing practices.

Since then a variety of community programmes have been developed and shown to be effective in the prevention of behavioural problems in young children and in the support of positive

parenting (Cox 1993; Olds *et al.* 1997; Webster-Stratton 1998). However, these programmes require specifically trained staff and a great deal of input to access and maintain the co-operation of mothers and children. How realistic, feasible and appropriate is it for generic health services such as primary care or paediatric health surveillance clinics to develop this degree of therapeutic sophistication for emotional and behavioural problems?

Promotion of young children's mental health by GPs

The study by Cullen (1976) is of interest because it involved an intervention by a single GP and because of the long-term follow-up. The author, a GP in a rural community in Australia, arranged to see the mothers of 124 children for a series of interventions spaced at intervals of 3 months in the first year and at 6 months in the succeeding 4 years of the child's life. Child-rearing concepts and attitudes were explored. When compared with a control non-intervention group of children, those in the index group showed fewer behavioural problems at 6 years of age from mothers' reports and the children themselves expressed more positive feelings towards their mothers. However, a greater number were late for school and boys were more excitable and hard to control. The author wondered whether the confidence of the boys' mothers in the intervention group might have been affected by too cautious an approach to disciplining problems. Follow-up of these children 20 years later (Cullen & Cullen 1996) suggested long-lasting favourable effects for the girls in the experimental group, who reported fewer neurotic symptoms. A larger proportion had also attained a university degree or diploma, and fewer were overweight.

The study demonstrated that mental health promotion interventions can be carried out systematically by GPs and that, through regular supervision, doctors may be able to influence parental actions and have some long-lasting effects on their children's behaviour. It seems unlikely, however, that the majority of primary care doctors or even paediatricians would regard this area as one for priority development and one in which they would be prepared to invest such a degree of time and effort.

Attempts at training primary care community nurses or health visitors and doctors to promote parenting in order to reduce behavioural problems in young children have reported positive but also often inconsistent or equivocal results and remain an area requiring further exploration (Cox 1993; Bower *et al.* 2001). It is important to establish and evaluate what is the minimum intervention that may be taught, is realistically used by primary care staff and results in worthwhile mental health gains for children.

There have been more focused pilot interventions for specific problems; these deserve further evaluation. For example, group therapy sessions have been set up for mothers who are frequent attenders to primary care and been followed by reduced consultation rates suggesting better coping strategies with concerns over children's health problems (Benson & Turk 1988). General counselling by paediatricians for parents on consistent and effective management of childhood behaviour may be helpful

for young children with combined physical and behavioural problems.

Work with adolescents

The primary care setting may prove a resource for promoting mental health in adolescents. In a preliminary investigation, a GP invited youngsters registered at the practice to attend his surgery for a general health discussion. Following a single-letter approach, over half the youngsters attended, and this resulted in consultations found by the doctor to be both enjoyable and productive, with effective discussion of general health issues and also of personal problems (Donovan & McCarthy 1988). Westman & Garralda (1996) investigated the feasibility of inviting 14–15 year olds to a health promotion clinic to explore mental and physical health and to identify those at high risk of depression. Although overall attendance rates were low (22%) a high proportion of attenders had psychiatric disorders and the authors calculated that the clinic had probably attracted all adolescents with depression registered at the surgery. Specific training for GPs has been shown to have beneficial effects on the quality of medical consultations with adolescents and to achieve improvements in knowledge, skill and self-perceived competence (Sanci *et al.* 2000). These are basic requirements for the development of more specific mental health promotion initiatives in primary care.

Work with parents of children with psychiatric disorders

Adult psychiatric services now have several decades of experience in developing links with primary care. Controlled trials of patients with mood disorders have documented beneficial effects of interventions in primary care techniques, such as anxiety management, intensive patient education, medication adherence counselling, behavioural treatments to improve coping strategies and problem-solving (Kendrick 2000). Parental mastery in dealing with mood disorders could influence children's mental health and their own ability to manage mood changes. Supportive care by social workers attached to general practice can result in valuable clinical and social benefits to patients with neurotic disorders (Corney 1987). In so far as psychiatric disorders in parents influence childhood disturbance, these interventions could have beneficial effects on the children's mental health.

This is more directly the case for disorders starting in the puerperium. Counselling mothers with postnatal depression by health visitors or nurses in general practice can lead to substantial clinical improvement. This may be expected to have implications for the mother's ability to respond to the child and to promote child health and psychological development (Wickberg & Hwang 1996).

It can be concluded that, generally, educational or therapeutic interventions—not necessarily focused on any particular treatment modality but involving ongoing support, advice and guid-

ance with child-rearing in well-being clinics—can be instituted in general practice and may lead to favourable behavioural outcomes in young children. The challenge lies in how much these interventions can incorporate more sophisticated psychotherapeutic components, be generalized across services and evaluated rigorously.

Future directions

The main mental health task for primary care remains attention to children and adolescents presenting with primary behavioural, emotional and psychosomatic problems. Secondary to this is the screening for associated psychiatric disorders amongst children presenting with somatic symptoms, and the promotion of child adolescent mental health. All of these tasks have organizational and service development, educational and research components.

Attention to children and adolescents presenting in primary care with behavioural, emotional and psychosomatic problems

Nature of presenting problem

As for any presenting problem, the primary care doctor needs to make a well-informed judgement as to whether:

- 1 the presenting complaint is a mild short-lived problem, understandable on the basis of environmental changes and intrinsic vulnerabilities, and likely to resolve spontaneously;
- 2 whether it is causing handicap and therefore requires attention in its own right, whatever its origins and transient nature; and
- 3 whether adequate attention can be provided at the surgery or whether it requires specialist referral.

Knowledge on the nature of the common and severe psychiatric disorders will form the basis of these decisions. Increased teaching on these basic concepts in medical and nursing school and in postgraduate general practice training programmes should facilitate this task. There is an ongoing need for academic institutions to develop, update and document the quality, breadth and reach of teaching and training programmes to ensure universal coverage.

Information and advice

A wealth of information is now available to families on a variety of child mental health problems. GPs and primary care teams are in a good position to draw parents' and youngster's attention to suitable written and electronic information and to complement this with clarification of the meaning of the symptoms presented and basic advice about its management. Although there are existing guidelines specifically designed to help family doctors identify and manage child mental health problems, these need further development and evaluation. It is important to find ways

of distilling the main knowledge on management principles of child psychiatric disorders in a way that can be conveyed in an authoritative and empathic manner by a generalist medical service during a brief intervention.

Referral to specialist services

For clearly diagnosable psychiatric problems in children who are not already under the care of mental health services, the primary care clinician needs to make a decision about whether and how to refer. Existing research indicates that psychiatric referrals by primary care doctors are generally appropriate (children with the more severe problems and associated psychosocial complexity). However, increasing awareness of child and adolescent psychiatric problems by parents and primary care teams alike is likely to result in more referrals than specialist services can possibly accommodate. Protocols refining the criteria for severity, psychosocial complexity and likely response to treatments will need to be developed and audited jointly by child and adolescent mental health and primary care services. This is where the development of consultation-liaison activities or of primary care mental health worker posts may be specially helpful and should be monitored against measures of success of the referral process.

Primary care interventions for the milder/moderate psychiatric problems

Most reports on primary care interventions for children and adolescents with mental health problems have been based on the 'shifted' outpatient clinics in primary care by mental health professionals or counsellors. This may have the advantage of destigmatizing, facilitating attendance and accessing more children with milder problems who would not normally be referred to specialist services. At the same time, and given the limited resources available generally for child and adolescent mental health, shifted outpatient clinics run the risk of providing sophisticated interventions for problems that do not require them at the expense of treating more severe disorders in the specialist setting.

An alternative approach is that of adapting more complex specialist interventions for the primary care setting for primary care doctors and their staff to deliver opportunistically during consultations. This strategy has the advantage of being more primary care syntonetic, it may be more realistic and less demanding of resources. By giving primary care doctors/paediatricians confidence in the management of psychiatric disorders, it might also reduce the use of psychotropic medication in primary paediatric care and halt the recent alarming increase. However, it calls for a serious effort to improve the training of GPs and paediatricians in psychiatric diagnosis and in the use of psychosocial management techniques.

The two approaches ('shifted' outpatient specialist clinic vs. more child mental health care by primary care staff) are not incompatible and are likely to be developed varying across ser-

vices depending on local demand and professional attitudes. It seems important that both are researched in relation to clinical outcomes.

Screening for psychiatric disorders amongst children presenting with somatic complaints

The high levels of psychiatric disorders amongst schoolchildren and adolescents attending primary care with somatic complaints and the willingness by parents to take up treatment at the surgery when disorders are identified suggest that screening for psychopathology during consultations is appropriate. Given the comparative high frequency of emotional disorders, psychosomatic concerns, associated stressful psychosocial circumstances and high primary care attendance rates amongst those with disorders, it would seem appropriate to target these problems and situations in screening and for management. Screening questionnaires or open questioning by clinicians may be used varying in different settings. Their relative advantages and disadvantages can easily be audited.

Screening children at high risk in primary care

Health screening is one of the roles of primary care and paediatric health clinics, of health visitors and school nurses and doctors. It would seem logical for child mental health to be part of this screening, particularly but not exclusively in work with young preschool-age children. Future research can helpfully investigate the potential of these services to inform parents and children on child and adolescent psychiatric problems, their role in prevention and at the interface with the community parenting support programmes which are being developed for young children at risk.

Primary care psychiatry is slowly beginning to emerge as a child and adolescent mental health service. New clinical initiatives need to be developed and evaluated rigorously for short- and long-term effects and for user attitudes.

Genetic counselling and the role of the genetic counsellor

Genetic counselling is distinctive from other topics discussed in this book. The nature of the clinical contact could not be described as treatment, although at times it may be therapeutic. Other consultations focus on the diagnosis and treatment of a health problem, or upon surveillance to ensure a health problem does not occur. In genetic counselling, by contrast, whether or not the client is affected, the contact centres on the sharing of information in order to allow the client to make fully informed decisions. Genetic counselling focuses on providing clients with a range of information that will allow them to make informed decisions with regard to family planning (Kelly 1986). A range of areas may require coverage to achieve this. First, a discussion of the nature of the disorder is important so that the clients have a clear conception of the potential range and severity of the disorder, the impact on the quality of life and the treatment options open. Secondly, it is necessary to ensure that clients appreciate the mode of transmission of the disorder and how this influences the risk of being affected. Thirdly, the options for determining whether particular individuals are at risk either of being carriers or affected require discussion, together with the potential implications when this is detected. Finally, genetic counselling may consider the choices available to couples considering prenatal planning to reduce the likelihood of having an affected child.

Genetic counselling is an educational and consultative, rather than a prescriptive service. People presenting for genetic counselling often do not have a health problem at the time of presentation. Because the goals for genetic counselling are primarily educational, the counselling process tends to be driven more by the patient or client than would be the case in many medical or psychiatric consultations. Although the term 'counselling' is used, the type and extent of this process is rather different in genetic than in mental health counselling. Most consultations will extend from one to three visits only and, where there is more than one consultation, many of the additional visits are information-gathering rather than 'counselling'. Unlike mental health counselling, where an objective may be to enhance understanding of one's emotional state and explore alternative ways of managing difficult situations, genetic counselling rarely takes on such an introspective dialogue but rather focuses on communication of information necessary to help clients make informed choices.

Changes in genetic counselling over time

The recognition of familial transmission of some diseases and a desire to influence marriage and family planning dates back as far as the Talmud, when the nature of haemophilia was recognized (Walker 1996). Key shifts in genetic counselling have followed from an understanding of genetic mechanisms. The earliest phase occurred in the post-Mendelian era, when there was an appreciation of the modes of single gene inheritance, but where there was no ability to determine whether presymptomatic individuals carried the gene or not. In that period, diagnosis of the medical disorder and determination of the mode of inheritance were key features of the counselling process, which was generally led by a medical geneticist. Problems occurred when diagnosis was uncertain, when the relationship between diagnosis and mode of inheritance was variable, or when non-Mendelian inheritance occurred. The information given to families was limited information based on the mode of transmission and their place in the pedigree. There were also serious abuses of the limited scientific information during the eugenics movement. Inaccurate conclusions were drawn about the inheritance of mental retardation and psychiatric disorders in one generation and the probability of their occurrence in subsequent generations. A coercive approach to family planning, including forced sterilization, was taken in a number of countries. Despite a radical change in the 1940s with respect to the role of the genetic counsellor and government in relation to reproductive choices, genetic counselling remained limited by scientific knowledge.

Genetic counselling changed with the advent of accurate biological markers of disease and especially molecular genetic techniques. The advance here was to identify *within* affected families those individuals who will develop or pass on the disorder. A number of new activities developed at this point. For autosomal recessive and X-linked disorders, this involved the detection of carrier states. For autosomal dominant disorders of late onset, early diagnosis, with all its complexities, became possible. Prenatal diagnosis was feasible for a range of serious disorders, allowing couples at risk selectively to terminate pregnancies of affected fetuses. As other medical advances have occurred, preimplantation diagnosis has allowed couples to select unaffected embryos for implantation and avoid the distress of therapeutic abortion. These genetic advances opened the possibility of population-based screening programmes.

Further developments have occurred when advances in genetics have provided an explanation to patterns of inheritance that had previously proved puzzling. One such breakthrough occurred with fragile X, where the elucidation of the expanding trinucleotide repeats explained the ‘Sherman paradox’ (Sherman *et al.* 1985) in which males appeared normal although their position in a pedigree indicated they must carry the disease gene and, under the expectations of X-linked inheritance, should have expressed the disorder. The determination that fragile X represented a *dynamic mutation* that changed over generations not only explained the puzzling inheritance pattern but also allowed more accurate information to be given to family members (although in some cases there is also greater uncertainty). The accuracy of prediction of risk and disease severity has improved for other dynamic mutations, including Huntington disease and myotonic dystrophy. Similar advances occurred with respect to *imprinting* (see Skuse & Kuntsi, Chapter 13), in which parent of origin for the mutation may affect the phenotype, and *mitochondrial inheritance* (Clarke 2000) in which DNA is almost exclusively inherited from the mother.

A further stage in genetic counselling is just beginning, with two key advances. One is in the detection of *susceptibility genes*, or genes of minor effect. Unlike the genes of major effect that account for Mendelian disorders, susceptibility genes increase the risk of disease but they are neither necessary nor sufficient for its development. Other factors, genetic and/or environmental, must be present for disease expression. Most common diseases, including the bulk of psychiatric disorders, are ones in which the genetic contribution is of this type. Furthermore, the variants of genes influencing risk of the disorder occur at high frequencies in the general population, unlike the rare mutations in Mendelian disorders. The role of the dopamine D₄ receptor (DRD4) in attention deficit hyperactivity disorder (ADHD) provides such an example. A number of studies confirm that the presence of a set of allelic variants, present in some 15–20% of the population, increases the risk of ADHD by a factor of 1.5 (Thapar *et al.* 1999). However, many individuals with ADHD may not have the high-risk DRD4 allele and others who do have it do not have ADHD.

Current developments in genetic counselling are also influenced by the advances in techniques that detect smaller chromosomal abnormalities (see Skuse & Kuntsi, Chapter 13). Cytogenetic screening for major chromosomal abnormalities in people presenting with a range of physical and psychological abnormalities has been performed for several decades, but now new cytogenetic and molecular techniques can detect more subtle variations where the distinction between normality and abnormality is less clear. Counselling families with respect to such findings can be difficult as it may be unclear whether to consider the finding as aetiologically relevant. Even when an aetiological link seems likely, the range of the phenotype associated with a new abnormality may not be defined, making it difficult to give useful genetic counselling.

Tasks of the genetic counsellor

A range of professionals are involved in genetic counselling. Clinical geneticists are medically trained with advanced training in genetics. Much of genetic counselling is carried out by other medical doctors who diagnose and treat genetic disorders, and by obstetricians in relation to prenatal screening. Genetic counsellors come from a variety of non-medical backgrounds, including nursing and social work, but have developed specialist knowledge of genetics and counselling. Professionals with a more pure scientific background have a key role in developing and interpreting diagnostic tests. If the anticipated demands for genetic testing in the future are made, it may be that primary health care providers will need training to deliver information regarding testing and risks (Reynolds & Benkendorf 1999). Within this chapter, the terms ‘genetic counsellor’ and ‘geneticist’ are used interchangeably to refer to all these individuals. Because genetic counselling deals with a wide range of situations, the tasks for the counsellor may vary, as summarized in Table 66.1. For any one clinical situation, aspects of the clinical problem may overlap (e.g. making a diagnosis if a genetic disorder in one child may lead to pre-conception counselling in relation to future children). Nevertheless, because each clinical problem requires slightly different tasks from the geneticist, they are considered separately.

Diagnosis of genetic disorders

Geneticists may be called upon to help make a diagnosis of a genetic disorder, either prenatally or later. A range of medical skills is required for the task and diagnosis may be based on a characteristic history, physical examination for congenital anomalies and dysmorphic features, and laboratory investigations, including genetic tests. Although it is increasingly possible to detect mutations, most diagnoses of Mendelian disorders are initially made on the basis of other features, although molecular testing may be used to confirm clinical opinion. Diagnostic issues with respect to chromosomal anomalies are somewhat different. When the observed chromosomal anomaly has been previously linked to the phenotype observed, cytogenetics is often the definitive diagnostic tool. Determining whether there is a risk for other family members usually involves parental chromosomal analysis to determine whether the abnormality has arisen *de novo* (in which case the risk to other family members is small) or whether one parent carries a balanced translocation or even the same abnormality (in which case the risk may be substantial). The wider family is unlikely to be at risk.

Once a diagnosis is confirmed, the geneticist needs ample time to discuss it with the affected person and/or their family, bearing in mind that the information may represent a double tragedy: confirmation that something is seriously wrong and also that other family members are at risk. This may be a time when the family needs considerable extra support. While it is appropriate that the genetic counsellor is available, the potential benefit of

Table 66.1 Tasks undertaken as part of genetic counselling.

Type of clinical problem	Tasks to be undertaken
1 Diagnosis of genetic disorder	Use of appropriate physical examination and medical/genetic investigations to determine presence of genetic disorder Advise individual and/or family of nature and impact of disorder Counsel family on implications of disorder for affected individual and support family in adjusting to diagnosis Consider risk for wider family and determine method of communication
2 Preconception counselling for couples at risk	Confirm nature of couple's risk (diagnosis of disorder and mode of inheritance) Explanation of degree of risk and nature of disorder Consider appropriateness of medical/genetic tests on couple (carrier testing) Consider prenatal diagnosis
3 Prenatal diagnosis	Counsel couple on prenatal diagnostic strategies Counsel couple with positive screening result Counsel couple with definite fetal abnormality
4 Presymptomatic testing	Discuss utility of results for screening and treatment of affected individuals Consider financial and psychological drawbacks of identification Consider impact on wider family Specific considerations attached to testing of children
5 Carrier determination	Education about risks to client and offspring Determination of appropriateness of carrier testing
6 Population screening for: Disorders where early diagnosis and treatment is possible Moderately rare disorders with significant impact on quality of life and/or longevity Common, usually genetically complex disorders	Advise on practical feasibility, sensitivity and specificity of population screening Advise/manage characteristics distinguishing genetic from other screening programmes Complete or shared management of screening programmes Monitor effectiveness of screening in relation to enhanced population understanding of individual risk and altered reproductive behaviour

lay support groups for the disorder should be considered. The geneticist should have a clear plan about informing families of the potential risk to other family members. It is often tempting when families are distressed to postpone discussion of the genetic basis of the disorder. While this may be appropriate in the acute phase of adjusting to the diagnosis, the risk of delay is that the family could move on to other professionals for further treatment without being apprised of the genetic aspects of the disorder. Risk also needs to be discussed in the context of the wider family and a plan made for how others will be contacted. This may be a particularly sensitive topic when there has been little communication between branches of the family or if there has been a rift. In some cases, this is expedited if communication is initiated from doctor to doctor. Going against the wishes of the patient to inform other family members is undesirable because of the violation of confidentiality and requires careful weighing up of the conflicting ethical issues.

Pre-conception counselling for couples at risk

Couples present for genetic counselling because they believe themselves to be at risk of having an affected child. A necessary first step is confirmation of the putative diagnosis and its mode

of inheritance. Although this may prove difficult, it is essential to obtain as clear a picture as possible, as basing information on an incorrect diagnosis can lead to highly inaccurate risks. Family history for both sides is important to clarify that the risk is not compounded, as well as to reduce guilt and blame. As for all tasks in genetic counselling, it is important to ensure that the couple have a full and accurate understanding of the disorder under consideration. Where the affected relative was distant, they may have no direct experience of the disorder. On the other hand, first-hand experience may be biased with respect to severity or management of the disease in the relative, and the couple may have a distorted view. The discussion of the disorder should take into account both the impact of the disorder on the child and family and also the types of treatment that are currently available. Some consideration of treatments likely to be available in the future is also helpful.

Depending upon the disorder and its mode of inheritance, it may be possible to define the couple's risk more accurately with genetic tests. On Mendelian principles, a normal sibling of someone affected with an autosomal recessive disorder (such as phenylketonuria) has a two in three chance of being a heterozygote carrier and a one in three chance of not carrying the gene. Similarly, a person whose parent has a late onset autosomal

dominant disorder (such as Huntington disease) has a one in two chance of inheriting the disorder and a similar chance of being normal. For many disorders, molecular tests can indicate who carries the mutation.

The issues surrounding this testing in relation to the individuals are discussed under carrier detection and presymptomatic testing, respectively. Although there are other important considerations, it should be borne in mind that test results could define a couple's risk more precisely. Finally, should the couple decide they wish to have children, the options for prenatal diagnosis should be discussed.

Prenatal diagnosis

The aim of prenatal diagnosis is to detect severe abnormalities (both genetic and otherwise) at an early stage of fetal development. In most cases, this is to allow parental choice on whether to continue with the pregnancy; in rare cases, it is to allow prenatal intervention. A number of features should be in place before considering prenatal diagnosis with a view to potential termination (Harper 1998).

- 1 The disorder must be sufficiently severe to warrant termination of pregnancy.
- 2 The treatment options should be absent or unsatisfactory.
- 3 Termination of an affected pregnancy should be acceptable to the couple considering prenatal diagnosis.
- 4 An accurate prenatal diagnostic test must be available.
- 5 There should be a reasonable chance that the pregnancy is affected.

In relation to child psychiatry, prenatal diagnosis currently is only available for disorders associated with mental retardation, such as fragile X and Down syndrome. However, this is likely to change in the next decade as susceptibility genes for severely disabling disorders such as autism are identified.

Three main clinical situations arise in relation to prenatal diagnosis. As indicated above, a couple who present for pre-conception genetic counselling may choose to take up a prenatal diagnostic test. In such cases, the geneticist will have been involved from an early stage and have ensured that the criteria outlined above are met. Second, and more commonly, a couple may have a positive result from a routine prenatal screening, either by blood tests (the most common being for Down syndrome and neural tube defects) or by fetal ultrasound. This is discussed in more detail below, under Population Screening. Finally, geneticists may be called in when a prenatal diagnostic test arranged by the obstetrician is abnormal. The role of the geneticist will be to clarify the effects of the abnormality and to support the couple in making a decision whether to proceed with the pregnancy and in adjusting to that decision.

Prenatal diagnosis is possible for chromosomal abnormalities and for many Mendelian disorders. The most commonly used techniques are amniocentesis and chorionic villous sampling (CVS; Wilson 2000). Amniocentesis is the first choice for low-risk pregnancies where cytogenetic abnormalities are in question. Although it is the safer technique, a potential drawback is

timing: sampling is best performed at 15–16 weeks' gestation and a result is often not available before 18 weeks. CVS, which usually takes place at 10–12 weeks, provides good samples for molecular and enzymatic analysis but has a higher complication rate. The technique of isolating for genetic analysis fetal blood cells that are normally present in the maternal circulation is still under evaluation; the technique appeals because of its lack of invasiveness, but circulating fetal cells are rare and its reliability in detecting fetal abnormalities has not yet been adequately demonstrated (Goldberg 1997).

Presymptomatic testing

Molecular genetic tests allowing detection of genetic mutations that will subsequently lead to a disorder in currently healthy persons, or presymptomatic testing, is frequently considered in families with later onset disorders, but raises many difficult issues. Presymptomatic testing should be differentiated according to whether there are any therapeutic implications of a positive test result. In some conditions, including the hereditary cancers (both early onset, such as familial adenomatous polyposis, and later onset, such as breast/ovarian cancer as a result of *BRCA1* and *BRCA2*), a positive presymptomatic result has direct implications for screening and surveillance of individuals carrying the mutation, whereas a negative test result obviates the need for such time-consuming, expensive and sometimes uncomfortable investigations. For other conditions, such as Huntington disease, there are at present no therapeutic consequences of a positive result and the reasons for requesting testing are more complex. The uptake of presymptomatic testing has, not surprisingly, varied according to treatment implications of a positive result. Uptake for Huntington disease has been around 10–20% (Crauford *et al.* 1989; Quaid & Morris 1993), compared with about 50% for hereditary breast cancer, where early treatment is uncertain, and 80% for familial adenomatous polyposis, for which early surgical intervention has a significant health impact (Harper 1998).

The emphasis will vary depending upon the extent to which genetic status has therapeutic implications, but in all cases pre- and post-test counselling should discuss several issues, as well as the potential medical benefits. Pre-test counselling should explore the impact on family relationships. The test results of one family member have implications for the risk of others. If a grandchild of a person affected with Huntington disease tests positive, this implies that his or her parent also carries the gene, and that parent usually gains knowledge of this, even if he or she did not wish to be tested. Impact on reproductive plans should be raised and the extent of family support in relation to both positive and negative results, especially if a number of family members are being tested. Counselling should also consider the potential effect of a positive result on employment and health insurance. Although the studies are limited (Braidstock *et al.*, 2000) and individual responses vary widely (Wahlin *et al.* 1997), follow-up studies of Huntington disease where careful pre- and post-test counselling is given do not indicate that there

is greater long-standing emotional distress following test results and, furthermore, that emotional status is not predicted by whether the test is positive or negative (Braidstock *et al.*, 2000).

With regard to presymptomatic testing of children, there is agreement amongst geneticists that children should not be tested for disorders for which there are no therapeutic consequences until they are of an age to give consent themselves (Clarke *et al.* 1994). A survey indicated that non-geneticists were more likely to offer presymptomatic and carrier testing of children at parental request; one commonly stated reason for testing was to reduce parental anxiety (Clarke *et al.* 1994). Although the impact has not been examined in children, it is noteworthy that the adult studies did not find reduction in anxiety to be a long-term effect of testing (Braidstock *et al.*, 2000). In relation to diseases such as cancers in which a positive test result may alter the screening practice, it has been proposed that genetic testing should be permitted at an age no sooner than the earliest age of onset of first cancer (Kodish 1999). Such a policy has the advantage of delaying testing in some cases until an age at which children can participate in the consent process while not jeopardizing the child's health.

Carrier detection

A carrier is someone who carries a single copy of a genetic mutation (and also a single copy of a normal gene, making them *heterozygous*) and is healthy at the time of study. Some individuals, by their position in the pedigree, are potential or obligate carriers. With the exception of carriers of late onset dominant disorders, carrier status is therefore of importance only for subsequent generations. The risk that offspring of a carrier will be affected will vary, depending upon the mode of inheritance. Under autosomal recessive inheritance, if both parents are carriers, on average one in four offspring will be affected and two in four carriers. With autosomal dominant transmission, 50% of children on average will inherit the gene (and disorder). Because many autosomal dominant disorders have variable expression or reduced penetrance, where the disease apparently skips a generation, a one-to-one correspondence between genotype and phenotype cannot be assumed, and specific tests to determine carrier status may be appropriate. Under X-linked inheritance, where the mutation is passed on by a female carrier, 50% of all males will develop the disorder and 50% of female offspring will be carriers. Where the mutation is passed on by an affected father, all female offspring will be carriers whereas all males will be normal. Female carriers will vary in phenotype, depending upon X inactivation. Advances in molecular genetics have revolutionized carrier detection and either molecular or other biological markers are available for many disorders. When the gene responsible for the disorder has been identified, carrier testing can be virtually 100% accurate. When there is only rough gene location from linkage strategies, genetic status will be less certain.

The first task for the genetic counsellor is to ensure that the client understands the mode of transmission and chances that

their children will be affected. For autosomal recessive disorders, the partner must also be a carrier for the offspring to be affected. For a rare recessive disorder with a general population prevalence of 1 in 40 000, the risk of a partner also being a carrier is 1 in 100 and the risk of an offspring being affected 1 in 400. However, if the carrier is from a special population in which the prevalence is higher, and is also likely to marry within that population, as with Tay–Sachs disease and Ashkenazi Jews, the risks of a partner also being a carrier may be substantially greater. For autosomal dominant and X-linked disorders, it is generally not important to consider the partner's genotype, but the chances of offspring being affected are very much greater. There are no clear thresholds of recurrence risk for deciding when carrier detection should be carried out and risk to offspring should be considered along with ease of carrier detection and the wishes of the client.

Although parents with one affected child may press to have other children tested for carrier status, this should be resisted until the children themselves are of an age to give informed consent (Clarke *et al.* 1994). In cystic fibrosis where genetic carrier testing has been available for some years, uptake amongst siblings of affected people has been poor. A number of reasons have been identified, including the difficulty their parents have discussing genetic issues and feeling that affected siblings would have difficulty accepting their decision to be tested (Fanos & Johnson 1995a). The finding that beliefs about carrier status were not influenced by educational or income level suggests that emotional issues play an important part in attitudes about screening (Fanos & Johnson 1995b).

Population screening

Population screening involves identifying those with genetic disorders or at risk of having offspring with genetic disorders amongst the general population or large subgroups of the general population. The two main aims of population screening are detecting diseases for which early treatment improves prognosis and the identification of severe disorders in fetuses, or a genetic risk of such disorders, to allow couples to make informed reproductive decisions. There is a potential conflict between the public health aim of reducing disease and the genetic counsellor's desire to maximize individual choices. Population screening may occur at four time points.

1 Prenatal screening to detect fetal abnormalities and diseases for which termination, or treatment, would be considered is routinely conducted through ultrasound for structural abnormalities and maternal blood testing (for Down syndrome and neural tube defects).

2 Newborn screening detects treatable disorders, such as phenylketonuria and sickle cell anaemia. The possibility of using newborn screening to identify severe but untreatable disorders, such as Duchenne muscular dystrophy, so that parents are aware of the genetic risk prior to the birth of a sibling, has been more controversial.

3 Population screening in adult life for common carrier states,

such as cystic fibrosis and beta thalassaemia, has been implemented in a limited fashion.

4 Population screening has started for common genetic variants that may influence disease, both in a Mendelian pattern, such as hypercholesterolaemia associated with low density lipoprotein (LDL) receptor abnormalities, and as a susceptibility allele, such as apolipoprotein (Apo) E4 in late onset Alzheimer's disease. Cascade screening is an intermediate strategy involving systematic contact of more distant at-risk family members with the offer of testing.

Genetic population screening differs from other forms of population screening not by the nature of the test (indeed, many of the screens do not look directly for mutations) but rather because it detects disease of genetic origin, for which there may be implications for other family members. A general criticism of many of the genetic screening programmes is their failure to evaluate the wider family impact of screening. Many of the principles of population screening have emanated from screening of family members of affected individuals; however, it is not clear that this extrapolation is appropriate in relation to informed decision-making or the psychological consequences of screening (Marteau & Croyle 1998).

Unlike individual genetic testing regarding a disorder that has occurred in the family, in population screening clients may have little knowledge of the disorder. There is a general concern about the extent to which informed consent is obtained for screening. In relation to screening for Down syndrome, although the findings suggest that all women wish to be given the choice whether or not to participate in such screening, the policies in many centres may not be presented as voluntary and women may not be given sufficient information to make informed decisions (Al-Jader *et al.* 2000). Furthermore, screening tests such as the triple marker serum test for Down syndrome have a high false-positive rate and moderate specificity (Piggott *et al.* 1994). A lack or misinterpretation of information subsequent to a positive serum result (indicative of significant but still low risk) is common (Gekas *et al.* 1999) and some of the associated distress of a positive screening result might be avoidable with better pre-test information (Hall *et al.* 2000).

The finding that the higher the rate of participation in testing, the poorer the quality of information is of considerable concern (Marteau & Croyle 1998). Those who take part in population screening usually perceive themselves at low risk and expectations of a negative result may lead to higher levels of distress when a positive one is received. The problem of potential false reassurance has been highlighted in cystic fibrosis, where negative test results may exclude only some of the cystic fibrosis mutations but may lead test participants to believe they are definitely not carriers (Axworthy *et al.* 1996; Clausen *et al.* 1996b). Being informed of carrier status may have impact on one's self-perception. Although cystic fibrosis carrier status has no impact on health of carriers, there is variation in reports with some suggesting that those informed of carrier status can have a more negative perception of their own health (Axworthy *et al.* 1996; Clausen *et al.* 1996a).

There has been considerable debate over the merits of population screening for fragile X. As the most commonly inherited form of mental retardation, detection with genetic counselling has the potential to promote greater reproductive choice. A cascade system was evaluated in Australia, with detection of fragile X from those presenting with developmental delay/mental retardation followed by genetic testing of all relatives at risk for the disorder or carrier status (Turner *et al.* 1997). Uptake of testing amongst relatives was high, with a substantial reduction in the rate of children born with fragile X. However, the recommendations from the American College of Medical Genetics are that population screening for the carrier state should not be conducted at present because of concerns about whether consent to such testing and its wider implications could be reliably informed (Park *et al.* 1994).

There are further concerns about informed consent and decision-making with respect to 'multiplex' genetic testing, which is likely to be increasingly available from primary care doctors. Multiplex tests assess a person's genotype for a range of different genes, much in the way current laboratory tests determine a range of blood chemistries. However, current testing kits are not organized to assess genetic risk for a particular condition, e.g. to examine a range of risk genotypes for atherosclerotic disease. Because the use of such tests may provide the simplest and least expensive way to assess risk for one condition, there is concern that unwanted genetic information in relation to a different gene may be acquired, and without fully informed consent (Council on Ethical and Judicial Affairs 1998).

Practical aspects of genetic counselling

Referral for genetic counselling

It is useful to consider at the referral stage whether a request for genetic counselling is appropriate. Almost all child psychiatric disorders show some degree of genetic risk (Rutter *et al.* 1999; see also McGuffin & Rutter, Chapter 12), but this does not mean genetic counselling is necessarily appropriate. The quality and precision of the evidence in favour of genetic factors requires consideration. Table 66.2 presents a summary of disorders that may present in childhood in which it is thought that genetic factors have a significant role. Heritability refers to the proportion of variance explained by genetic factors in discriminating between those affected and those not, and it is important in determining the extent to which familial aggregation results from genetic vs. environmental factors. The sibling recurrence risk is helpful to families in giving practical information about the probability of having another affected child. This recurrence risk will include both genetic and environmental causes of recurrence. There is an absence of firm data for either statistic for several of the disorders, including obsessive-compulsive disorder and anorexia nervosa, where it is commonly believed that genetic factors are important. Without such data, it is not possible to provide genetic counselling. A related consideration is the

Table 66.2 Psychiatric disorders with childhood onset and probable significant genetic aetiology*.

Disorder	Heritability	Sibling recurrence risk
Autism	>90% (Bailey <i>et al.</i> 1995)	5% (Bolton <i>et al.</i> 1994; Smalley <i>et al.</i> 1988), broader phenotype up to 30% in males, 10% in females (Bailey <i>et al.</i> 1998)
Idiopathic mental retardation	Unknown [†]	Mild retardation, no family history: 5–35%, higher when male index case positive family history in first-degree relative: 37–39% Severe retardation, no family history: 3–10% positive family history: 5–15% (Bundey & Carter 1974)
Attention deficit hyperactivity disorder	60–90% (Thapar <i>et al.</i> 1999)	Uncertain, perhaps as high as 25% (Biederman <i>et al.</i> 1986; Faraone <i>et al.</i> 1991)
Tourette syndrome	Unknown [†]	9% for Tourette, 17% for chronic tics, 11% for obsessive-compulsive disorder [§] (Pauls <i>et al.</i> 1991)
Bipolar disorder	~80% (McGuffin <i>et al.</i> 1994)	15–20% risk of severe affective disorder [§] (McGuffin & Katz 1986)
Obsessive-compulsive disorder	Unknown [†] (Pauls & Alsobrook 1999)	Variable from no increased risk to 17%, 10% best estimate [§] (Pauls & Alsobrook 1999)
Schizophrenia	60–70% (McGuffin <i>et al.</i> 1984)	10% if no first-degree relative affected; up to 45% if both parents affected; up to 45% if both parents affected (McGuffin <i>et al.</i> 1994)
Anorexia nervosa	Uncertain [‡] (Bulik <i>et al.</i> 2000)	Uncertain: 0–10% (Kipman <i>et al.</i> 1999)

*Includes only disorders where inheritance thought to be multifactorial.

[†]Indicates absence of studies with sufficient data to determine heritability/recurrence.

[‡]Indicates wide variability amongst currently available heritability/recurrence estimates.

[§]Risk is for first-degree relatives; no evidence of differential risk for parents and siblings.

consistency of the findings across studies for the role of genetic factors. For example, heritabilities of oppositional and conduct disorder vary from 7 to 74% without any clear explanation (Simonoff 2001), there is similar inconsistency for depressive symptoms (Simonoff 1995) and inadequate data on childhood anxiety disorders. It should be noted that many of the data on heritability involve symptoms rather than disorders and it remains to be demonstrated that genetic factors operate in the same way for symptoms and disorders.

A second consideration is the extent of impairment or disability caused by the problem. For example, traits such as emotionality and sociability are strongly genetic but infrequently impairing in their own right. Although professionals should not impose their view as to which traits or disorders are sufficiently undesirable to warrant genetic counselling, issues of severity, impairment and treatability should be considered by families and professionals alike.

The childhood disorder for which there is the strongest case for formal genetic counselling is autism (see Lord & Bailey, Chapter 38). Twin studies indicate a high heritability (Bailey *et al.* 1995) and several family studies concur that the sibling recurrence risk is 5–6% for autism and pervasive developmental disorder (Rutter *et al.* 1997). The disorder is lifelong, essentially untreatable, severely impairing and creates a heavy burden on families. Although individual genes are not yet isolated, there are replicated linkage findings from several groups and it is a

matter of time until individual genes are identified (International Molecular Genetic Study of Autism Consortium 1998; Barrett *et al.* 1999). As with almost all other genetically mediated child psychiatric disorders, the genetic influence appears to involve a number of susceptibility genes. At present, there is more systematic experience of genetic counselling in autism than any other child psychiatric disorder, bar mental retardation. Although formal genetic counselling may not be appropriate for some other child psychiatric disorders, it might be helpful for parents to know that genetic influences may play a part in their child's difficulties. This might particularly be the case if parents have inappropriately blamed themselves, but research is required.

When and by whom genetic counselling is delivered will vary. The clinicians diagnosing and caring for an affected child should alert the family to a genetic component. Whereas families may need to adjust to the diagnosis before genetic counselling is undertaken, it is important that they have access to genetic counselling before planning further children. If genetic counselling is to be offered by the clinician looking after affected family members, such counselling is best undertaken in an appointment specifically designated for this purpose.

Particular issues may arise when a child is being considered for adoption and there is a family history of a serious disorder. Genetic counselling may be sought from the social worker/adoption agency or prospective family. It is expected

that adoption agencies discuss with prospective parents factors from the child's background, whether these are genetic risk, adverse experiences or known health problems, that might have an impact on child-rearing. Mental disorder in the birth parents may contribute to children being put up for adoption but many of these disorders will not be evident until adult life. For disorders such as Huntington disease, presymptomatic testing may be requested. In considering the child's best interests, there is a tension between ensuring that children placed for adoption will not subsequently be rejected, and protecting the child's right to choose whether or not to be tested at an age when they are able to consent independently. Although there are no firm guidelines at present, these are needed (Nuffield Council on Bioethics 1998); most practitioners consider that testing should be undertaken only in exceptional circumstances. In other instances, adoption agencies and prospective parents may request information about recurrence risk. It is generally good practice to provide interested parties with information about recurrence and also the nature of the disorder. Limitations may occur in gaining accurate information regarding both biological parents. The latter is important because of the evidence for strong assortative mating for severe psychiatric disorder (Mednick 1978). It has been suggested that adopted children might be informed about known genetic risks from their birth parents at age 18, when they are able to request knowledge of the identity of their birth parents; otherwise, adopted children are at a disadvantage with respect to knowledge of their potential genetic risks (Nuffield Council on Bioethics 1998).

Assessment

A first step in genetic counselling is confirming the diagnosis in the proband. In some cases the referral may contain sufficient information, in others it may be necessary to obtain additional medical records or to examine the proband personally. The latter two are relatively straightforward when the couple seeking counselling are the parents of the proband. In other circumstances, the couple seeking counselling may feel uncomfortable about discussing this with other family members, particularly the parents of the proband. Further complications may occur for disorders like autism, where a developmental history is paramount for diagnosis and when the affected individual is now adult. Despite these challenges, every effort should be made to clarify the correct diagnosis. Table 66.2 demonstrates that the recurrence risks for autism and mental retardation may be very different, and these two disorders are easily confused with a sketchy retrospective history. The same would apply to autism and Rett syndrome, in which a gene on the X chromosome has been shown to cause at least some cases (Amir *et al.* 1999; Wan *et al.* 1999).

In taking a history and examining the proband, it is important to consider the possibility of identifiable medical/genetic causes of the disorder and also that of phenocopies. In relation to autism, 5–10% of cases may be caused by a recognized medical disorder, the most common of which will be tuberous sclerosis

and fragile X (Rutter *et al.* 1997). In such instances, the genetics of autism will be the genetics of the medical disorder; for both of the above disorders, this is substantially different from idiopathic autism. The term 'phenocopy' refers to a disorder that appears identical to the genetically mediated disorder but where the aetiological factors are very different. For practical purposes, this is usually where an environmental cause for the disorder can be identified. In autism, congenital rubella is one such cause. There has been much debate about whether the association of autism with obstetric complications (usually with milder levels of adversity) indicates a causative role (Goodman 1990); the further association of such complications with congenital anomalies suggests that abnormal development in the fetus may be responsible for the obstetric complications (Bailey *et al.* 1995; Bolton *et al.* 1997). Nevertheless, it is likely that severe perinatal adversity associated with structural brain damage could cause autism. The same applies to other causes of brain injury, including severe head injury or encephalitis. There is much debate currently about the possible ill-effects of the measles, mumps and rubella (MMR) vaccine (Wakefield *et al.* 1998), but there is a lack of scientific evidence for a causative role (Medical Controls Agency 1999; Taylor *et al.* 1999). The importance of identifying phenocopies for genetic counselling lies in the different expectations regarding recurrence risks. In such cases, the recurrence risk can be considered either as the prevalence rate in the general population or, if the environmental risk is familial, as the joint probability of recurrence of the environmental risk in a subsequent child and the chance that the environmental risk will cause the disorder. Although the latter probabilities are usually unknown, it is nevertheless useful to consider whether the relatives are at increased risk for the occurrence of a similar environmental event.

In gathering information, a systematic family history is crucial. This is aided by letting the family know prior to their appointment about the type of information required. Obtaining a family history has a range of aims. First, one is confirming that the pattern of inheritance fits with what is expected. In child psychiatric disorders that are usually multifactorial, finding a Mendelian pattern of inheritance alerts the clinician to the possibility of an alternative diagnosis or a chromosomal abnormality associated with the disorder. However, seeing a pattern consistent with Mendelian inheritance in a particular family is entirely different from inferring that Mendelian inheritance is occurring. In idiopathic autism, where there is a highly skewed sex ratio in favour of males, it would not be surprising for families to show a pattern of affected relatives consistent with X-linked inheritance. However, there is at present no evidence for susceptibility genes for autism on the X chromosome (International Molecular Genetic Study of Autism Consortium 1998) and it would be highly misleading to give the recurrence risks of X-linked disorders. When the findings in any one family differ from the characteristic picture, a number of possibilities should be considered. These include new mutations and non-paternity, as well as an absence of information or misinformation, possibly misdiagnosis, of other relatives.

Second, the occurrence of other disorders in the family history may also raise suspicions about the correct diagnosis. A history of fragile X in a maternal uncle might warrant re-examination of fragile X status in the proband. Related to this, a history of multiple miscarriages in the parents alerts suspicion to a possible chromosomal abnormality. Third, in multifactorial disorders where heavier family loading is thought to indicate greater disease liability within the family and therefore predict a higher recurrence risk for individuals (Carter 1976; Falconer 1981), such information might be used to alter the recurrence risk information given to families. In practice, there are few empirical data to vary recurrence risk dependent on family history for any of the child psychiatric disorders. One possible exception may be idiopathic mental retardation, as indicated in Table 66.2. It is not clear whether families with two autistic children should be given higher risks; 1 in 20 two-child families with an autistic child would be expected to have a second affected child. Fourth, in obtaining the family history, it is important to enquire about both sides of the family, even when it appears that risk is conferred by one side of the family only. However, the risk for the couple seeking counselling depends upon the genetic contribution of each side. The family history from the 'unaffected' side may reveal other genetically mediated problems of equal risk to the couple. Obtaining a family history from both sides has the added benefit of diffusing any possible blame of one side of the family.

Fifth, obtaining the family history often guides the clinician to the preconceived notions of the couple with regard to the cause of the disorder in their family. Quite unwarranted extrapolations about the behaviour of relatives, leading to blame of one side of the family or assumptions that the recurrence risk may be higher for their family, are not uncommon. Finally, the family history may alert one to current or past difficulties experienced by the parents that might interfere with their interpretation of information. In autism, an association with depression and other emotional disorders has been consistently described (Szatmari *et al.* 1991; Bolton *et al.* 1994; Smalley *et al.* 1995), although the cause is not understood (Bolton *et al.* 1998). Whatever the reason, depression amongst clients receiving genetic counselling could influence their perception of risk (Marteau 1999).

Communication

When families attend for genetic counselling, it is essential to clarify at the outset the questions they wish to have answered. It is helpful to find out who has sought the referral and, if not the family, how they view it. There will be a small minority of families who do not accept the diagnosis; without this preliminary, genetic counselling is unlikely to be helpful to families. Clients may have additional questions about the risk for other family members having an affected child; the usual policy is to give counselling only to the couple attending the clinic (while extending the invitation to see other family members if they wish and it is appropriate). A further question for families can be whether

there was a causal role of environmental factors. Families may wish to know whether there are any measures they can take to reduce the chances of having an affected child.

In feeding back on risk, it is important to discuss the range of severity. With autism, this includes the broader phenotype of speech and language delay, literacy problems and social eccentricities. Whereas these are substantially more common, they are also much less impairing and this is important to emphasize to families (Rutter *et al.* 1997). Similarly, the couple may be preoccupied with the risk of the disorder present in their family and it can be helpful to remind them of the risks that apply to all couples, which are roughly 1 in 50 of having a child with a significant mental or physical handicap.

There is a general view that genetic counselling should be non-directive, making information available to families but not advising them on how to proceed. In practice, this may be difficult to achieve. For example, in counselling families with regard to autism, giving a sibling recurrence risk of 5% may sound less than 1 in 20. Similarly, placing the emphasis on the 95% probability that a sibling will be unaffected sounds more positive. It is easy for phrases like 'only' or 'as high as' to slip in, giving the client a view of the counsellor's perspective. The view that counselling should be non-directive developed in response to the abuses during the eugenics movement. However, Michie *et al.* (1997) found that counsellors made an average of 5.8 'advice' comments and the same number of 'evaluative' comments per counselling session, throwing into question the perception of the counselling process as non-directive. This may not be undesirable; in another study, 80% of clients at risk for having an offspring with a blinding disease reported they wished to receive an opinion from their genetic counsellor on what course of action to take (Furu *et al.* 1993) and, in another study, patients receiving non-directive counselling perceived their risk to be higher than those obtaining more directive counselling, possibly feeling in the former case that the neutral counsellor was withholding information (Shiloh & Saxe 1989).

A great deal of information is exchanged during genetic counselling and often a range of different recurrence risks are given to families. It is advisable to write directly to families following the consultation to summarize the recurrence risk (and other) information they have been given. It may be appropriate to offer follow-up sessions to the clients, particularly if there is a large difference in how each member of the couple views the information they have been given.

Problems and limitations in counselling for child psychiatric disorders

Giving information with respect to recurrence risks depends crucially on correct identification of the disorder. Despite the advances in the last 15 years with respect to operationalized diagnoses, there remain a number of cases where individuals with a severe impairing disorder fall short of diagnostic thresholds or where symptomatology crosses over diagnostic boundaries (Angold *et al.* 1999). Because the genetic evidence comes from

cases meeting the strictest criteria, it is unclear to what extent the same risks are applicable to clinical variants. In autism, this arises with respect to Asperger syndrome and other disorders of the broader phenotype, and where autism coexists with profound mental retardation or ADHD. Similar issues will apply to Tourette syndrome and the lesser phenotypes of transient and chronic motor tics and obsessive-compulsive disorder (Pauls *et al.* 1991). There are situations for which genetic counselling is requested and recurrence risks cannot be given. For example, people with high-functioning autism marrying and wishing to have their own families; there are no studies to guide them as, depending on the number of genes and whether they act dominantly or not, risks could be either higher or lower than the sibling recurrence risk.

A related issue is that of genetic heterogeneity. Where information on recurrence risks is available, it is based on the aggregate risk of all families with affected probands. Genetic heterogeneity is the rule and current diagnostic categories almost certainly include cases with varying degrees and types of genetic risk. Comparison of monozygotic twins with autism suggests that clinical features are unlikely to be a good marker of genetic heterogeneity, as the within-twin pair variance was essentially as great as that between twin pairs (Le Couteur *et al.* 1996). In giving families an averaged recurrence risk, it is possible that this is highly inaccurate for individual families. One of the ambitions of molecular genetics is to be able to give families more precise risks, but large studies of families will be necessary.

Future directions

It is certain that advances in molecular genetics will have massive effects on genetic counselling for child psychiatric disorders. As susceptibility genes are discovered, it is likely that the demand for genetic testing will increase, both among families with affected relatives and the general population. However, it is unclear as yet how helpful it will be in identifying the genetic status of individuals when the genotype relative risk (the risk of developing a disorder given a particular genotype) is in the region of 1.5–2, as has been reported for ApoE4 in Alzheimer's disease (Post *et al.* 1997) and DRD4 in ADHD (Thapar *et al.* 1999). For multigenic disorders, it so far appears that knowledge of genotypic status for one susceptibility gene modifies the empirical recurrence risk only slightly (Nuffield Council on Bioethics 1998). Being able to account for more than one gene will require knowledge of interaction among the genes being evaluated. Even if all susceptibility genes are discovered, the accuracy of individual risk will not exceed the concordance rate for monozygotic twins (who share all their genes), which is around 50–60% for many psychiatric disorders.

Key steps following the identification of susceptibility genes will include understanding the structure and function of the gene as a way of elucidating disease pathogenesis; clarifying the interplay amongst a range of genetic susceptibility factors to give more precise information about individual risk; and under-

standing the links between genetic susceptibility and environmental factors, both for aetiology and treatment (Rutter & Plomin 1997). Although a major long-term aim of the human genome project has been the identification of genes to allow more effective treatment of human disease, this has not yet been forthcoming, with developments in gene therapy being particularly disappointing (Li & Huang 2000). Treatments providing more specific environmental interventions may prove more effective. Discovery of susceptibility genes may also help to identify which environmental risks are sufficiently severe to cause disorder in the absence of genetic risk.

Implications for genetic counselling are potentially huge. With multiple susceptibility alleles, risk information for families is likely to be more complex and novel modalities for helping families to understand the information will be important. However, if the demand for genetic counselling increases, there may be a greater expectation that primary care will provide information (Reynolds & Benkendorf 1999). The anticipated demand for susceptibility gene testing will also need to be evaluated in relation to the potential diversion of health care resources from other activities. Furthermore, considerable effort is being put into identifying susceptibility genes for disorders where the magnitude of genetic risk factors and the phenotype they affect remain uncertain, such as anorexia nervosa. Although molecular genetic knowledge may help to answer these questions, it is possible that requests for counselling will precede sufficient knowledge for its delivery.

A related concern is that genes conferring susceptibility in a particular situation may be protective or beneficial in another. For example, the long repeat variant of the DRD4 allele has now been replicated in a number of studies as a risk allele for ADHD; however, a (unreplicated) study suggested that the alternative short repeat allele was a risk factor for Tourette syndrome (Grigorenko *et al.* 1997). Although this finding has not been replicated, it highlights the potential complexities that a genotype could increase risk for one disorder but be protective for another, or have selective advantage either in the heterozygous state or in combination with other genes or environments.

As susceptibility genes for multifactorial disorders are identified, research examining the interplay between genetic susceptibility and environmental risk will be considerably more fruitful. A key question will be whether knowledge of the genotype is helpful in developing prevention and treatment programmes, or whether these are more effectively applied to a wider population without knowledge of genotype. In part, this will depend on the extent to which genotypes have specific and powerful effects on the outcome of intervention; in further part, it will depend on the extent to which knowledge of genotype alters behaviour and compliance with treatment. It will be important to understand how genotypic information may influence people's perception and motivation (Marteau 1999). One experimental study suggested that giving genetic risk information as genetic rather than non-specific risk reduced people's perception of the disease as potentially preventable (Senior *et al.* 2000). In another study, smokers who were told they were genetically

predisposed to develop lung cancer were not more likely to quit smoking, but were more fearful about the effects (Lerman *et al.* 1997). On the other hand, the finding that high-risk status, such as pregnancy and heart disease, may enhance success in quitting smoking highlights the importance of how risk and possibilities for change are presented (Law & Tang 1995). Much more knowledge is required about the impact of genetic testing on self-perception and health behaviour. With the identification of susceptibility genes for child psychiatric disorder, new pressures for testing children are likely to occur. As with Mendelian disorders, it will be important to weigh up the clear disadvantages of testing at an age when the child cannot give informed consent with the potential benefit.

The possibility that genotyping could be used for diagnostic purposes in child psychiatry has been raised. For Mendelian disorders, there has been a close correspondence between genetic mutation and diagnosis, although many disorders have more than one genetic cause. However, genotyping is often not used for diagnosis but rather for counselling family members. Although the present evidence is limited, susceptibility genes may affect more than one disorder; it has been suggested (but not yet confirmed in subsequent studies) that the same variant of DRD4 that increases susceptibility to ADHD is also associated with attachment disorders (Lakatos *et al.* 2000). It is unclear to what extent genotyping may help with planning treatment or determining prognosis, but current evidence suggests that pairs of monozygotic cotwins can vary enormously in phenotype (Le Couteur *et al.* 1996). It is as yet unclear what clinically useful information genotypic profiling will add to a careful consideration of the phenotype, and it is unlikely to replace the latter.

It is hoped that identification of susceptibility genes and individual gene testing will lead to more effective interventions. Pharmacogenetics is one area that may benefit, because variation in drug-metabolizing enzymes and receptor pharmacology is genetically influenced. Such analysis could detect variation indicating that drugs are less likely to be effective, may be most effective in different doses or in conjunction with another drug, or could produce more side-effects (Catalano 1999). On first sight, such testing would appear wholly beneficial, helping to target and specify treatment. However, the issues surrounding genotyping becomes more complicated if the variation that predicts drug response is also associated with other clinical characteristics, e.g. with worse prognosis, or probability of recurrence. It has been suggested that identification of susceptibility alleles will allow early detection of individuals at risk (Rutter & Plomin 1997), but it remains to be seen whether this will be viable, with regard both to the size and cost of the testing programmes, the accuracy and precision of the results, and the potential benefits of treatment in the absence of any symptoms. With regard to ADHD, it may be cheaper, more accurate and equally effective to base early intervention programmes on reports of hyperactivity symptoms, regardless of DRD4 genotype. The use of genetic testing will become the preferred alternative only when the health benefits of this form of screening are clearly demon-

strated, and it is shown that they outweigh the potential drawbacks of genetic testing.

Pre-implantation diagnosis of fertilized embryos will lead to important changes in prenatal genetic testing. Where it has been implemented with respect to Huntington disease, it has two potential benefits. By selecting for implantation only those embryos without the mutation, it not only removes the need for termination of pregnancy but also, where genotype of the parent at risk has not been confirmed, it may avoid disclosure of parental genotype where this is not wanted (Maat-Kievit *et al.* 1999). However, there may be practical difficulties as well as legal barriers to maintaining confidentiality of embryonic status (Braude *et al.* 1998). If pre-implantation selection becomes generally available, it may have wider influences on fetal selection. Although there has been general agreement that prenatal diagnosis with a view to selective abortion should occur only for disorders that are severe and for which there is no treatment, it might be that lower thresholds would be applied to pre-implantation methods. This could raise questions about selecting against susceptibility genes associated with some psychiatric disorders and also in favour of genes associated with beneficial traits, such as intelligence, or in favour of a particular sex (Wertz & Fletcher 1993).

Concern continues about the way in which insurance companies may discriminate against people who have participated in genetic testing (Harper 1995). The possible conflict between obtaining genetic information to improve one's lifestyle and modify health risks and the threat of not being eligible for insurance is a real one. It is unclear to what extent regulation of insurance companies will be possible. It is possible that similar issues might be taken up by employers as a method for controlling the future health status of employees. If genetic testing were to be enforced as part of occupational health screening, this could well be discriminatory and a breach of human rights (Nuffield Council on Bioethics 1998).

The future for genetic testing and counselling is exciting, important in improving health, but also filled with possible pitfalls and abuses. Involvement of the wider community is essential in developing new policies. More important than testing *per se* will be the development of interventions that make best use of genotype information. Planned research is needed to determine whether genotype information results in health improvement.

Acknowledgement

Thanks to Professor Theresa Marteau for reading an early draft and making invaluable suggestions.

Services for Children and Adolescents with Severe Learning Disabilities (Mental Retardation)

Sarah H. Bernard

Introduction

It is widely recognized that children and adolescents with severe learning disabilities are at risk of developing behavioural or emotional problems and have an increased likelihood of physical and sensory disabilities, epilepsy and physical injury as compared to the general population (Rutter *et al.* 1970; Bregman 1991; Dunne *et al.* 1993; Borthwick-Duffy 1994). These young people are dependent on others for the acquisition of their basic needs and have problems compounded by social stigmatization (Goffman 1963; Gibbons 1985). Their parents, siblings and extended family also have their own needs (Friedrich *et al.* 1985), and while recognizing that it is the child who is the patient, frequently it is the whole family that is in need of a service (Robards 1994). Generic child and adolescent mental health services are unable to meet these multiple and complex needs in a comprehensive manner; accordingly, specialist but integrated multidisciplinary services are required. These should be able to offer flexibility in the light of changing and multiple needs. Service providers have to take into account the age of the child, the level of the child's learning disability, physical disability, the structure and ethnicity of the family and the many other variables which influence how the child's behavioural or mental health problems might best be assessed and managed (Bernard 1999). As the difficulties posed by having a severe learning disability continue into adulthood, service provision has to do likewise.

The twentieth century witnessed great changes in the provision of care for people with learning disabilities (Ryan & Thomas 1987; Blunden 1990; Hassiotis *et al.* 2000). In the UK, the move away from institutionalized care began in the 1960s with public attention drawn to the plight of those in the asylums (Ryan & Thomas 1987). In 1971, the government White Paper 'Better Services for the Mentally Handicapped' paved the way to the development of individualized care in the community with the subsequent closure of the large asylums.

Other factors that have influenced these changes include the normalization principle, which emphasizes that people with a learning disability 'should have access to patterns of life and conditions of everyday living which are as close as possible to the regular circumstances and ways of life of society' (Nirje 1970). Service provision continues to strive to achieve this goal, with the acknowledgement that people with a learning disability are

entitled to a valued role in society (Wolfensberger 1983). O'Brien described five key accomplishments for people with learning disabilities, these being a community presence, relationships, competence, respect and choice (O'Brien 1987). All should be considered when planning services.

Despite massive moves forward in service provision, children and adolescents with severe learning disabilities remain relatively poorly provided for (Fraser & Murti Rao 1991; Royal College of Psychiatrists 1998). Where services do exist they tend to be fragmented and lack co-ordination (Richardson *et al.* 1986; Slatter & Black 1986) although some groups of children and adolescents with specific disorders appear to be better served than others, e.g. those with Down syndrome (Byrne *et al.* 1988). The various agencies involved (including health, education, social services and the voluntary sector), recognizing this gap in service provision, have now begun to address how services might be better developed to meet the needs of these young people (Audit Commission 1994; NHS Executive 1998).

This chapter focuses on the prevalence of various needs and how services may meet them, with particular reference to families' needs for preventative services, accurate diagnosis, specialist mental health services (to include assessment, treatment and management) residential services, education, family support, help in the transition to adult life, and a helpful legal framework

Terminology and classification

The terms used to refer to people with learning disabilities have changed over time, reflecting changing attitudes. Currently, in the UK, the term 'learning disability' is the most widely accepted term used to refer to people who have a level of intellectual functioning significantly below the average. This, statistically, is at least 2 SD below the mean IQ of 100, giving a measured IQ of 70 or less. Low IQ alone cannot be used to define learning disability. The individual has impairments in other areas, including the development of adaptive skills, self-care, social skills, communication, academia, leisure and employment (see Volkmar & Dykens, Chapter 41). It is also recognized that to have learning disabilities, the impairments should have been evident prior to 18 years of age. Whereas 'learning disability' is the terminology

recognized in the UK, this is not the situation internationally. In the USA, this term refers to children with specific educational problems, with 'mental retardation' being the term used to define people with a global impairment. Other terms used include 'intellectual disability', 'developmental disability' and 'mental handicap' (Russell 1997).

Historically, other terms have been used. In the early twentieth century, 'idiocy', 'imbecility' and 'feeble-mindedness' were the accepted labels of the time but, partly because of the negative connotations of such terms, the accepted terminology altered to 'mental subnormality' in 1959, 'mental handicap' in 1983 and, in the 1990s, to 'learning disabilities' (Ryan & Thomas 1987). Terminology continues to be debated because, with each change in label, the associated stigma gradually recurs. It seems to arise from society's perception of the disability, rather than from the term used as a descriptor. 'Mental retardation' remains the internationally recognized term even though it is felt by some to be derogatory. Parents are often confused by the variety of labels, especially by whether 'learning disability' refers to global or specific deficit. Some continue to prefer 'mental handicap', believing that it reflects the devastating impact.

Educational services have introduced alternative terms: in the UK, for example, 'moderate' and 'severe' learning difficulties has been the terminology since the Warnock Report of 1978.

The World Health Organization (1980) suggested a model that puts the person's disability into a social context using the terms 'impairment', 'disability' and 'handicap'.

- Impairment is defined as any loss or abnormality of psychological, physiological or anatomical structure or function that may be temporary or permanent.
- Disability is the restriction or lack (resulting from an impairment) of ability to perform an activity in the manner or within the range considered normal for a human being.
- Handicap is social disadvantage resulting from the impairment and disability. Thus, the disease, effect of the disease on the body, performance and ability to carry out a social function are accounted for, with handicap clearly defined as the result of an impairment and not the cause of it (Robards 1994).

Terminological confusion has had an impact on service provision and terms such as 'behavioural disturbance' as opposed to 'psychiatric disorder' have added to this, with the contribution of psychiatrist vs. psychologist coming into question (Fraser *et al.* 1986). Criteria have been suggested in an attempt to define 'problem behaviour' (Zarkowska & Clements 1988). The behaviour should be inappropriate for the person's age and level of development, dangerous to the person or to others, constitute a significant handicap, cause significant stress and be contrary to social norms. Many professionals found this term unhelpful and the term 'challenging behaviour' became accepted. This is defined as 'behaviour of such an intensity, frequency or duration that the physical safety of the person or others, is likely to be placed in serious jeopardy, or behaviour which is likely to limit seriously, or delay access to or the use of, ordinary community facilities' (Emerson *et al.* 1988).

There are some difficulties in using the classifications of

behavioural and emotional problems that were designed for those without a learning disability. Physical problems, for example, alter presentation: less mobile children cannot exhibit some of the symptoms of hyperactivity or conduct disorder. In spite of these difficulties, it is clear that certain disorders are more common in children with severe learning disabilities, especially pervasive developmental disorders (see below; see also Volkmar & Dykens, Chapter 41). The applicability, reliability and validity of current international systems of classification, including ICD-10 and DSM-IV, for children and adolescents with severe learning disabilities have been questioned (Einfeld & Aman 1995). Despite these difficulties, the diagnosis of psychiatric disorder serves the function of informing about the clinical condition, assisting in the evaluation of treatment outcomes, establishing causal connections between psychopathology and clinical presentation and identifying at-risk populations (Russell 1997).

Prevalence of specific needs

The prevalence of mild learning disability, as defined by an IQ of more than 2 SD below the mean, is 2–3%, but this has been shown to vary with socioeconomic circumstances. The prevalence of severe learning disability, 3 SD below the mean, is 3–4 per 1000, this figure being little influenced by socioeconomic factors and having a strong organic or genetic aetiology. There are many population studies of prevalence of learning disabilities that vary in criteria used. Total population studies include the Isle of Wight study (Rutter *et al.* 1970) which investigated children aged 9–10 years using an IQ criterion of under 70 and demonstrating a prevalence of 2.5%. Other studies replicated these findings also using an IQ criterion to define learning disabilities (Birch *et al.* 1970; Granat & Granat 1973). Studies that used the combination of IQ and impairment find a much lower prevalence, between 0.5 and 1.5% (Rutter *et al.* 1970; Gostason 1985).

There is an increased prevalence of certain specific disorders in people with learning disabilities. These include neurological deficits, epilepsy, sensory deficits, communication disorders and behavioural and mental health problems. The prevalence of these disorders varies with age. Epilepsy occurs in 20–50% of people with severe learning disabilities, this frequency increasing in specific conditions such as tuberous sclerosis and neurodegenerative disorders. Of people with severe learning disabilities, 15–40% have cerebral palsy, 10–30% serious visual impairments, 60–85% severe communication disorders and up to 5% have auditory deficits (Fryers & Russell 1997).

Children and adolescents with severe learning disabilities are at enhanced risk of developing mental health problems similar to those that affect their non-disabled peers; and show an even greater degree of risk of the development of certain specific disorders, including autistic spectrum disorder and attention deficit disorders (Rutter *et al.* 1970; Corbett 1979; Dossetor & Nicol 1981; Gilberg *et al.* 1986; Cormack *et al.* 2000). About

Table 67.1 Estimates of prevalences in very rare disorders.

Syndrome	Prevalence
Down	1 in 600 (age dependent)
Fragile X	1 in 1000–3000
Lesch–Nyhan	1 in 100 000–200 000
Phenylketonuria	1 in 4500–15 000
Rett	1 in 10 000–15 000 (females)

one-half of children, aged from 0 to 15 years, who had severe learning difficulty also showed a psychiatric disorder, according to an epidemiological study by Corbett (1979). In addition, children without a specific diagnosis are still at risk of developing behavioural problems or ‘challenging behaviours’ (Einfield & Tonge 1996). Studies that have looked at challenging behaviour in children with severe learning disabilities have shown 8% to have behaviours presenting severe management problems and a further 14% to show milder problems of this nature (Keirnan & Keirnan 1994).

Risk factors for the development of behavioural problems in children with severe learning disabilities include limitations in daily living skills, with one study of children aged 4–11 years finding this a better predictor than poor communication (Chadwick *et al.* 2000). This study also demonstrated that children who were ambulant had more problems, although those problem behaviours that were less dependent on walking were as common in non-ambulant children. Other studies have confirmed these findings, with the severity of physical disability having a direct relationship on ratings of behavioural and emotional problems (Cormack *et al.* 2000).

Other specific behavioural problems that are more common in those with severe learning disabilities and have service implications include severe sleep disorders (Wigg & Stores 1999), severe self-injury (Oliver 1995) and communication problems. These have been found to be associated with a skills deficit (Chadwick *et al.* 2000).

There are certain behaviours associated with specific conditions (Flint 1996; see also Skuse & Kuntsi, Chapter 13). These ‘behavioural phenotypes’ include overeating in Prader–Willi syndrome (Clarke *et al.* 1995), severe self-injury in Lesch–Nyhan syndrome, sleep disturbance in Smith–Mageniss syndrome and social disinhibition in Williams syndrome. The diagnosis of these disorders and knowledge of the associated behavioural problems enables interventions to be planned aimed at minimizing these difficulties (Berney 1997). Despite this, it is recognized that many of these syndromes are rare, as indicated by the estimates of prevalence in Table 67.1 (Berney 1997).

Children with very rare disorders will only account for a small proportion of the caseload of a local service. This has resulted in expertise in these disorders being concentrated in a few regionally or nationally based services, allowing both clinical and research expertise to be developed. The advantage of this approach is that the needs of these small groups of children can be considered in a systematic way with individual variables ac-

counted for. Obvious disadvantages are geographical, with families having to travel long distances to be seen, the child not being seen within their own environment and intensive community work not being practical. To overcome these obstacles it is vital that specialist services liaise locally and transfer the skills to those providing the local long-term services to the child and their family.

Service needs

The move away from institutionalized care to community care has had, as expected, major influences on service provision for people with learning disabilities. Children and adolescents with learning disabilities are now recognized as requiring a child-based service integrated into other services for young people (Children Act 1989). The aim of service providers is to ensure that the person’s medical, emotional, cognitive, behavioural, social, educational and legal needs are being met (Turk 1997), while recognizing the prerequisite of good liaison with the multitude of professionals and agencies involved (Hall & Prendergast 1990). In the UK, various statutory bodies have attempted to ensure that the child’s service needs are provided, with the passing of the Children Act (1989) in which these children are referred to as ‘children in need’, and the Education Act which encourages integration and access to the national curriculum for all children.

Mental health services for children and adolescents with severe learning disabilities should not be considered in isolation. This group of young people will also fall into the remit of the community paediatric services and, some believe, the psychiatrist should be a core member of this team. If this is not the case then it is essential that the two teams are able to work closely together, with the main areas of responsibility being clearly defined (Sturge 1989). When considering the role of the specialist mental health services, the Royal College of Psychiatrists (1992) outlined a model of service provision for children and adolescents with learning disabilities and mental health needs. They suggested that skills should cover the following.

- Prevention and amelioration of mental health problems.
- Diagnosis of cases with often complex and multifactorial presentations and aetiologies.
- Focused and specialist treatment interventions.
- Multi-agency liaison and collaboration with professionals involved in clinical management.
- Prevention of complications.

A subsequent report in 1998 (Royal College of Psychiatrists 1998) again emphasized the need for specialist services with the proposal that such services should be comprehensive and able to cater for children and adolescents of all ages and all levels of disability. Specialist areas of input were expanded upon, with autistic spectrum disorders, serious psychiatric disorders and hyperactivity being highlighted as major areas of service need. Behavioural disorders associated with epilepsy, emotional disorders, aggression, self-injury, eating and sleep disorders, child

abuse, offending and substance abuse all need particular consideration. The types of specialist interventions need to include diagnostic services, adjustment counselling, behaviour modification approaches, family work, individual therapies and pharmacological therapies.

Generic child and adolescent mental health services are not usually able to offer the specialist provision. In one study, only 32% of child and adolescent psychiatrists offered a service to those with severe learning disabilities (Joint College Working Party 1989).

Specific areas of service need

Preventative services

Prevention may be either primary, secondary or tertiary. Primary prevention, ensuring that the condition does not occur at conception, takes the form of pre-conceptual counselling with minimization of the risk factors associated with specific conditions. Examples include dietary advice and the use of pre-conceptual folic acid to reduce the risk of neural tube defect, and immunization to prevent congenital rubella.

Recent developments in molecular genetics have allowed the identification of abnormal gene sequences in rare conditions associated with learning disabilities. As a result of this, individuals may now be screened for many more disorders than before. It is hoped that the identification of these abnormal gene sequences could also lead to specific interventions and therapies aimed at preventing the development of these disorders (Muir 2000).

Secondary prevention of specific conditions is possible as a result of prenatal screening and diagnosis, with selective termination of an affected pregnancy. Conditions that may be screened for include neural tube defect (anencephaly, encephalocele and spina bifida) and Down syndrome. Tertiary prevention aims to prevent the complications of a disorder. An example of this, for children with severe learning disability, would be the prevention of a behavioural disturbance.

Primary prevention

Primary prevention of learning disability demands a knowledge of the underlying aetiological factors contributing to the disorder. These include genetic, organic and sociocultural influences that give rise to the deficits in cognitive functioning in a multifactorial manner. In those with severe learning disabilities, the genetic and organic factors have a major role, with socioeconomic factors exerting a lesser influence (Dykens 2000; Muir 2000; see also Volkmar & Dykens, Chapter 41).

The report of the Commission of Enquiry on Mental Handicap (1965) discussed the principal preventative measures as being related to health education, better obstetric services, control of epilepsy, early identification of disorders, routine neonatal testing, genetic counselling and alleviation of cultural

and environmental deficiencies. Health education must be at both a local and national level, with the importance of work being done at school level recognized.

With the rapid growth of genetic knowledge of the last three decades, thought has been given to the role of genetic counselling services. These services offer detection of risk factors, the ability to make accurate diagnoses and assist in the diagnosis of rare disorders. Genetic counselling for families who have a child with learning disabilities or are at risk of having an affected child poses practical and ethical dilemmas. In a small number of conditions there is the possibility of the reduction of risk factors, neural tube defect being an example with the use of periconceptual folate. More often, the role of the clinical geneticist, in collaboration with other disciplines, is the ability to offer accurate diagnoses, prenatal testing of pregnancies with termination being the only preventative intervention available (see also Simonoff, Chapter 66).

Secondary prevention

Diagnosis of congenital abnormalities during the antenatal period may be achieved as a result of chorionic villus sampling, amniocentesis and ultrasonography. More invasive procedures include fetoscopy. The ethical and moral considerations surrounding prenatal diagnosis have not advanced as rapidly, posing serious dilemmas for many professionals and families (West 1988; Boyd *et al.* 1998; Green *et al.* 1993). One group of disorders in which the benefits of both screening and prenatal diagnosis has been considered extensively is neural tube defect.

Defects of the neural tube include the following.

- *Anencephaly*: the most severe form of neural tube defect, resulting in exposure of the brain and spinal cord and causing abnormal development of the brain and spine.
- *Encephalocele*: a defect in the skull, usually occipitally, with protruding brain.
- *Spina bifida*: failure of closure of the spine, with protrusion of meninges through the defect and abnormal development of the spinal cord.

Anencephaly is almost always a lethal condition but encephalocele and spina bifida, while usually resulting in severe if non-lethal consequences, have a variable outcome from severe global intellectual and physical disability to minimal or no problems.

Neural tube defect was one of the first disorders in which a prenatal screening programme was developed with the identification of a biochemical marker in maternal serum. This marker, maternal serum alpha-fetoprotein (MSAFP), was found to be elevated in women carrying a fetus affected with an open neural tube defect. Unfortunately, although the marker was reasonably sensitive and specific, it could be elevated in a number of situations and was highly dependent on accurate knowledge of the gestation of the fetus. There were also situations in which false-negative results occurred. This led to questioning of the advantages and disadvantages of the screening programmes of neural tube defect, with some believing that it was only of benefit to mothers living in areas where there was a high risk of neural tube

defect (Standing *et al.* 1981). It has also been commented that the screening programme was weighted towards fetuses that were, in any case, incompatible with life.

There were, subsequently, studies of women's experiences of MSAFP screening that concentrated on the anxiety created as a result of screening. One study of 179 women undergoing screening demonstrated a more positive attitude towards the pregnancy following screening. This study used the state-trait anxiety inventory to assess anxiety levels but responses were not considered in conjunction with the management of the women at the time of screening (Bennett *et al.* 1980). Other studies demonstrated a raised level of anxiety in women with both positive and negative outcomes of screening, with anxiety being reduced with good family and social support (Robinson *et al.* 1984).

Amniocentesis, a diagnostic test used to detect a number of disorders including neural tube defect and Down syndrome, creates anxieties because of both the possible serious outcome of the test, but also because the investigation itself carries risks of damage to the pregnancy whether it is normal or not (Marteau *et al.* 1993).

Ultrasonography during the antenatal period may be used as either a screening or diagnostic investigation. It is routinely used to assess gestational age and fetal growth. An obvious benefit of this procedure is the reassurance of not detecting an abnormality in an at-risk pregnancy (Tsoi *et al.* 1987), but there is a high rate of detection of false-positives leading to unnecessary anxiety for many women (Boyd *et al.* 1998).

Down syndrome is another disorder in which serum screening can now be offered, giving an estimate of the risk of an affected pregnancy. Between 36 and 76% of those affected can be detected antenatally, although take-up rates for the programme vary (Wald *et al.* 1997). Although there are concerns about the false-positive results of screening (Boyd *et al.* 1998), there are also concerns about the effects of false-negative results, with one study of 179 parents of children with Down syndrome demonstrating an adverse effect on parental adjustment when the child was born following a false-negative screening result (Hall *et al.* 2000).

Decision-making after the detection of a fetal abnormality is influenced by a number of factors including the nature of the abnormality, the counselling received, and the family's own experiences, religious and moral beliefs. Some women, despite the identification of a pregnancy affected with a congenital abnormality, will refuse termination of pregnancy (Meryash 1992). The psychological impact on families undergoing these procedures has been recognized (Berne-Fromell *et al.* 1983) and the professional support that is subsequently needed has been highlighted (Donnai 1987). There are also eugenic concerns that are particularly relevant to those with severe learning disabilities (Seller 1982; Lilford 1989; Richards 1989). While acknowledging the problems arising as a result of prenatal diagnosis, the benefits are also evident (Pueschel 1991). There has been an argument that termination of pregnancies that might result in a child being affected with a disability devalues the life of people

with disability, although others believe it is the right of the fetus to be born healthy (Pueschel 1991).

A small number of conditions can be treated in the neonatal period, so neonatal screening programmes are essential if early detection is to be achieved. Examples of particular disorders are phenylketonureia and congenital hypothyroidism.

Phenylketonuria, a disorder of amino acid metabolism, has a reported incidence of 1 in 10 000 live births. There is a variable deficiency of phenylalanine hydroxylase, and the condition, if untreated, creates an accumulation of phenylalanine in the body tissues, with subsequent cellular damage including brain damage. Untreated cases that are not detected at birth have a dramatic cognitive decline in the first year of life, with treatment being unable to reverse this. Neonatal screening enables the disorder to be detected prior to a build-up of phenylalanine and the subsequent cellular destruction that ensues. Implementation of an appropriately low phenylalanine diet in the neonatal period prevents brain damage. Despite this, there are reports that, even in treated cases, there are some clinical deficits, including problems with concentration and abnormalities of visuomotor and spatial skills (Thompson *et al.* 1990).

Congenital hypothyroidism, occurring in 1 in 4000 live births, is another metabolic disorder that if treated early in the neonatal period prevents the severe developmental delay and gross retardation that results from lack of thyroxine.

Tertiary prevention

Reduction of the additional handicaps associated with learning disabilities is also important. These include sensory problems and the complications of epilepsy. Early detection of problems, to minimize these secondary handicaps, is important although the benefits of routine health screening on a regular basis have been debated (Hall 1991). It has been suggested that current health surveillance which includes a neonatal and 6-week check, monitoring of neurologically damaged children, and detection by those closely involved with the child, such as parents, health visitors and general practitioners, is adequate (Hall 1991). Concerns are that parents are not best able to monitor their child's development and that early detection of problems will not occur (Bax & Whitmore 1985). Advantages are that many disorders will be detected neonatally or at the 6-week check and further surveillance is costly, with a low detection rate.

Diagnosis

The diagnosis of the underlying cause of the child learning disability is, in general, the remit of the paediatrician, sometimes in conjunction with a clinical geneticist (for a scheme of investigation see Bailey, Chapter 10). Occasionally, the child may be referred to a mental health service because of a behavioural problem, with the nature of this problem suggesting a specific medical diagnosis, such as Lesch-Nyhan syndrome. The diagnosis of disorders such as these is dependent on a knowledge of the behavioural phenotypes associated with rare syndromes, a

thorough history, careful physical examination, specialist investigations and good liaison with paediatricians and clinical geneticists.

The diagnosis of childhood psychiatric conditions in children with severe learning disability is one obvious remit of the specialist mental health service for this group of individuals. Before being able to make such diagnoses there must be a detailed assessment, including the history of the disorder, observations of the child at home and at school, and information from others involved in their care, including teachers and carers. An assessment of the child's level of functioning is invaluable in allowing appropriate behaviours for the child's cognitive level to be accounted for.

Even with detailed information there are difficulties in attaching diagnostic labels to children with severe learning disability and behavioural problems. Despite this, it remains important to identify conditions such as autism, attention deficit disorder and the other childhood psychiatric disorders that have diagnostic and treatment implications for the child and their family.

Interventions

Behavioural approaches

The most widely accepted intervention for behavioural problems in children and adolescents with severe learning disability is behavioural modification (Yule & Carr 1987). However, there is limited research evidence to support the long-term benefits of such an approach, with the prognosis remaining poor for adulthood (Oliver & Head 1990). Early interventions for cognitive or behavioural problems are often home-based. One well-studied intervention of this nature is the Portage scheme (Shearer & Shearer 1972). This involves regular visits by a trained home advisor who provides short-term goals and training methods. Initial studies of this intervention demonstrated impressive gains, but the scheme was aimed at children with mild or specific learning disabilities. Despite some criticisms, this home-based input became popular, particularly in the USA. The gains made by those families offered this service continued to be demonstrated as being greatest for those whose children had mild problems or who were disadvantaged, with the benefits questioned for those with severe learning disabilities (Clements *et al.* 1982; Robards 1994).

Other early interventions have also been developed. Some, it was hoped, would reduce the level of the child's disabilities and increase their level of cognitive functioning. The Infant Health and Development Programme offered enrichment for children of low birth weight but, while demonstrating improvements up until the age of 3 years, there was little evidence that this was sustained (Richmond 1990). It was also evident that those children with IQs of less than 70 were less likely to benefit from this approach.

In general, punitive forms of behavioural modification have been superseded by programmes aimed at improving skills while addressing undesirable behaviours (Zarkowska & Clements

1988). Parent training programmes, recognized as benefiting children with conduct disorders with no global developmental delay, are also reported to be of benefit in the learning disabled population (Brightman *et al.* 1982; Webster-Stratton 1984). Long-term follow-up of such interventions remains sparse (Baker *et al.* 1980). Difficulties with behavioural approaches centre on poor compliance and low rates of participation, and it is evident that families who benefit most come from a relatively well-educated background (Baker *et al.* 1981).

Behavioural approaches rely on a detailed assessment of environmental events that precipitate and maintain behavioural disturbances (see Herbert, Chapter 53). This type of assessment is referred to as functional analysis, and involves detailed history-taking, direct measures and observations and analysis of the situations in which problem behaviours arise. Many procedures have been identified as a means of carrying out a functional analysis, with the ultimate aims being a clear description of the problems behaviours, predictors of when the problem behaviours occur, consequences of maintenance of the problem behaviours, the development of hypotheses to account for the behaviours and supporting evidence via direct observations (O'Neill *et al.* 1997).

Other psychological approaches

Whereas behavioural modification and behavioural psychotherapy are the best recognized psychotherapeutic interventions for behavioural disturbance in children with learning disabilities, there are a number of other psychological approaches that have also been implemented. These include individual therapies, such as drama therapy, play therapy, art therapy and psychodynamic psychotherapy, group work, family and marital therapies. There is a lack of research evidence to support the benefits of these interventions, but anecdotally it has been argued that, in some cases, there has been a reduction of behavioural problems (Waitman & Conboy-Hill 1992; Lindsey 1997).

Medication

Historically, medication has been used to sedate and calm people with severe learning disability and severe behavioural disturbance, although good practice dictates that medication should only be indicated in cases where there is a treatable underlying psychiatric disorder. An example of one such disorder is attention deficit hyperactivity disorder. Whereas there is a lack of systematic research in the learning disabled population, stimulant medication is effective in children with mild to moderate learning disability, with the benefits decreasing as the level of learning disability increases (Gadow 1985). In the learning disabled population it has also been demonstrated that stimulant medication is more likely to create side-effects, with social withdrawal being a particular problem (Handen *et al.* 1990). In a survey of 100 child psychiatrists in the UK, only half of the prescribers were willing to use this medication on children with learning disability, despite it being recognized that this group of

children have higher rates of attention deficit symptomatology (Bramble 1997).

With the development of a massive range of psychotropic medication, research into the benefits for children with learning disability and behavioural problems is awaited, although there is anecdotal evidence that certain classes of medication, including the selective serotonin reuptake inhibitors (SSRIs), might benefit children with severe learning disability, autistic spectrum disorder and the resultant severe behavioural problems that they experience (see Heyman & Santosh, Chapter 59). Scientific evidence remains essential if adverse effects are to be minimized without clear evidence of clinical efficacy.

Other intervention approaches

Conductive education has been advocated as a means of optimizing the level of functioning in children with developmental disabilities (Hari & Tillemans 1984). A holistic approach is used, with trained therapists stimulating the children. There is little objective measurement of outcome, but reports indicate the benefits are unlikely to be greater than conventional approaches (Baird *et al.* 1991). The Dolman–Delacato method of stimulation offers intensive programming exercises aimed at accelerating the child's development (Pennock 1991). It has been criticized by many leading professionals for not offering benefits substantial enough to justify the heavy demands imposed on families (Cummins 1988).

Inpatient treatment

The treatment setting is generally based in the community and aimed at offering both home- and school-based interventions. Rarely, the child presents with a problem of such complexity or severity that inpatient assessment is required. This enables investigative procedures to be performed, including detailed neuropsychiatric monitoring of conditions such as epilepsy where skilled observations are required over a period of time. Other investigative procedures are more readily offered on an inpatient basis, with video-telemetry of seizures to monitor frequency and associated behavioural problems not being possible in the community. Neuroimaging, while generally provided on an outpatient basis, frequently requires general anaesthesia in severely disturbed individuals with a learning disability and, at times, a 24-h period to ensure recovery from sedation is indicated. Intense behavioural observations can also be undertaken that would not be possible in a community setting, although moving a child from their usual setting has the disadvantage of altering the child's behaviour.

Treatments might also need to be monitored with the child in an inpatient facility. Medication, although not the first line of treatment for behavioural disturbance, does have an important role in these children. Side-effects are a concern and can be atypical so inpatient manipulation of medication may be necessary. Specific groups of young people with learning disability who require inpatient care are adolescents with a possible psychotic

disorder who are presenting a danger to either themselves or others in the community; severe eating disorders in which the child's health is in danger; severe self-mutilation; and conditions associated with epilepsy or neurodegenerative disorders. Such service provision is, by nature, highly specialized and regionally or nationally based. Units can bring problems (e.g. institutionalization), but they can deliver intensive assessments and therapies (Newman & Emerson 1991). Research into inpatient treatments for children and adolescents with severe learning disabilities is extremely sparse. There are very few inpatient settings specifically aimed at addressing the needs of this group and (as in generic child and adolescent psychiatry), the treated group is heterogeneous and ill-defined (Jacobs 1993).

Other studies have looked at the adult population with learning disabilities and seriously challenging behaviour. A postal survey of 19 specialist behavioural treatment units indicated that these units were able to offer assessment, intervention and containment but, while usually underoccupied, with a mean of 12 places, were still felt to be too large. These units were able to offer one-to-one staffing but could not provide outreach facilities. There was a low turnover of occupancy. The advantages of such specialist residential units were that extreme and complex behavioural disturbances could be assessed and managed in a setting with the appropriate level of skills and staffing. Disadvantages were isolation and the problem of generalizing complex behavioural programmes back into the community (Newman & Emerson 1991). While these issues are considered for adult residential units they are applicable to children's inpatient and residential settings. Additional concerns for children include removing the child from their family, with the risk of care being offered in a less nurturing environment.

Education

The educational provision for children with severe learning disabilities has undergone a change in many countries, with the emphasis now being on integration into mainstream schooling wherever possible and ensuring that, should this not be possible, children still access as normal a curriculum as possible. In the UK, the Education Act of 1981 lacked clarity and there was wide variation in the provision of educational resources with a lack of accountability. As a result of professional and parental concerns, a code of practice was developed which emphasized the need for integration, parental involvement and the legal obligation of the local authority to provide appropriate education. The majority of children with severe learning disabilities are now educated in day school provision with additional specialist input when indicated. Rarely, children with severe learning disabilities have such disturbed behaviour or complex medical needs (e.g. epilepsy) that they require residential provision. Residential schools are able to offer the intensive and expert input required on a 24-h basis, ensuring the child's safety while addressing their educational, behavioural and long-term health needs. Educational provision is considered in more detail by Howlin (Chapter 68).

Voluntary organizations

Voluntary organizations have an important role as part of the multi-agency provision for families with a child with a severe learning disability. In the UK, these organizations provide a massive and highly varied network of information and support that is an essential part of service provision (Crombie & Coid 2000). They include organizations which address a wide variety of issues encountered by people with a learning disability (Mencap), issues for those with a specific condition (Down Syndrome Association, Fragile X Society, Debra, and many more), specific behavioural or medical problems (Challenging Behaviour Foundation, National Society for Epilepsy), specific religious groups (Ravenswood for the Jewish community), and other locally, nationally and internationally based organizations. There are difficulties in assessing the benefits offered, as the groups are so diverse (Crombie & Coid 2000), and uncertainties about the involvement of health professionals in these groups (Black 1988). Despite this, many families find this source of support informative and a valuable addition to their support network.

Statutory and legal issues

Children and adolescents with severe learning disability are a highly vulnerable group of individuals open to abuse and exploitation (Mental Health Foundation 1993). Certain factors increase the risk of abuse, including lack of knowledge of what is acceptable behaviour from others, dependency on others for meeting personal needs and the inability to speak for themselves. Those presenting with a severe behavioural disturbance may, rarely, require methods of control or restraint involving physical interventions to ensure the child's safety (Lyon 1994).

In the UK, the Children Act (1989) provides a legal framework for the provision of services for children with learning disabilities while continuing to recognize that these children are 'children first'. The Act draws upon legislation relating to children, allowing safeguards to be implemented. Particular areas that are addressed include accommodation of children with disabilities, provision of a disability register and optimization of opportunities with the reduction of disabilities. The Act aims to ensure that services are integrated and multidisciplinary. The role of parents and families are emphasized, with the understanding that there will be partnership between them and the professionals involved. Child protection issues are paramount. The Act takes into account the transition period and outlines social services departments' statutory responsibilities in this area.

The impact of the Act on issues surrounding the care, control and safety of children with learning disabilities has been questioned. The legality of physical restraint that might have to be used, although rarely, was a major issue. A lack of legal guidance became apparent, with local authorities being expected to offer

their own interpretations or seek legal advice (Lyon 1994). As a result of a detailed research report into the area, guidelines were formulated for professionals, parents and carers, which gave advice to people caring for children with severe behavioural problems (Lyon 1994). Issues including restraint, locking of doors, consent and suspicions of harm are discussed using practical examples and the application of civil and criminal law. The overriding principle remains, as stated in the Children Act (1989), that the child's welfare remains paramount.

Consent in relation to children and adolescents with severe learning disability is an issue that requires careful consideration when planning interventions for those who present with severe behavioural disturbances and may require hospitalization or long-term medication. In the UK, the law reflects a strong belief in civil liberty with the right of the individual to refuse medical treatment even if doing so is not in his or her best interests (British Medical Association 2001; see also Little, Chapter 71). This right assumes that the individual is competent to make such decisions. Children and adolescents with severe learning disabilities have the same legal status as those without learning disabilities. Parents of children aged 16 years and under are able to consent to medical treatment for their child if that child lacks sufficient understanding and intelligence of the situation. For those aged between 16 and 18 years who are considered not to be competent, then the consent of the parents or legal guardian remains valid (Lyon 1994).

Impact on the family

The news that a child has a severe learning disability has major and devastating consequences for the family (Raech 1966; Althouse & Wald 1980; Wallander & Varni 1998). There is an initial period of shock and disbelief followed by confusion, blame and guilt (Drotar *et al.* 1975; Blacher 1984; Cunningham *et al.* 1984; Carr 1988). After the initial stages of shock, families move to a period of confusion and subsequently through an adjustment phase to one of acceptance (Wright 1976). How families are told of the diagnosis has important consequences, with delay causing distress and dissatisfaction (Carr 1975). Lack of information at the time of being given the diagnosis and lack of professional support has also been documented; this adds to the distress the family suffers (Walker *et al.* 1971). To be able to offer support at this time, professionals need adequate and appropriate training (Forrest *et al.* 1982; Standish 1982; Delight & Goodall 1988). A knowledge of the underlying cause of the child's learning disability serves a number of important functions, including relief from uncertainties and alleviation of guilt, assistance with the resolution of grief and the ability to plan for the future. In many cases, appropriate support groups can then be identified (Turk 1997; Black 1988). An understanding of the cause also allows accurate genetic counselling to be offered. In a few specific disorders, the diagnosis contributes to the types of treatments and interventions that may be offered (Turk 1997).

Support and respite for families

Once the early days and months following the diagnosis have passed, families frequently find that caring for their child is demanding and exhausting. The input required is continuous, with families finding that they lack support. Parental stress is increased if the child has limited self-help skills (Sloper *et al.* 1991), poor communication, a disrupted sleep pattern (Wigg & Stores 1999) or behavioural problems (Quine 1986). Socioeconomic difficulties and marital problems also add to the burden of care (Hirst 1985). Mothers have been found to experience the highest levels of stress, with one 15-year study demonstrating that whereas over one-third of families functioned well, a further third had major difficulties in coping. In this study, as in others, marital instability and behavioural problems were more likely in those families finding the situation difficult (Koller *et al.* 1992). Certain factors have been found to contribute to family functioning: social networks, problem-solving skills, general and specific beliefs, utilitarian resources and good health and morale (Frey *et al.* 1989).

Respite care is a valuable service provision for families of children with severe learning disabilities (Jawed *et al.* 1992). The burden resulting from having a child with severe learning disabilities is both an emotional and physical one. Many hours each day may be taken up with caring for the child; one study indicated a total of 7h every day of the week (Dupont 1980; Beresford 1994). Almost two-thirds of these families had stopped having holidays and contact with friends was reduced. Mothers tend to take a major proportion of the burden of care (Carr 1975). Parents have been found to benefit from home-based respite in particular, but this type of provision is relatively rare. One study of 160 families which looked at the different types of respite provision found that families receiving residentially based local authority respite were unaware of alternatives. Families from ethnic minority groups and from lower socioeconomic backgrounds were also less likely to have access to home-based provision (Stalker & Robinson 1994). The need for a flexible approach was emphasized.

There is often a delay in parents getting the respite they require. One study found that 90% of family-based respite care schemes in the UK had waiting lists, with almost 60% of families waiting over 1 year (Prewett 1999). Many families find that the amount of respite they receive is inadequate (Stalker & Robinson 1994; Treneman *et al.* 1997).

The demand for respite care has been studied, with the indication being that the use of respite is related to the child's level of disability (Geall & Host 1996; Treneman *et al.* 1997). Younger children are less likely to use respite (Halpern 1985). Family factors are also important, including the level of family distress and lack of family support (Factor *et al.* 1990).

Siblings

The needs of siblings have also been studied. There are positive as well as negative effects for siblings (Gath 1973; Eisenberg *et*

al. 1998). Siblings at risk of problems include those in families where parental stress is high and where the disabled child receives a disproportionate amount of attention. Isolation and stigma also create additional risks. Further negative factors are overidentification with the child with disabilities, caregiving responsibilities, and pressure to compensate. Positive effects, such as personal growth experiences, have been described. The place of residence of the disabled child does not seem to exert much influence on the outcome of siblings; but, in those families where the child is in residential care, there may be a less warm relationship but one without conflict. In the long term, siblings may take on the responsibilities that had been the remit of the parents. Many brother–sister relationships have been found to be warm and involved (Wilson *et al.* 1992).

Transition period

The transition period from adolescence to adulthood is a time of stress for the young person with a learning disability, and also for their family (Beckman 1983; Carr 1988; Brooks & Bouras 1991). The individual is predisposed to the development of mental health problems. This area of service provision is recognized as being one with many unmet needs and, where provision does exist, it has been found to be poorly planned and often unsatisfactory (Chamberlain 1993; Hirst & Baldwin 1994). Families find that there are few opportunities for independent living, a lack of information about future services, little help with communication difficulties and little practical help (Richardson & Ritchie 1986; Quine & Pahl 1992).

Service planning should involve the active participation of the young people involved and their parents and carers (Tausig 1995). Specific resources are needed with service structures designed to cross the barriers between child and adult provision. Multi-agency collaboration, as in all services for those with learning disabilities, is essential and minority groups must be catered for (Young Adults Transition Project 1998). Some authors have emphasized the need for the young person to leave the family home by the age of 20, as sudden and unplanned moves occurring because of the breakdown of the primary carer are traumatic (Lawrenson *et al.* 1997). The need for the young person to develop their own identity is also important and attempts to move away from the family home may be hampered by parental overinvolvement and the individual's frustrations which can lead to aggression (Kymissis & Leven 1994).

Up to 35% of adolescents with learning disabilities have been found to have a psychiatric disorder (Eaton & Menolascino 1982; Ruedrich & Menolascino 1984). Low IQ in childhood is also associated with the development of emotional problems in adolescence (Douglas *et al.* 1968) but adolescents with learning disabilities and psychiatric disorders are a poorly researched group. Few professionals have specific training in this area and, possibly as a result of the complex problems with which these young people present, few choose to work in this field (Kymissis & Leven 1994).

Parents with a learning disability

The move from institutionalized care to care in the community has led to an increased number of people with learning disabilities having relationships, marrying and having children. The eugenic fears of the early twentieth century have, in general, been superseded by concerns about competency to parent and whether training can influence this (Feldman 1986). There is little systematic research in this field, with studies being hampered by biases in selection, small sample size and unclear measures (Dowdney & Skuse 1993). Problems in controlling for variables such as socioeconomic factors also raise questions about the reliability and validity of some studies. The definitions of learning disabilities and of competent parenting add to the complexity of this area of research.

The measures that have been used to investigate parenting ability fall into three groups.

- 1 Global measures use the physical and emotional development of the child as outcome measures of adequate parenting. These measures are relatively non-specific but have indicated positive and negative findings.
- 2 Direct observational assessments; an example of one such schedule is the HOME scale (Feldman 1986) which measures the quality of the home environment.
- 3 The least satisfactory measure is one of parental failure resulting in abuse, neglect and family breakdown (Dowdney & Skuse 1992).

There have been a number of studies that have considered factors that influence parenting. It appears that in parents whose IQ is over 55–60, IQ alone does not predict parental competency (Dowdney & Skuse 1992). Other factors that exert an influence include parental ability to plan and make judgements and a commitment to the child. The characteristics of the child also have an influence, with age, sex, temperament and the child's own disabilities being important. Family size, family relationships and the support offered by the extended family are also influential. The ability to work in partnership with professionals is another key predictor (Andron & Tymchuk 1987).

Interventions that have been attempted aim to increase parenting abilities. These address caregiving skills and play skills and some try to improve the situation in families where abuse or neglect has occurred. Some success has been documented in learning care skills, but parents have had problems in generalizing skills and the skills are not maintained over time. In general, the prognosis has been gloomy (Andron & Tymchuk 1987).

Conclusions

The twentieth century witnessed massive changes in attitudes towards people with learning disability, and with these changes came a shift from institutionalized and custodial care to individualized and community-based service provision. Many of these

changes have been politically driven, rather than based on systematic research evidence. It would be hoped that, in the twenty-first century, the provision of services is formulated with a clearer knowledge and appreciation of the underlying aetiology of learning disability, consideration of psychopathological processes and a greater understanding of appropriate interventions that might optimize the functioning of this highly vulnerable group of people within society.

Specific areas that demand consideration include the prevention of primary, secondary and tertiary disabilities and handicaps associated with severe learning disability, early identification of behavioural or mental health problems and the development of appropriate diagnostic criteria that take account of the global intellectual impairment that these people have. Effective interventions, both psychological and psychopharmacological, should be based on research evidence, with an understanding of outcome both in the short and long term.

It is to be hoped that the major challenge of the provision of efficient and effective services for young people with severe learning disability will be addressed, and that services continue to develop, ensuring liaison with all involved, including researchers, clinicians, purchasers, providers, politicians and the individuals and families receiving these services.

Introduction

There are many reasons why children may, at some point in their school lives, experience difficulties that disrupt learning and for which they will require special educational help. As has been recognized since the late nineteenth century, there are those pupils with sensory or physical disabilities that interfere with their ability to learn or to attend school (Currey 1898). These include children with visual or hearing impairments, epilepsy, physical disabilities or chronic illness. There are children who, because of developmental delays or disorders, lack the cognitive, linguistic or social skills needed to cope with ordinary schooling. This would apply to children with intellectual disabilities, language disorders, autism or certain other genetic conditions. There are also children with more specific problems (e.g. in reading, spelling, mathematics or motor skills) who will require help in these areas if they are to gain access to the wider teaching curriculum. There are children with severe emotional and/or behavioural difficulties that make it difficult for them to be taught in ordinary classes. Finally, there are many who require special educational help because of a combination of these difficulties.

Different needs clearly have different implications for educational provision. In order to cater for pupils with sensory or severe physical disabilities, there may be a need for special facilities, such as wheelchair access, particular equipment (computers and dedicated software, communication aids, etc.), or adaptations to the modes of teaching. Access to medical treatment may also need to be available. For those with more pervasive cognitive difficulties, the educational curriculum and teaching approaches may require much more radical modification.

The extent of an individual's disabilities will also affect educational goals. Some children may be so severely disabled that they are unlikely ever to lead independent lives. For the majority, however, although their difficulties may interfere with schooling, this should not ultimately reduce their chances of having a full role in society. Scholastic attainments are obviously important, but these must be of an appropriate kind and level, and of potential *practical* value, and hence may differ greatly from one child to another. Moreover, school is a crucial social environment, and attention needs to be paid to broader aspects of children's social, emotional and behavioural development. There is a need, too, to prepare pupils for life during the years after schooling. This is not just a question of appropriate preparation

for employment but also of learning to live in the broader community, developing friendships, and learning how to get along with individuals who do not share the same problems.

Historically, at least in much of North America and Europe, the main focus of education for children with special needs was on special teaching and special equipment. This resulted in the establishment of segregated schools (Gordon 1885; Lettsom 1894) whose strength lay in the development of highly specialized and disability-specific teaching methods. However, even at that time, it was recognized that the separateness of special schools had problems as well as advantages (Cole 1989) and it was evident that a *range* of facilities was needed to provide adequately for all pupils. For example, the majority of children with even quite significant physical and sensory disabilities can be well catered for within mainstream schools *if* the necessary physical aids are provided, and if teachers are adequately prepared to deal with the social and emotional difficulties these pupils also experience. For some other children, particularly those with severe cognitive or behavioural difficulties, separate provision, at least at certain stages of their education, may be needed. However, there are many permutations in between, all of which will have certain advantages as well as possible drawbacks. No one form of provision is likely to suit all, nor should choice of school be made simply on the basis of a diagnostic label. Instead, individual assessments of the child's needs, skills and disabilities are required, with decisions about placement being based on what best suits that particular child, and his or her family. It must also be recognized that as the child grows and changes, changes in educational provision are likely to be needed, so *flexibility* of placement is also crucial.

The arguments for and against inclusive education more generally are addressed in the next section. The remainder of the chapter discusses the educational options for pupils whose special educational needs stem from relatively mild, transient or specific disorders, and the role of more specialist services for those whose disability is profound, pervasive and persisting.

The movement towards inclusive education

It has been estimated that around 20% of school-aged children will require additional help within school and that for approxi-

mately 2% of pupils the extent of their problems will severely restrict access to regular educational provision (Warnock 1978). Historically, these children tended to be excluded from mainstream schools. However, in the USA, Public Law 94–142 (Education for All Handicapped Children Act 1975) stated that, for all handicapped children between 3 and 21 years, state provision was to ensure that ‘special classes, separate schooling, or removal . . . from the regular education environment occurs only when the nature . . . of the handicap is such that education in regular classes with the use of supplementary aids and services cannot be achieved satisfactorily’. Pressure for integration has since steadily increased across the developed world (Meijer *et al.* 1994) and UNESCO’s (1994) Salamanca Statement called for the inclusion of pupils with special educational needs into mainstream schools.

Nevertheless, there are few empirical data to support claims that ‘there are strong educational and social grounds for educating children with disabilities with their peers’ (Department for Education and Employment 1998). There is little agreement as to what is meant by special educational needs and limited information on which children are most likely to benefit from inclusion.

What is inclusion?

The term ‘inclusion’ has come to replace ‘integration’ within the special educational field, largely because of concerns that ‘integration’ had become too narrowly interpreted as simply *placement* in a mainstream setting, without any regard to the quality of that placement (Lewis 1995; Burack *et al.* 1997; Farrell 1997; Florian 1998). However, there is controversy as to what inclusion actually means. Definitions range from ‘extending the scope of ordinary schools so that they can include a greater diversity of children’ (Clark *et al.* 1995) to ‘a set of principles which ensures that the student . . . is viewed as a valued and needed member of the community’ (Uditsky 1993). In the UK, the Department for Education and Employment (1997) refers to the ‘right’ of pupils to be educated in mainstream schools, despite acknowledging a continuing need for special schools. A subsequent report (Department for Education and Employment 1998) notes ‘inclusion is a process, not a fixed state’. It can involve ‘the placement of pupils with special educational needs in mainstream schools; the participation of all pupils in the curriculum and social life of mainstream schools; the participation of all pupils in learning which leads to the highest possible level of achievement; and the participation of young people in the full range of social experiences and opportunities once they have left school’.

The human rights argument for inclusion

The Centre for the Study of Inclusive Education (CSIE 1996) states that ‘segregation in education because of disability or intellectual disability is a contravention of human rights as is segregation because of race and gender’. It has even been suggested

that it is unethical to conduct research that might produce findings in favour of segregation (Booth 1996). In contrast, others argue that the aim of education should be to meet individual needs and to help *all* children to have an active role in society (Burack *et al.* 1997; Farrell 1997). For some children, education in a special setting will be required in order to achieve these aims. There is also the question of *whose* rights should take precedence because the rights of the child, the parents or other pupils may not always be compatible. The right to choose is another issue, and research indicates that parents’ attitudes to inclusion are affected by many different factors (Palmer *et al.* 1998). Parents of younger children or those already in mainstream schools are more likely to prefer inclusion than parents whose children are older or in segregated placements. The nature of the disability may also be important and, for example, parents of a child with Down syndrome tend to favour integration more than those with an autistic child (Kasari *et al.* 1999).

Empirical evidence for inclusion

Despite the extensive literature for and against inclusive education, arguments on both sides are based more on opinion or notions of political correctness than hard evidence. Most of the favourable reports are descriptive accounts of children, or schools, for whom the process has appeared to be successful (Thomas *et al.* 1998; Tilstone *et al.* 1998). Empirical research is limited (Hegarty 1993; Farrell 1997) and randomized controlled trials virtually non-existent. Matched control studies are also difficult to find, because children in specialist settings tend to show more academic and behavioural problems than pupils of similar IQ integrated in mainstream schools (Madden & Slavin 1983).

The very variable profile of children with disabilities and the lack of data on their cognitive, linguistic, social and behavioural characteristics also mean that it is almost impossible to generalize from one study to another. Even terminology is a problem. Learning disability has a different meaning in the UK than in the USA, and although children may be referred to as having mild, moderate or severe intellectual impairments, the degree of cognitive delay involved is rarely defined.

Further difficulties arise from the limited focus of many outcome studies and variability across settings. Educational provision in some of the segregated settings evaluated is sometimes far from adequate and not necessarily representative of standards elsewhere (Hornby *et al.* 1997). In contrast, much integration research in the USA has been conducted in well-resourced (often university-based) nurseries (Guralnick & Groom 1988) and the successful findings have not necessarily been replicated in less advantaged settings, or with older pupils.

International trends towards inclusion

In the UK, the proportion of children in special schools has fallen steadily from around 2% in 1978 to 1.5% in 1996 (Norwich 1996). Italy has a total integration policy (although education is

only compulsory between ages 6 and 13) and in Sweden less than 1% of pupils are in special schools. In the USA and Denmark the overall figure is between 1 and 2%, rising to around 4% in the Netherlands, Germany and Belgium (Meijer *et al.* 1994). However, there is wide regional variation. In the USA, the proportion of school districts pursuing a full inclusion policy varies from 100% in some states to 1% in others (Katsiyannis *et al.* 1995). In England and Wales, three-quarters of local education authorities reduced the numbers of pupils in special schools over the past two decades but the remainder reported an increase, of up to 25%, in numbers in special provision (Swann 1991).

Education for children with mild to moderate intellectual disabilities

Implications of inclusion for intellectual and personal development

Much of the research and political debate concerning integration has focused on children with mild to moderate intellectual disability and, for them, there are strong arguments in favour of inclusion. In principle at least, integration should avoid the stigma of negative labelling and, by enabling children to learn with and from their peers, should enhance academic skills, social adjustment and self-esteem. Moreover, once a child is placed in separate education he or she is likely to remain there, with chances of reintegration diminishing with age (Farrell & Tsakalidou 2000).

In an early review, Carlberg & Kavale (1980) concluded that integration led to more positive social and learning outcomes for children with mild retardation, although not for those with *specific* learning difficulties. Self-esteem was also said to be enhanced (Lakhen & Norwich 1990; Cole & Meyer 1991). However, other research indicates that, wherever these pupils are placed, their school experience is often very negative. Several studies (Zigler & Hodapp 1987; Gottlieb 1990; Bear *et al.* 1991) have found that integration resulted in lower self-esteem and increased stigmatization and rejection by peers. Many pupils with special needs in mainstream schools also prefer to be taught in separate classes, although this may depend on how they view themselves in comparison to their typically developing peers (Harter 1984). Other reviews (Danby & Cullen 1988; Lindsey 1989; Hornby 1992; Burack *et al.* 1997) have failed to find evidence of enhanced educational attainments, social skills, self-esteem, or peer acceptance within integrated settings. Indeed, Hornby *et al.* (1997) conclude that the only obvious advantage of integrated provision is its lower cost.

The few methodologically sound studies reported (Madden & Slavin 1983; Burack *et al.* 1997) suggest that although integration *can* be successful, this only occurs if mainstream teachers are appropriately trained and when teaching is adapted to children's individual needs. So-called 'maldumping' (placing children in mainstream settings without adequate support)

simply results in educational deprivation and social alienation (Stainback & Stainback 1990).

Improving the curriculum and classroom structure within mainstream settings

The poor progress of many pupils in special schools may be caused not by segregation *per se*, but by the poor quality of teaching they receive there (Giangreco 1997). Over a decade ago, Bickel & Bickel (1986) suggested that rather than concentrating on the issue of integration, it would be more productive to think in terms of 'powerful effective education' for all children and to adapt what is known about good educational practice to meet special needs. More recently, Ainscow (1995) concluded that the effectiveness of special educational provision is inextricably linked with a school's effectiveness in optimizing teaching for all pupils. Research on the factors that constitute an effective school is complex (Reynolds 1991), but the findings are clearly relevant for pupils with intellectual disabilities (Hopkins *et al.* 1996; Lipsky & Gartner 1996).

To maximize the chances of success, the curriculum and teaching programmes should be appropriately individualized and structured (Deno *et al.* 1990; Center *et al.* 1991; Lewis 1995; Farrell 1997). Goals should be clear to both teachers and pupils and be modified according to children's skills and needs (Bickel & Bickel 1986; Fuchs *et al.* 1990). The use of more directive teaching methods, together with reinforcement, feedback and monitoring techniques, is associated with improved classroom behaviour (Nowacek *et al.* 1990), as is the amount of time spent on learning tasks (Rich & Ross 1989). Other studies indicate that integration is enhanced when class size is small, e.g. in the successful preschool studies of Guralnick & Groom (1988), the total number of pupils was only eight. When this is not possible, carefully structured small group teaching can play an important part in enhancing both academic and social skills (Cooper & Spence 1990; Sebba *et al.* 1993; Ware 1994; Ainscow 1995) and is said to profit pupils with intellectual disability as well as their peers. There may be a need for some individual teaching, especially when the child is acquiring a new skill, and extra assistance in the classroom is usually required for this. However, unless properly planned, pupils with special needs can become excessively dependent on the teaching assistant, and this in turn may prove a barrier to inclusion.

Alternative approaches

Because of the conflicts faced by teachers trying to cope with the demands of perhaps 30 other pupils, as well as the child with special needs, various alternatives to full-time integration have been explored.

'Resource room' model

The 'resource room' model, although poorly defined, usually means a separate classroom where children with special needs

can be offered individual teaching. Studies by Rich & Ross (1989), Lingard (1994) and Marston (1996) suggest that a *combination* of resource room and regular classroom teaching results in improved educational progress. In principle (although not always in practice), the use of resource rooms had fallen out of favour until recently because of concerns that these were simply a means of excluding difficult pupils from the classroom and could lead to isolation for both students and teachers. However, government policy in the UK now appears to be moving once more in this direction.

Partial integration

This can involve children in special units spending some of the school week in mainstream classes, either on the same site or in another school close by. Despite criticisms of 'tokenism' (Hall 1996) and claims that the availability of a 'continuum' of provision is counter to the philosophy of inclusion (Booth 1994), there is clearly a need for better evaluation of these alternative procedures (Warnock 1992; Kauffman & Hallahan 1995; Borthwick-Duffy *et al.* 1996; Little & Witter 1996). The little research that does exist indicates that placement on the same site as the mainstream school and the development of programmes that can be implemented within regular classrooms are necessary in order to achieve real integration (Burack *et al.* 1997).

Specialist teaching programmes

Despite vast numbers of publications offering advice on 'the making of the inclusive school', and how to improve the curriculum, environment, support structures and general attitudes, there is virtually no empirical support in favour of one particular approach or another. Co-operative learning (groups of students working together to achieve mutual goals) has been recommended in a number of studies but there is little evidence that this is more effective than individual learning (Tateyama-Sniezek 1990). Self-evaluation and self-monitoring programmes (Sainato *et al.* 1992), the Adaptive Learning Environment Model (ALEM; Wang & Walberg 1993), Direct Instruction, Mediated Learning (Dale & Cole 1988), Instrumental Enrichment (Feuerstein *et al.* 1980), or 'creative' action planning techniques (Forest *et al.* 1996) all have their advocates, but experimental evaluations are either non-existent or equivocal (Hornby *et al.* 1997). Even within the extensive literature on the effectiveness of behavioural or cognitive behavioural approaches, the majority of reports are of single cases, or small samples without control groups (Sulzer-Azaroff & Gillat 1990; Cole *et al.* 1994; Ayres *et al.* 1995).

Improving acceptance by peers

Without specific intervention, integration is unlikely to increase social competence in children with intellectual disabilities or to improve acceptance by peers (Hall 1994; Hendrikson *et al.* 1996). Social interactions may occur more frequently in

integrated settings, but children with developmental delays still remain relatively isolated; spontaneous joint play is infrequent and close friendships are rare (Saintano *et al.* 1992; Guralnick *et al.* 1995; Burack *et al.* 1997; Siperstein & Leffert 1997). Acceptance is more likely to occur if the perceived differences between the handicapped child and his or her peers are slight (Truesdell 1990). Nevertheless, programmes that have focused on training normal peers to initiate interactions or implement co-operative learning strategies have been successful in increasing the frequency and quality of social responses and in enhancing academic skills (Acton & Zarbatany 1988; Fox 1989; Topping 1990; Putnam 1993). Although caution is needed in interpreting the results of much of this research (Topping 1990), peer tutoring, at least if adequately structured, seems to be far more effective than attempts to change the attitudes of normal peers by indirect methods, such as teaching tapes, stories or simulations. Positive results, in terms of academic gains, social maturity and increased empathy, have also been reported for the peer tutors (Maheady *et al.* 1988; Hornby *et al.* 1997). 'Circles of friends' or carefully structured pairings of normally developing and disabled children are among other strategies reported to promote social inclusion but evaluations are few and generalization is often limited (Kishi & Meyer 1994; Newton *et al.* 1996).

Improving teacher training and support

While mainstream classrooms and curricula *can* be adapted to meet the needs of children with mild to moderate intellectual disabilities, this is not an easy task for most teachers who are already working under considerable pressure. A survey of pupils with special educational needs in mainstream schools found that the quality of teaching was unsatisfactory in around half of all lessons (Her Majesty's Inspectorate (HMI) 1989). Although training in special education is crucial in order to improve this situation, financial restraints mean that full-time courses have been increasingly replaced by cheaper, part-time modular courses (Deno *et al.* 1990; Nowacek *et al.* 1990). Moreover, even the best-trained teachers are unlikely to be effective unless they have adequate support.

Giangreco (1997) identified a number of common features in schools where inclusive education seemed to be thriving. These included collaborative teamwork and a shared framework for teaching, clear role relationships among professionals and effective use of support staff. 'Meaningful' individual educational plans (IEPs) for pupils and procedures for evaluating teaching effectiveness were also important. Consultation services, by specially trained professionals who can offer teachers continuing help in the classroom, may also be effective (Dyson 1990; Fuchs *et al.* 1990; Jordan 1994) although others claim that such interventions can undermine teacher status and independence (Farrell 1997). Jenkins & Heinen (1989), in a study of 337 children with special needs, found the majority preferred to receive additional help from their own teacher rather than from a specialist, because this made them feel less conspicuous. The

provision of specialist support teachers (*not* untrained classroom assistants) working alongside the class teacher may be more appropriate, but support teaching often fails because of inadequate liaison and planning (Thomas 1992).

Teachers' attitudes clearly have an impact on the success or otherwise of inclusive programmes. In a recent review, Scruggs & Mastropieri (1996) found that although 65% of teachers supported the general concept of inclusion, only 40% believed this to be a realistic goal for most children. Around half indicated that they were willing to teach children with special educational needs and considered that these pupils would benefit from inclusion. However, only one-third believed that mainstream classroom teaching was the best option and 30% suggested this could have a negative impact on other students in the class. Less than one-third considered that they had the necessary teaching expertise and the majority felt that classroom sizes would need to be reduced and resources greatly improved if inclusion were to be successful. Other research has also indicated that regular education teachers have little confidence in their ability to modify their teaching procedures or the classroom environment to accommodate pupils with special needs (Schumm & Vaughan 1991; Whinnery *et al.* 1991).

Attitudes to inclusion tend to be less positive amongst teachers of older pupils (Hanrahan *et al.* 1990) and the move towards school league tables and 'payment by results' in the UK is unlikely to improve this situation. There is some evidence too (Gersten *et al.* 1988) that effective class teachers in normal schools may be *less* tolerant of children with special needs, presumably because of their higher expectations and standards. Unless calls for greater inclusion can be reconciled with the increasing demands for higher standards and the need to meet the requirements of the National Curriculum, many teachers will understandably feel that they are being faced with an impossible task. There is no evidence that exposure to pupils with special needs has any positive effects *per se*. Instead, adequate preparation and training in the skills necessary to promote progress and minimize difficulties, and a far higher level of ongoing support, are required to improve both attitudes and practice.

Parental views

Research suggests that parents will support mainstreaming, but only if they consider resources are adequate (Bailey & Winton 1987; Simpson & Myles 1992). Parents with children in mainstream schools generally express satisfaction with the placement (surveys vary from 65 to 88%; Lowenbraun *et al.* 1990; Kidd & Hornby 1993), although there is a marked preference for special units in the mainstream setting, rather than placement in regular classes. However, around 70–80% of parents with children in segregated provision are also satisfied with these placements (Meyers & Blatcher 1987; Kauffman 1991). There is little evidence to suggest that parents are either overwhelmingly for or against inclusive education (McDonnell 1987) and Hornby *et al.* (1997) suggest that this in itself reinforces the importance of maintaining a continuum of specialist placements.

Recommendations for successful inclusion

Vaughan & Schumm (1995), in a 2-year study of primary schools in large urban areas in the USA, concluded that to achieve 'responsible inclusion' there were a number of essential components.

1 For pupils. A continuum of services should be available, including withdrawal for small group teaching and access to special education classrooms. Alternative teaching strategies and modifications to the curriculum should be offered to meet individual needs—these pupils should not be expected to profit from the same teaching and curriculum as other students. There should also be continual monitoring of the curriculum and teaching provision in order to ensure that students' needs are met.

2 For teachers. They should be allowed to choose whether or not to be involved in teaching inclusive classes—it should not be imposed on everyone, regardless of attitudes or expertise. Ongoing professional development should be available to all staff and there should be adequate provision of human and physical resources. Inclusion should *not* be expected to reduce educational costs.

3 For the community. The inclusive models developed by individual schools should be adapted to suit the needs of the pupils, parents and local community. There should be an agreed philosophy and policy on inclusion, providing guidance to teachers, parents and colleagues. A standardized policy of inclusion should not be imposed on schools.

Education for children with 'specific' learning disabilities

Language disorders

Language impairments are among the most common of childhood disorders. In a recent study in Ontario, 19% of 5-year-old children were found to have speech and/or language difficulties (Beitchman *et al.* 1996). Of these, 49% had a diagnosable psychiatric disorder (mainly attention deficit hyperactivity disorder or anxiety/depression) and many subsequently developed other cognitive problems, especially related to reading. Although many children with early language delays eventually 'catch up' without intervention (Whitehurst & Fischel 1994; Rescorla *et al.* 1997), in a substantial proportion of cases (estimates vary from 50 to 90%) linguistic and other impairments are both persistent and pervasive (Tomblin *et al.* 1992; Beitchman *et al.* 1996; Stothard *et al.* 1998). Scholastic problems related to reading, spelling and mathematics are common and there is a significant risk of later emotional, social, behavioural and psychiatric problems (for review see Stevenson 1996). However, educational provision remains very inadequate. Despite some evidence for the effectiveness of language therapy (see meta-analyses by Nye *et al.* 1987; Swanson *et al.* 1999), such input is rarely sustained beyond the junior school stage and advice and

support for regular class teachers are limited (Davison & Howlin 1997). Howlin *et al.* (2000), in a follow-up study of 20 individuals with severe developmental language impairments, found that although half were educated in specialist (often residential) placements during the primary years, by secondary school 50% were in mainstream schools with little or no additional support. One-third were in settings for children with mild retardation or learning difficulties and the remainder were in schools for children with mixed disorders. The group also experienced frequent changes of school throughout childhood. Post-school education was very limited which, in turn, adversely affected later job prospects and social opportunities.

Assessment of intervention programmes is complicated because of the heterogeneity of language impairments. On the whole 'general stimulation' programmes tend to have less impact than those utilizing more direct approaches (Nye *et al.* 1987), but comparative studies are sparse. Interventions with a focus on the *social* use of language (Rinaldi 1992) are currently popular, as are programmes involving parents as therapists. These include the Language Interaction Intervention programme of Weistuch & Lewis (1985) and Weistuch & Byers-Brown (1987) and the Hanen approach (Weitzman 1992). The use of normally developing 'peer confederates' (Goldstein *et al.* 1992) is claimed to reduce the adult prompt-dependant interaction on which children with language impairments often come to rely. More specific intervention programmes (e.g. that of the Speech Foundation of Ontario, Hayden & Pukonen 1996; or the ECLIPSE project of Schwartz *et al.* 1998) stress the need for individual assessment and involve the creation of an environment that is designed to elicit and enhance communication; the structuring of interactions with and by peers; and the use of naturalistic teaching strategies, together with specific techniques such as modelling, turn-taking, topic manipulation, conversational repair, scripts and time delay. Although single case reports indicate that these approaches can be very effective, there are no substantive group trials, nor is it possible to identify which of the various teaching components are most effective.

There are no well-designed studies of integrated vs. specialist teaching for children with developmental language disorders. The Language Acquisition Pre-school Program at the University of Kansas (Rice & Wilcox 1991) suggests that their integrated preschool model, involving parent participation and normal peers, significantly increases children's chances of remaining with their peer group in subsequent academic placements. However, in most areas preschool provision is scarce, available mainly in segregated settings and on a short-term basis only. Once spoken language appears to improve (even though many other difficulties persist) children are often transferred to mainstream school, without additional help or recognition of their needs. The history that follows is all too frequently one of educational failure, bullying by peers, school exclusion, social rejection, and low self-esteem. In adulthood, occupational levels are low and there is a high level of dependence on families (Haynes & Naidoo 1991; Howlin *et al.* 2000).

Reading and spelling difficulties

It is estimated that between 3 and 10% of school-aged children have persistent and marked reading and/or spelling disabilities (at least 2SD below predicted levels) and the adverse effects on educational progress have been well documented (see Snowling, Chapter 40). In the UK, the Department for Education and Employment's Code of Practice (Department of Education and Employment 1994a,b) lists the learning and behavioural deficits associated with literacy problems and requires schools to keep meticulous records of children's progress and difficulties. In principle, this should lead to all such pupils, regardless of their IQ, having an IEP, to ensure that their needs are met. In practice, lack of adequate classroom support makes it difficult to provide them with the intensive help they often require. The current government strategy of insisting on a set reading period each day, in itself, will do little to help children with specific difficulties in this area (Hurry 1999). Extra tuition for children with reading and/or spelling problems still tends to be provided outside the classroom, or in privately funded centres, both of which limit opportunities for participating fully in the school curriculum.

There is also little agreement on what remedial programmes should entail. Almost any type of intervention initially seems to produce short-term gains, but these are rarely maintained (Maughan & Yule 1994). Overall, the approaches that are effective for children who are just beginning to learn to read (a combination of training in phonological awareness with explicit work on letter sound correspondence; Foorman *et al.* 1991) have been found to help children with reading delays (Hatcher *et al.* 1994). Adaptations of the Reading Recovery approach (intensive, structured, individualized reading programmes; Clay 1985) which incorporate additional phonological training (Bryant & Bradley 1985) also seem to be successful (Iverson & Tunmer 1993; Tunmer 1994; Sylva & Hurry 1995). However, Sylva & Hurry (1995) found that the improved performance of pupils receiving such intervention tended to disappear after 18–24 months. Moreover, control children, who received phonological training alone, made similar progress to pupils *in the same schools* receiving the total package. Snowling (1996) suggested that this may be because the extra support provided to the poor readers relieved the stress on their teachers, leading to improvements in the classroom situation more generally.

Research with 'dyslexic' children (those with specific reading or spelling difficulties) has also indicated that a variety of different strategies can be effective but often the improvements do not generalize to other reading problems or to new situations. Lovett *et al.* (1990), for example, found that training in word recognition significantly increased children's sight vocabularies, but they were still unable to recognize new words. Children provided with phonological training improved in their ability to read non-words (Lovett *et al.* 1994) but word identification skills did not increase. The Colorado remediation project (Wise *et al.* 1990; Olson & Wise 1992) found that computer feedback using synthesized speech could help to improve reading.

Children given segmented feedback (e.g. ‘d/ish’, rather than ‘dish’) showed particular improvements in their ability to read non-words. However, outcome also depended on the amount of direct monitoring by adults—when left to work independently children tended to skip the difficult words unless they were assured of whole word feedback. There was also an interaction between the severity of children’s reading problems and response to treatment. Onset–rime feedback (‘d/ish’) worked less well than vowel–consonant feedback (‘di/sh’) for children with the most severe difficulties, while the opposite was true for the least severely disabled readers.

On the whole, a combination of direct training in reading *plus* phonological awareness is now considered to be most effective. Although there has been considerable research into the effectiveness of individualized teaching programmes (based on analysis of the child’s specific pattern of deficits and skills), Snowling (1996) suggested that there is still ‘no compelling evidence that dyslexic children who read in different ways should be given different kinds of remedial teaching’. Raban (1991) also noted the importance of other factors, such as teacher effectiveness, classroom organization, time spent on reading and the provision of resources. Parental participation in the programme can help to enhance outcome, but only if they are given appropriate guidance in what to do (Whitehurst *et al.* 1994). Simply encouraging them to listen to their child at home has little effect (Toomey 1993). Similarly, classroom assistants *can* have an important role, but only if they are fully trained to understand and implement the literacy programme. The use of older reading-disabled peers is also suggested as an effective means of enhancing reading in young children ‘at risk’ of reading failure (Jul 1994). Nevertheless, the benefits, even of the most effective programmes, tend to be short-lived, and research is needed to identify the factors required to maintain longer term progress (Snowling 1996).

Behavioural and emotional problems

The term ‘emotional and behavioural disorders’ covers a vast range of problems. It may include children with conduct disorders, antisocial behaviours, hyperactivity, attention deficits, psychiatric or mood disorders, or a combination of these. The causes may be genetic, environmental or constitutional. Moreover, many of these children have additional learning difficulties and hence it is not surprising that they present such a challenge to educational services. However, judgements as to whether a child has behavioural or emotional problems often depend more on the attitudes, policies and practices of the school, or the tolerance level of individual teachers than on any objective criteria. A child who shows very disruptive behaviour in one setting may not do so elsewhere (Werthamer-Larsson *et al.* 1991) and the role of schools in maintaining or minimizing disruptive behaviours has been widely investigated (Rutter 1983; Hallinger & Murphy 1986; Reynolds 1991). In some cases, transfer to a different class or a move to a school where teachers are more sensitive to the child’s needs may be sufficient significantly to reduce

the level of problems. In others, intervention may need to be much more complex.

Ideally, detailed assessment of the child’s behavioural difficulties, family circumstances, social competence, learning strategies and academic capabilities is required in order to address the many and complex problems associated with this group of disorders. Programmes such as those of Hechtman *et al.* (1996) illustrate the many facets of therapy that may need to be included. These can involve cognitive-behavioural therapy, interpersonal problem-solving and social skills training, parent training and counselling, and play or other individual therapies. Remedial input to enhance general academic skills, memory, auditory and visual processing, and sequencing is also essential (Hechtman *et al.* 1996). Unfortunately, apart from those children enrolled in specialist multimodal programmes, few are likely to be offered anything other than relatively brief interventions, which may be home-, clinic- or school-based, but rarely all three.

Management techniques within the classroom

Although only a partial approach to the problems faced by a child with emotional and/or behavioural problems, strategies based on behavioural principles have been shown to be very effective. This approach has a number of advantages, in that it does not require removal of the child from the class and the basic techniques can be adapted to the particular needs of an individual child or classroom. On the whole, placing the focus of intervention on positive on-task behaviours is more effective than concentrating on disruptive behaviours (McNamara & Jolly 1990; Herbert 1995; Barkley 1997). Scott (1998) and Warner-Rogers (1998) provided a number of guidelines for enhancing performance in children with conduct disorders, hyperactivity and/or attention deficits. Instructions should indicate what the child *should* be doing (‘Please speak quietly’) rather than what he or she should *not* do (‘Don’t shout’). The task should be explicit (‘Put the cars in the cupboard’, rather than simply ‘Tidy up’) and single instructions are more likely to be obeyed than a string of orders. If it is necessary to stop the child before he or she completes an activity, advanced warning should be given (‘You will have to get off the computer when the bell goes’). ‘When–then’ commands (‘When you’ve finished that page then you can play outside’) should replace vague threats (‘You’ll be sorry if you do that’), and all directions should be given firmly and clearly. The consequences, both positive and negative, of the child’s actions should be clear, consistent and immediate and must always be followed through. Tasks should be broken down into small steps, thereby allowing greater opportunity for positive feedback and avoiding the need for prolonged attention. Positive strategies should always be in place before negative ones are employed. Although techniques such as extinction or time-out can be extremely effective (Barkley 1997), it can be very difficult to implement these consistently. Other children or staff may respond to activities that the teacher is trying to ignore, or the behaviour may escalate to such a level that ignoring is no longer an option. Time-out is all too often used as a synonym for

'removal from the classroom', which may act as anything but a deterrent for many children, and there is a danger of exclusion periods becoming increasingly lengthy.

Other behavioural approaches, such as token economies, differential reinforcement or response-cost, have been reported to be highly effective but much of this work has been conducted in specially designed or experimental classes (Carlson *et al.* 1992). The consistent use of these strategies may not be feasible for teachers coping with 30 or more pupils, although in smaller classes, or when additional help is available, it may be possible to adapt them successfully (for practical teaching guidelines see Abramowitz *et al.* 1992; Gordon & Asher 1994).

Research suggests that in order for schools to have a significant impact on severely disturbed or disruptive pupils, attention must also focus on factors outside the classroom, such as the wider school curriculum, organization and climate (Galloway & Goodwin 1987; MacAulay 1990). Nevertheless, even relatively minor changes to the classroom or timetable may have positive effects. Some children with hyperactivity and attentional problems, for example, seem to perform better on classroom activities in the morning. Brightly coloured materials may hold children's attention better, and the presentation of materials in small chunks, interspersed with brief breaks, is likely to benefit pupils with concentration problems (Warner-Rogers 1998). Modifications to classroom organization, alterations to seating arrangements or providing specially designated areas for study may also significantly reduce classroom disruption (Wheldall & Lam 1987; Ware 1994).

Strategies for *avoiding* problems can also have an important role. Remedial intervention for academic difficulties may prevent the escalation of secondary behaviour problems. Planning ahead can avoid potentially high-risk situations (those when the setting, peer group, or even a particular teacher is likely to exacerbate difficulties). Negotiating potentially difficult situations with children themselves, so that they feel part of the consultation and planning process, can also increase appropriate behaviours.

Although cognitive-behavioural approaches to therapy have little direct impact on attention problems (Abikoff 1991; Bloomquist *et al.* 1991), problem-solving and 'self-instruction' techniques can be effective in reducing impulsive reactions to frustration and enabling children to slow down and devise more effective ways of responding (Hinshaw & Melnick 1992; Petersen & Ganonii 1992). Anger management may also assist the child to recognize internal cues of anger and to develop strategies for decreasing or redirecting this (Novaco 1979). However, because many children with conduct and attentional disorders tend to have communication problems, verbally mediated techniques may need to be specially adapted (Hinshaw 1992). Training in communication and social skills may also enable these children to work more effectively and co-operatively with teachers and peers (Guevremont 1990; Cousins & Weiss 1993; Gray *et al.* 1994). (For more general texts on teaching approaches see Ayres *et al.* 1995; McNamara & Moreton 1995; Cooper & Ideus 1996; O'Brien 1998.)

Children who are excluded from mainstream school

As noted earlier, the push towards inclusion has coincided, in the UK at least, with governmental demands for a rise in classroom standards. Many teachers feel unable to meet these demands if they also have to cope with very disturbed pupils and the number of children officially excluded from school on behavioural grounds has risen sharply over recent years (from 3833 in 1991 to 12 458 in 1994–55; Department for Education 1995). Unofficial exclusions may be even higher and rates of exclusion have also risen within the special school system (Paffrey 1994). Boys are almost five times more likely to be excluded than girls, with rates being highest among African-Caribbean boys. The main reasons for exclusion are aggressive, violent or disruptive behaviours but schools (and local authorities) differ widely in both their reasons for and rates of exclusion and headteachers' attitudes and school status, policies and practices may play a greater part than a pupil's behaviour (Hornby *et al.* 1997).

The outlook for children excluded from mainstream school is bleak. Around 25% receive home tuition, although rarely for more than a few hours a week; 40% attend pupil referral units for half time or less (Young 1996). Those with very severe emotional problems may be offered temporary placements in psychiatric units but mainstream schools then tend to be even more unwilling to re-admit them (Hornby *et al.* 1997). Indeed, many mainstream schools remain reluctant to accept pupils who have been excluded from another school. These children frequently also come from disrupted homes and, without the stability that school can offer, many then simply drift into a life of delinquency and further deprivation.

Although the cost of exclusion to pupils, their families and to society more generally has been widely publicized, the question of how to deal with it remains largely unsolved. There is general agreement that effective intervention for children with complex behavioural and learning problems requires better training and resources for teachers, together with the expertise and input of a network of interagency support (Department for Education and Employment 1994b). However, many teachers tend only to use such services when the classroom situation has totally broken down, rather than at an earlier stage when there is some chance of remediation (Hanko 1993). Stainback & Stainback (1990) conclude that it should be possible to reintegrate these children with adequate help for teachers but such provision is frequently lacking. The old notion of 'contagion' (Redl 1966) has proved hard to dispel in an age of increasing classroom violence and many teachers have no wish to submit other students, or themselves, to the disruption that a very disturbed child can cause.

A range of on- and off-site provision for these children has been provided over the years in the form of resource rooms, tutorial classes, educational guidance centres, intermediate treatment units and, more recently, 'pupil referral units'. The stated goal of such facilities has been to offer individualized remedial teaching and general support to 'challenging' pupils *on a*

temporary basis while maintaining links with the parent school. However, there have been many concerns about their general effectiveness, poor physical and educational standards, limited access to the normal curriculum and tenuous links with the parent school (Mortimore *et al.* 1983; Galloway & Goodwin 1987). The high proportion of pupils from disadvantaged backgrounds or those from minority ethnic groups (especially those of African-Caribbean origin) is also a cause for concern (ILEA 1981).

Despite recent calls by the Department for Education and Employment (1998) in the UK for an increase in ‘pupil referral units’ in order to reduce rates of exclusion from schools, past experience suggests that separate centres of this kind are expensive, discriminating and stigmatizing and do little to facilitate children’s return to mainstream school (Galloway & Goodwin 1987). An alternative solution, also strongly supported by present government policy, is the provision of specialist schools for pupils with emotional and behavioural problems (formerly known as ‘maladjusted schools’). However, again, relatively few children (around 20% or less) subsequently return to mainstream school and reintegration rates are even lower for pupils in boarding schools (Dawson 1980). Nevertheless, there may still be a place for residential provision for children whose difficulties are largely brought about by a severely disturbed or deprived family environment and for whom placement away from home may offer some chance of progress.

Post-school

Although children with mild to moderate intellectual disabilities, and those with more ‘specific’ learning difficulties, can and should profit from mainstream education, it is increasingly clear that this will not be achieved without adequate support for all involved. Unless this is forthcoming, the social exclusion experienced by these children may well extend into adult life. Drop-out rates from school are extremely high (generally between 35 and 50%; de Bettencourt *et al.* 1989) and access to *appropriate* tertiary education is limited (Bursuck *et al.* 1989). Employment rates are poor, with only around 50–60% of individuals with specific learning or behavioural problems finding work, and even higher unemployment rates (60–70%) among those with mild intellectual disability (Hasazi *et al.* 1989). Earnings, job status and stability are low (Zetlin & Murtaugh 1990) and work experience is frequently very negative (Szivos 1990). Long-term dependence on parental support is also typical (deBettencourt *et al.* 1989; Hasazi *et al.* 1989; Howlin *et al.* 2000). Although there has been an increase in vocational training programmes—Zetlin & Murtaugh (1990) report 75% participation in post-school educational programmes in the USA—few such courses are of high academic or vocational level. Thus, students may find it difficult to gain access to courses that adequately meet their needs, and drop-out rates are high (Harrison 1996). Better transition services to facilitate the move from school or college into employment are also essential.

Special education for children with physical and sensory handicaps

Physical disabilities

The desirability of integrating children with physical handicaps into normal classrooms has been recognized for well over a century (Charity Organization Society 1893, cited in Cole 1989). However, the difficulties experienced by these pupils are multiple and complex. For example, while many children with cerebral palsy are of normal IQ, they may also be incontinent or have seizures, their uncontrolled movements may upset other children, they may be unable to communicate effectively, and emotional and psychiatric problems are common (Harris 1998). Cerebral palsy is also associated with increased behavioural difficulties (McDermott *et al.* 1996), high rates of visual and hearing problems (Capute & Accardo 1991) and around 30–60% have some degree of intellectual disability (Evans *et al.* 1990). Kohn (1990) and Harris (1998) discuss the many components required for a comprehensive package of educational care but, in practice, ‘integration’ often involves simply the provision of physical aids, some—often inadequate—adaptations to the physical environment, and the use of support staff or classmates to assist the class teacher. Few mainstream schools have adequate access to trained nursing or physiotherapy help, and little guidance is provided on how to deal with the child’s educational, social and emotional problems, particularly those related to teasing, isolation or low self-esteem. Although children with physical disabilities are a very heterogeneous group, on the whole research indicates that those of normal IQ do better, both socially and academically, in mainstream settings (Carr *et al.* 1981; Carr 1982). However, as is the case with other disabilities, tolerance among teachers and peers tends to decrease with age (Hunt 1981; Anderson *et al.* 1982) and in secondary school, when access to the normal curriculum is particularly important in terms of future academic progress, real inclusion often becomes more difficult to achieve.

Hearing impairments

One in 770 children is born with a significant hearing loss and for 1 in 2000 the loss is profound (Gregory & Hindley 1996). Around 25% will show additional intellectual, physical or sensory problems, and emotional and psychiatric difficulties are also common (Roberts & Hindley 1999). In addition to these complications, the strength of the deaf advocacy movement, particularly in the USA, has resulted in the debate over appropriate education becoming particularly contentious. The poor signing skills of many hearing parents or teachers (Gregory & Hindley 1996), and the fact that deaf children of deaf parents often make better academic and social progress than deaf children of hearing parents (Schilling & DeJesus 1993; Spencer 1993; Prendergast & McCollum 1996), has led to claims that this latter group is best educated in specialist schools (residential if necessary). Remedial interventions, such as cochlear implants,

have been condemned because they deny children's right to belong to the deaf community (Balkany *et al.* 1996); and fluency in signing, with its own grammar and idiom, is considered to be a crucial educational goal. However, as Groenveld (1998) points out, this may have the result of alienating children from their families and neighbourhood. Consequently, 'bilingual education' (the combination of a formal deaf signing system with written and spoken language) has become more widely adopted, both in special schools and some mainstream placements (Hindley & Brown 1994). Nevertheless, success is at least partly dependent on the adequacy of adults' signing skills (Gregory *et al.* 1995), the degree of liaison with and amount of support offered to parents, and the effectiveness of teachers in fostering pupils' spontaneous communication (Wood *et al.* 1986). Early intervention programmes, involving a combined oral-visual approach, are suggested as being particularly important in avoiding the 'cultural divide' that may otherwise develop between hearing parents and their deaf children (Meadow-Orlans 1987; Reed & Hindley 1998)

The poor cognitive and educational attainments of many deaf children and their increasing social isolation as they grow older are well documented (Hindley & Brown 1994). Although some authors have argued strongly in favour of integration for all children with hearing impairments (Lynas 1984), others, such as Gregory *et al.* (1995), suggest their difficulties are often greatly underestimated by mainstream teachers, and hence they may do better in the more supportive atmosphere of a special school or unit. However, the choice of an appropriate placement will depend on many other factors, such as age, IQ, level of hearing disability, presence of other impairment and, most importantly, on the quality of instruction offered (Roberts & Hindley 1999). (Two useful references on general educational approaches for deaf children in mainstream and special schools are Gregory *et al.* 1995; Watson *et al.* 1999.)

Visual problems

Children with visual difficulties are also likely to suffer from a range of additional problems including cerebral palsy, epilepsy, linguistic and hearing impairments, autism, intellectual disability and emotional and psychiatric disturbance (Hindley & Brown 1994; Groenveld 1998). In the UK, the majority of such children are still educated in segregated settings, and although more (around 60%) are in mainstream placements in the USA many are still educated in resource rooms or special classes. Again, educational outcome depends on the child's cognitive level, the presence of additional impairments, the quality of teaching and the availability of resources. More able children are likely to do better in appropriately adapted mainstream provision (Arter *et al.* 1999) than children of lower IQ, although they may also succeed in specialist placements (Chapman & Stone 1988). Resource room provision (albeit with careful preparation of staff, sighted pupils and their parents beforehand) can also be successful in increasing functional integration (Hegarty *et al.* 1982a,b).

Special education for children with severe and pervasive intellectual disabilities

Most research indicates that these pupils are less likely to profit from mainstream placements than those with milder or more specific disabilities (Ispa & Matz 1978; Carlberg & Kavale 1980; Rich & Ross 1989; Deno *et al.* 1990). Moreover, acceptance by peers and teachers tends to decrease with age and, although inclusion may succeed in the infant years, relatively few studies have reported on successful integration within secondary school (Budgell 1986; although see Beveridge 1996; Booth 1996). The degree of support available also affects integration and, unless this is adequate, children with severe disabilities may receive less individualized instruction in normal classes than in segregated classes. The role of support staff is crucial here (Center *et al.* 1991; Gregory 1996; Mencap 1999) but they need to be able to plan and carry out individually tailored teaching programmes with the child, and to work collaboratively with other staff and pupils in order to ensure social integration and academic progress. Working individually with a child with special needs in the corner of the classroom (or in the library or medical room) may actually increase rather than decrease segregation. All too often, lack of adequate preparation and of systematic and on-going training for support workers, and their isolation from other teaching staff (Lopez 1994; Farrell 1996), has meant that their role tends to focus more on the minimization of behavioural difficulties, so that the child is tolerated but certainly not assimilated.

One of the strongest arguments proposed by advocates of inclusive education for children with severe intellectual disabilities is that it has a positive impact both on their social development and that of their typically developing peers. However, social interaction is unlikely to occur unless the environment, teaching materials and children's activities are appropriately structured (Steele & Mitchell 1992). Although support staff play an essential part in encouraging interactions between the child with disabilities and his or her classmates, their presence may actually interfere with social integration (Farrell 1996) and it may be more productive for them to focus on training other pupils to interact with the child with special needs. Team teaching and co-operative learning approaches are important (Ware *et al.* 1992) and the structuring of collaborative learning activities between handicapped and non-handicapped children helps to improve classroom behaviours (Putnam 1993). There is little evidence that simple exposure to non-handicapped peers improves either language or social skills (Lewis 1995). If peers are taught to prompt, respond to or initiate social and verbal interactions this can enhance communication skills and academic and social attainments in children with intellectual disabilities, although there are problems with maintenance over time and generalization across settings (Hundert & Houghton 1992; Saintano *et al.* 1992; Stainback *et al.* 1994). Moreover, although guided contact with their disabled peers may have a positive impact on other pupils' attitudes (Farrell 1996), joint spontaneous interactions remain limited and close

reciprocal friendships are very *unlikely* to develop (Gottlieb 1990; Saintano *et al.* 1992; Burack *et al.* 1997).

The enthusiasm for integration expressed by politicians and educational theorists is not necessarily shared by teachers. Ward *et al.* (1994) and Forlin (1995) found that teachers were much less positive about integration than administrative personnel. The most negative views were expressed by teachers who were more experienced and those working with very severely disabled children. Stress levels among class teachers were often high, and there were concerns about inadequate support and their lack of choice in decisions about the placement of a child with special needs.

There are also other practical dilemmas pertaining to the integration of this group of children. For example, whereas communication skills seem to be enhanced when therapists employ 'facilitative' teaching styles to encourage initiations and spontaneous language (Mirenda & Donnellan 1986), in mainstream classes the interactional styles of both teachers and other pupils tend to be mainly directive (Bayliss 1995).

While many children with severe intellectual disabilities respond best to structured individualized teaching programmes, this approach may limit inclusion within the classroom (Philps 1994; Rouse & Florian 1996). Achieving the correct balance between fostering social skills and encouraging individual learning can prove very difficult. Moreover, because the main educational goals for this group of pupils often concern the development of self-help and independence skills, it is difficult to incorporate these within the more academic National Curriculum. For this reason Jordan & Powell (1994) suggest that the notion of 'Curriculum principles for all' makes better educational sense than a 'curriculum for all'.

Although curricular content and teaching standards in specialist schools have been widely criticized, evaluations of good practice are limited. For example, although language training programmes and social skills training packages are becoming increasingly popular, there are no comparative studies of their effectiveness. Behavioural (and more recently cognitive-behavioural) approaches have also been widely employed and single case or small group studies suggest that these strategies can be effective in minimizing behavioural problems, increasing self-control and in improving learning skills. Harris *et al.* (1996) report on a 'whole school' approach to reduce challenging behaviour in pupils with severe intellectual disabilities. Behavioural methodologies were combined with strategies to enhance communication and social skills, and many positive behaviour changes were recorded. Nevertheless, many teachers still found the demands made of them (recording behaviours, etc.) difficult to cope with, and did not feel they had adequate support. Generalization to other settings or staff members was also limited.

Finally, it is important to recognize that the extent of help offered to children with special educational needs is extremely variable. Indeed, one of the most significant factors determining whether pupils are offered specialist provision at all (either

within or outside mainstream schooling) is not related to the pupil's needs but 'the level of determination of the school or parent and whether or not the parent was represented by a lawyer or voluntary organization' (Audit Commission 1992).

Although children with severe disabilities can benefit from access to mainstream school (Hunt & Goetz 1997), Farrell (1997) concludes that 'full, functional integration . . . can never be a viable option for all . . . throughout their school lives'. He proposes that 'policymakers need urgently to review their existing provision so as to ensure maximum opportunities for integration for those children who will benefit, while providing high quality, if segregated provision for those who may not'. Properly planned resource bases or units within mainstream settings are suggested as providing the most flexible option, allowing full-time integration (with support as necessary) for some children, while providing others with the daily opportunity to mix with their mainstream peers.

'Syndrome-specific' approaches to education

Dykens (2000) noted that there are now over 750 known genetic causes of intellectual disability. Although behavioural data on most of these syndromes are sparse, there are a few conditions that have been studied more intensively, and for which research findings have important practical educational implications. Children with fragile X, for example, are relatively impaired (compared to mental age matched controls) in their visuospatial abilities, abstract reasoning, motor co-ordination and motor planning, and short-term auditory and visual memory. They have particular difficulty in processing sequential and novel information. On the other hand, they show relative strengths in vocabulary, simultaneous processing, and in learning verbally based factual material. Perceptual organization, visuospatial memory and fine motor skills are particular strengths in children with Cornelia de Lange syndrome. Short-term auditory memory deficits are typical of children with Down syndrome. Smith-Magenis syndrome is characterized by difficulties with sequential processing and in auditory, visual and motoric short-term memory. Arithmetic skills are poor while long-term memory (for facts and information) is good. Most individuals with Prader-Willi syndrome have specific deficits in arithmetic, writing, visual and auditory short-term memory and auditory attention, but are likely to do well on tasks involving visual organization and perception, long-term memory and in reading and vocabulary (for an overview of psychological functioning in many different genetic syndromes see Udwin & Dennis 1995).

Despite claims that 'the cause of mental retardation has little relevance in planning an educational program' (Blackhurst & Berdine 1993), it is increasingly evident that knowledge about the deficits associated with particular syndromes can help teachers to develop strategies to circumvent deficits and build on children's strengths, and to adapt teaching methods to suit pupils' specific profiles of skills and difficulties (Hodapp &

Fidler 1999). (For teaching guides to specific syndromes see Saunders 1999 for fragile X; Waters 1999 for Prader-Willi syndrome; Lewis & Wilson 1998 for Rett syndrome; and Lorenz 1998 for Down syndrome.)

Children with autism

Educational approaches for children with autism have been studied in particular detail, and many different educational programmes are suggested as having a significant impact on outcome (Howlin 1998; Volkmar *et al.* 1999). Although data to support most such claims are minimal, the importance of structure has been well documented over the last 25 years. Studies by Rutter & Bartak (1973) confirmed that autistic children exposed to structured task-orientated 'academic' programmes made better educational and social progress than children in less structured environments. The TEACCH (Treatment and Education of Autistic and Related Communication-handicapped Children) programme (Schopler & Mesibov 1995; Schopler 1997) provides a framework for teaching that emphasizes the need for structure, appropriate environmental organization and the use of clear visual cues to circumvent communication difficulties. The programme also takes account of developmental levels and the importance of individually based teaching, as well as incorporating behavioural and cognitive approaches. A recent controlled study by Ozonoff & Cathcart (1998) reported significant short-term gains in preschool-age children with autism following the introduction of a daily TEACCH session into their home programme, but no controlled school-based comparisons have been conducted.

Many other approaches to education, focusing specifically on strategies to overcome the fundamental impairments in autism, have been reported (Olley & Reeve 1997; Siegel 1999). Quill (1995), for example, provides detailed information on programmes designed to improve social and communication functioning. The Picture Exchange Communication System (PECS; Bondy & Frost 1996) uses symbols, pictures or objects to enhance communication skills in the classroom. Lord (1995) and Wolfberg & Schuler (1993) report on the effectiveness of using normal peers to enhance social interactions and play. Butera & Haywood (1995) describe the Bright Start Programme, which concentrates on the development of cognitive and metacognitive abilities. Jordan *et al.* (Jordan & Powell 1995; Powell & Jordan 1997; Jordan & Jones 1999) describe a variety of innovative techniques (including the use of computers) that can be used to enhance learning. Cumine *et al.* (1998, 1999) provide practical suggestions for teaching children with autism and Asperger syndrome within mainstream settings. Koegel & Koegel (1995) illustrate how traditional behavioural techniques can be successfully adapted for use in more naturalistic school settings. The success of peer tutoring (Kamps *et al.* 1994) and cooperative learning groups (Dugan *et al.* 1995) has also been demonstrated. However, there are few comparative large-scale evaluations of any of these approaches.

In summarizing developments in education for children with autism over the last two decades, Harris (1995) notes the move towards more naturalistic approaches; the use of intrinsic rather than extrinsic reinforcers; the reduction of aversive procedures; the increasing emphasis on social relationships with peers; the development of more effective communication strategies (rather than a focus on speech); and the value of functional assessments in the reduction of behavioural problems. However, she also suggests that the current emphasis on *totally* non-aversive techniques may be inappropriate for the small minority of students whose highly dangerous or disruptive behaviours cannot be brought under control by other means.

The most effective programmes appear to be those that begin early (between the ages of 2 and 4 years), and have a relatively high adult:child ratio (Rogers 1996, 1998). There needs to be a focus on the maintenance and generalization of skills, and educational provision should also be able to meet children's social and emotional needs (Volkmar *et al.* 1999). However, for more able children with autism, this latter goal can prove difficult to achieve. In special schools it is often not possible to provide them with sufficient intellectual stimulation; on the other hand, unless extra support is provided within mainstream school, teasing and bullying by other pupils and lack of understanding from teachers may often result in severe emotional stress.

One approach that has given rise to particular controversy, mainly because of claims of 'recovery from autism' is the intensive (40 h per week over 2 years) behavioural programme of Lovaas *et al.* (Lovaas 1993, 1996; McEachin *et al.* 1993). However, problems in group selection and data collection complicate the interpretation of results and while Sheinkopf & Siegel (1998) concluded that while 'behavioural therapy is a *good* option for children with autism [it is still unclear] whether such a treatment approach is *better* than other treatments of similar intensity or structure'.

Arguments for and against inclusive education are as rife in the field of autism as for any other disability (Mesibov 1990; Simpson & Myles 1993; Burack *et al.* 1997). Some studies conclude that academic and social attainments are enhanced by inclusion, but the educational settings have usually been experimental in nature (Hoyson *et al.* 1984; Harris *et al.* 1991). Other research suggests that mainstreaming does not necessarily improve social, cognitive or language skills (Harris *et al.* 1990; Sigafos *et al.* 1994; Burack *et al.* 1997). Nevertheless, for autistic children of normal IQ access to the normal school curriculum is crucial for their future academic and employment prospects. Unless their very specific needs and difficulties are adequately understood, children may become extremely isolated, lonely and rejected, and hence adequate training and support for the regular classroom teachers is essential (Jordan & Jones 1999). In the absence of such support, it may sometimes be preferable for education in the early years to be provided in specialist autistic units where major behavioural or learning difficulties can be modified. Gradual integration into more normal provision can then be undertaken.

Early prevention of learning, emotional and behavioural difficulties

The failure of many intervention approaches, particularly with older children, has led to a heightened awareness of the need to intervene in high-risk groups of children before they even enter school. One of the best known forms of early intervention is the Head Start Program (current budget \$4.6 billion; Zigler 1999) although many variations also exist (Odom *et al.* 1999). The problems involved in evaluating these programmes have been widely discussed over the past two decades (Cave & Maddison 1978; Guralnick 1998; Bailey *et al.* 1999) but the short-term effects on children's cognitive, social and physical development are well established (Guralnick 1998). Early intervention of this kind also appears to bring about improvements in mother-child interaction and a reduction in problem behaviours (Webster-Stratton 1998). There is less agreement about the longer term benefits (Devaney *et al.* 1997). Barnett (1995, 1998a), in critical reviews of almost 40 studies, found that preschool programmes, including Head Start, produced persistent effects on academic achievement and social adjustment and participants were subsequently less likely to be placed in special education. However, the impact on IQ was more variable. There was little difference between Head Start and other public school, child care or home visiting programmes, although the better-funded models programmes tended to have a greater effect. Outcome also seems to be more positive if parents and teachers work together (Fantuzzo *et al.* 1997). Barnett (1998b) concluded that the long-term social and economic return from providing early education to deprived children far exceeds the cost. However, he and other authors (Ramey 1999; Ripple *et al.* 1999; Scarr 1999) also noted the very variable time span and quality of these programmes across different states, the relatively small number of children (under 1.7% of the total infant population) who gain access to them and the racial imbalance (poor blacks are significantly more likely to be enrolled than poor whites; O'Connor 1998). There remain many questions to be answered about the goals and structures of these early programmes and the types and ages of children for whom they prove most effective. Attention to wider social issues and the linking of preschool education to later schooling are also crucial (Guralnick 1998; Siegel 1999).

Amongst preschool interventions specifically for children with severe developmental delays, the Portage programme (Shearer & Shearer 1972) has probably been one of the most widely used in the USA and UK. Nevertheless, despite its widespread use, methodological problems and the lack of long-term follow-up studies mean, again, that the comparative effectiveness of this approach remains unclear (Sturmeay & Crisp 1986; Cameron 1997).

Clinical recommendations

Education has a major influence on the life of any child, but for

pupils with disabilities the quality of schooling they receive is likely to have an even greater and longer lasting impact. Access to appropriate education *from the earliest years* is therefore crucial. Any clinician involved in the care of children with special needs has a responsibility to liaise closely with families and educational professionals in order to ensure that the provision available will maximize opportunities for educational and social success. While it may not be appropriate to recommend specific placements, clinicians can have an important role in providing broad guidelines for a child's educational welfare. These will be based on a full understanding of the child's basic condition, knowledge of associated behavioural or cognitive impairments and, increasingly, of the particular profiles associated with underlying genetic disorders. Detailed individual assessments of the child's linguistic, cognitive, social and behavioural patterns, and information about family factors of relevance to educational placement, will also be required. Families also need advice on how to obtain information on the full range of educational provision available locally. Although these recommendations may be viewed as adding to the workload of already hard-pressed clinicians, failure to pay adequate attention to educational needs may well undermine the effects of any other forms of treatment. With such support, parents may be prevented from seeking out alternative, expensive and often unproven therapies.

Conclusions

Few educational professionals would disagree that pupils with special needs should preferably be educated on the same site as other children in their neighbourhood. However, there is little evidence to support the effectiveness of total inclusion for all children with special needs in regular classes. Current pressures on mainstream education may result in schools being both less able and less willing to cater for pupils who, almost inevitably, will demand more and achieve less (at least in academic terms). As Hornby *et al.* (1997) concluded, unless less idealistic and better considered policies for inclusion are adopted, the outcome could be far from beneficial for pupils with special needs, their families, peers and teachers. Instead, the aim should be to ensure that all children with special needs are provided with an education that enables them to make optimum academic, social and emotional progress and will offer them the best chance of integration as adults. This will require a flexible continuum of specialist provision, including special schools, resource units and special classes which, as far as possible, allow ready access to mainstream school and the normal curriculum. The perspective of the family, the teachers and other pupils should also be acknowledged and involvement with non-disabled peers fostered as early as possible. Finally, increasing knowledge about the genetic and cognitive deficits associated with intellectual disability should be harnessed in order to develop education programmes that build on children's specific strengths and minimize specific weaknesses.

Cultural and ethnic issues in service provision

Increasing attention is being paid not only to the enormous cultural and ethnic diversity in most societies but also to its relevance politically, socially and for health care (Young 1994). Hence, as Rutter & Nikapota (Chapter 16) emphasize, the need to consider cultural and social contextual issues applies across the whole of mental health services and not just to those that serve ethnic minorities. However, there are some considerations that apply particularly strongly to ethnic minorities, and it is on those that this chapter mainly focuses. First, attention is paid to some of the key points that apply in any multicultural multi-ethnic society; to the great majority of industrialized, as well as developing, nations. Secondly, some of the features that apply particularly to special groups (such as street children or refugees) are discussed. Thirdly, there is a brief account of services in developing countries.

Ethnic diversity in industrialized societies

Numerous general population surveys have highlighted the enormous cultural and ethnic diversity in most societies and its implications for society and for services (Smith 2000)—see, for example, Modood *et al.* (1997) with respect to the UK, and the National Research Council (2001) regarding the USA. Not surprisingly, studies of clinic attenders have shown the same. Thus, Kramer *et al.* (2000), in a report on a London teaching hospital clinic, found that families had originated from 43 different countries, although the majority (over four-fifths) of the children had been born in the UK and had English as their first language; nearly half came from ethnic minorities. Findings across studies are somewhat contradictory with respect to referral and diagnostic patterns. However, it appears that ethnic differences on both are rather inconsistent, although attitudes to services and expectations of them probably show more variation by ethnicity and culture (Nikapota *et al.* 1998).

The implication is that all services need to be culture-sensitive in ways that recognize that culture is not a static variable, and that they need to incorporate variations by religion, place of rearing, and language as well as skin colour (see Rutter & Nikapota, Chapter 16).

Service organization for ethnic minority groups

Implications for services go beyond the provision of adequate interpreter facilities, although this is an essential basic requirement for the minority of families who need them. Services must consider consultation patterns, become familiar with characteristics of ethnic minority populations in the area served, the mix of refugee, recent and settled second- and third-generation immigrant populations, and the access these groups may have to information on access to health and welfare systems (Guarnaccia & Lopez 1998). At least in the past, some Asian parents—whether from the Indian subcontinent or from East Asia—have tended to be reluctant to use mental health services, so that underutilization of services has been a feature even where there were no limitations to access (Stern *et al.* 1990; Loo & Rapport 1998). Many parents express uncertainty about the ability of services to understand their cultural perspective, and there are also perceptions of racial bias (Nikapota *et al.* 1998). Services must relate not only to parents' perceptions but also to young people's needs. A simple example of how needs may not be met is the discrepancy in the use of the criteria of colour and race by which ethnicity is assigned to a young person accessing services (Hodes *et al.* 1998; Waters 2000). A respectful cross-cultural approach is indicated, rather than an assumption of what is best for a given minority group.

One of the important issues that give rise to debate is the extent to which ethnic-specific services should develop. On the one hand, there is evidence that suggests that engagement of families may be greater within such services (Krause & Miller 1995; Thomas 1995; Guarnaccia & Lopez 1998). On the other hand, although this may be so for some groups, such as recent immigrants, it may not be so for many others, including second- and third-generation immigrants. There is a danger that separate services could make access to the best tertiary care services more difficult because the provision of care for ethnic minorities could become viewed as an 'offshoot' rather than a prime responsibility of the main service. Furthermore, such ethnic-specific services might find it more difficult to respond to intracultural diversity and to transgenerational differences or cultural dualism. The basic need is to develop strategies that will contribute to culturally sensitive clinical work in all service sectors.

An integral aspect of effective child mental health services are functional links with other agencies, such as child health, education and welfare systems. Cultural sensitivity is not limited to one agency although, in the search for culturally appropriate

solutions, conflicts among agencies can occur—such as in relation to policies for adoption and fostering of minority children (see below). Culturally sensitive collaborations with child health will be required not only for early intervention through parent training, but also for vulnerable groups of children with genetically transmitted illnesses (such as sickle cell disease) that are associated with particular racial groups.

The culture of school can support or create confusion for children by conflicting with the cultural values prevailing at home. Teacher attitude and problem identification may depend on the ethos of the school, physical environment of the school and perception of culture-related norms of behaviour among ethnic minorities. This has been illustrated in studies comparing teacher attitude to Asian and African-Caribbean children in the UK (Sonuga-Barke *et al.* 1993) and to Asian and Latin American refugee children in Canada (Rousseau *et al.* 1996). It was acknowledged that the better classroom behaviour reported of Asian children in a cross-ethnic Hawaiian study could, at least in part, have been a result of teacher bias as they were themselves Asian, although it seems likely that parent pressure on compliance with social norms, including respect and obedience towards adults, would have been a significant factor (Loo & Rapport 1998).

Clinical challenges

Assessment

Differences in psychosocial environments, social values governing behaviour and child-rearing patterns can result in differences in the meaning of behaviour (Rutter & Nikapota, Chapter 16). The first challenge is to appreciate the different cultural modalities for expressing distress, and the different cultural concepts of dysfunction or disorder. The second challenge is to develop strategies to facilitate culturally sensitive and clinically appropriate diagnoses. The need to recognize differences in sociocultural norms and values is acknowledged within the established classification systems, both the ICD-10 and DSM-IV, although the guidance given on how to judge differences in threshold according to different social and cultural norms is not made explicit, a point that has led to criticism (Canino *et al.* 1998). In fact, it may be extremely difficult to be explicit while at the same time avoiding the danger of stereotyping. It could be argued that what is needed is a basic framework of assessment that facilitates exploration of psychosocial factors, while at the same time allowing clinicians to be aware that there may be some aspects of the specific cultural background of the patient about which knowledge is required. One of the main strengths within established child psychiatry practice is that the basic principles of assessment do provide such a framework (see Rutter & Taylor, Chapter 2; Yule & Rutter, Chapter 7). This includes the use of multiple informants; exploration of parent perceptions of problems, parent expectations of the index child; and the assessment of risk and protective factors in the family (both nuclear and extended) and in social support networks. In addition, how-

ever, there will be instances where a clinician will have to obtain additional knowledge about a specific cultural aspect. This should be sought, just as one may have to obtain expert advice on any other clinical issue pertaining to accurate diagnosis.

In considering relationships among child, family and clinicians, there needs to be a recognition of the extent to which cultural issues may vary according to whether families are first-, second- or third-generation immigrants, and according to whether parents and children identify with the same culture. The extent to which the family may be in cultural transition, and the differences in the degree of acculturation or cultural dualism among different members of the family, may be causes of intrafamilial difficulty (Landau 1982; Burnham & Harris 1996). Clinicians need also to be aware of the possibility of bias resulting from an identification with the family members whose values approximate most closely with that of the clinician. There are many accounts of history-taking and assessment of minority groups, such as for Asian and African-Caribbean families in the UK (Dhivedi & Varma 1996; Lau 2000), and by Canino & Guarnaccia (1997) for Hispanic families in the USA. Evidence of the impact of such guidance on diagnostic sensitivity and therapeutic efficacy in child psychiatry derives largely from case reports rather than systematic case comparisons.

An important issue for minority children and adolescents is that of racial/ethnic/cultural identity and how this may relate to self-esteem, resilience or vulnerability. Ethnic identity is not a fixed entity but politicized views may demand that ethnic minority children retain their racial identity in relation to country of origin, despite the degree to which their attitudes reflect a cultural dualism. A review of research on race and self-esteem around black identity notes that the majority of studies demonstrate similar or slightly higher scores for black young people than comparison white groups, positive scores increasing with age (Gray-Little & Hafdahl 2000). Self-esteem in this context was defined as self-regard as a result of an appraisal process depending on individual social context and direct experiences both positive and negative. The review did not address issues of vulnerability but did note a positive relationship between self-esteem and racially consonant surroundings. Cultural identity does not necessarily follow racial or ethnic identity. Cultural allegiances seem to relate as much to social class and peer group as to ethnicity of child or parent (Tizard & Phoenix 1995). The reasons for opting for one or other cultural or ethnic identity are complex and may vary according to both the culture of origin and a young person's own experience. A study looking at academically successful African-American adolescents found that, where this was achieved through moving away from their culture of origin, the cost was 'racelessness' and emotional vulnerability (Arroyo & Zigler 1995). The clinical significance of issues of identity, linked to dominance and disadvantage, are well illustrated in a study of suicidal behaviour among Hawaiian adolescents (Yuen *et al.* 2000). Vulnerability was greatest in those adolescents who had a Hawaiian cultural identity and least among those with cultural dualism that related also to the dominant 'white' culture.

Therapeutic approaches

Parent perceptions and concepts of problems that differ from those of clinicians may, if not recognized and addressed, lead to non-engagement with therapy. There is a substantial body of guidance on how mainstream therapeutic approaches may be modified for use with children and families within different cultural or ethnic minority groups, and case history evidence of apparent clinical effectiveness, but there is at times the danger that boundaries and differences between cultures are emphasized to a degree that could mask differences within a culture and similarities between some cultural groups. In a discussion of themes that govern cross-cultural family therapy, Krause & Miller (1995) pointed out that developing effective communication between therapist and family in the clinical setting is not limited to working cross-culturally, or to family therapy; rather, it applies to all clinical situations. Evidence is emerging on the cross-cultural application of some therapeutic approaches, such as parent training, and of the behavioural psychotherapies. There is little empirical evidence on comparisons of different methods within a given cultural context. The same criticisms that have been levelled at the use of research instruments and methodologies cross-culturally may be applied equally to specific therapies. Often there has been insufficient systematic consideration of what, within these approaches, are core concepts and what are influenced by the values of the cultural background within which the therapy developed. For example, individual psychodynamic child psychotherapy (see Jacobs, Chapter 58) may be a clinically effective therapeutic approach for particular problems but may not be acceptable, feasible or appropriate within some cultures. Parents may find the ethos of a therapy that creates a boundary of privacy between child and the parent unacceptable if their cultural values place the boundary elsewhere (Maitra & Miller 1996).

It could be argued that had psychodynamic child psychotherapy developed in a South Asian rather than a European context, ideas about the inner world of the child and how best to address them may have led to a different strategic approach, given the prevailing values in these cultures of collectivism rather than individualism and self-expression. Although clinical experience suggests that behaviour therapy *is* useful in all cultures, an attempt to involve parents in the use of behavioural techniques based on play and positive reinforcement in Hong Kong found that these ideas conflicted with child-rearing modes and beliefs about problems (Lieh-Mak *et al.* 1984). The influence of culture-based attitudes to behaviour and problem perception are well illustrated in data on conduct disorder in the Indian subcontinent where conduct problems are considered as a disciplinary issue to be handled by the family and not a 'medical' problem (Minde and Nikapota 1993; Rahman *et al.* 2000), despite the fact that conduct disorder has the highest prevalence of childhood disorder in community-based data from India (Hackett *et al.* 1998; Malhotra *et al.* in press). Community-based programmes that, at a primary care level, advocate the use of behavioural approaches have yet to be systematically devel-

oped and reported on. Family therapy is used or considered to be desirable in all cultures where child psychiatric services have developed (see Jacobs & Pearse, Chapter 57). Principles underlying effective cross-cultural family therapy highlight the value of obtaining information about the family and the culture, of exploring the value system of the family, and the avoidance of assumptions based on race, colour and socioeconomic context (Krause & Miller 1995), and of appreciating the cultural transitions that the family as a whole or individual members may be experiencing (Landau 1982; Burnham & Harris 1996).

Another neglected area is the development of therapeutic approaches that utilize modalities and resources arising from within a culture; nevertheless, there are some examples. Cuento therapy, which makes use of cautionary folk tales, was effective in reducing anxiety in high-risk kindergarten and primary school children in Puerto Rican and other Spanish-speaking children in New York (Constantino *et al.* 1986). Describing a programme for a similar age group and population using culture-based art as a means for coping with stress, Canino (1995) remarked that therapeutic approaches that draw on culturally derived material can be ethnically empowering and culture-sensitive.

A further challenging area is the involvement of alternative practitioners in therapeutic approaches. The potential value of this has been discussed not only in relation to non-Western cultures where systems such as Ayurveda have been established for centuries, but also in relation to ethnic minority groups (Rack 1982). A review of intercultural psychotherapy (Tseng 1999) discussed the technical adjustments, theoretical modifications and practical guidelines for developing cross-cultural approaches and involving traditional healers with professional staff. The inclusion of traditional healers or alternative health systems can become a medicopolitical issue within local contexts and will also lead to debate as to the balance between benefit and risk. Where traditional healers are perceived as an important source of help, they should be involved, but the challenge will be how to do so while allowing them to retain their role. For example, where mental retardation is considered to be because of an inauspicious astronomical influence, this can cause harm; acceptance of disability and use of appropriate learning strategies for the child can be delayed. Traditional healers may themselves be appreciative of being involved in providing support in these situations, so long as they do not feel threatened. Kapur (1995) gave a useful outline of a treatment approach for dissociative reactions for use in India, which included the use, within a standard treatment protocol, of non-injurious culturally accepted solutions such as going to a traditional healer. Traditional healers may be used to identify mental health problems (Patel *et al.* 1997), deliver ethnoculturally determined patterns of treatment (Tharp 1991) and provide support in situations of stress, such as supporting families with AIDS (Ovuga *et al.* 1999). Although this is particularly an issue for developing countries, working with alternative systems of healing is also an issue gaining increasing prominence within Western societies.

There are initiatives in the UK (such as the Intercultural

Therapy Centre) that focus on providing help specifically targeted for ethnic minority groups (Kareem & Littlewood 1992; Thomas 1995). This has developed multidisciplinary and multicultural therapeutic services for black and Asian groups that stress the need to acknowledge racism and other social phenomena when developing models of treatment for immigrant populations, and encourage the use of cultural advocates to help empower families. Cultural consultants to aid acquisition of information about ideas and values within a culture and help therapists respect a client or patient's cultural identity is one of the trends found useful in developing culture-sensitive family therapy for ethnic minorities (Krause & Miller 1995).

Intrafamilial discord and divorce

Although extended family systems may protect the impact of interparental conflict on a child, they may also give rise to conflict. Divorce can, rather than ending conflict, lead to a perpetuation of conflict centring on contact and access. Cultural factors may be implicated in this. Conflict may arise when there are significant cultural differences between parents, or when the marriage was a social contract between two families rather than between two people, with divorce resulting in disruption of the social networks of the families concerned. In the first instance, the prevailing professional view (Roll 1998) is that it is nevertheless important for the child to have access to both cultures with some evidence that indicates that children are able to cope with and adjust to these differences. In the second instance, attitudes may become so fixed that the child's emotional security within the resident family could be threatened or be perceived to be under threat if contact occurs. The situation is common in Asian communities, both immigrant and in the Indian subcontinent. Child psychiatric opinion at present rests on what may be best practice in the view of the individual clinician. There is a lack of evidence to indicate what might be the long-term outcome for these children. Thus, it is not known whether allowing them to adopt the negative attitudes of the resident parent and family network towards their non-custodial parent may lead to better adjustment, or whether an insistence on some form of contact is the more favoured option.

Maltreatment

Debate continues on whether a universal definition for maltreatment and abuse is possible (Korbin 1991; see Emery & Laumann Billings, Chapter 20). There is now sufficient knowledge about what normative capacities ought to be for children and adolescents to define some criteria that could be universally applicable about what might constitute abuse in terms of damage to potential function. This does not ignore the fact that there will be situations in which a practice may be considered appropriate in one context and abusive in another, children in employment being one such example. There could be resistance within communities and cultures to the idea that abuse can and does occur. Communities within a country may vary with regards to the extent

that they are ready to accept, not only that abuse occurs, but also that action may be required to protect the rights of the child when they conflict with traditional community and family values. Difficulty may arise where issues of family loyalties lead to a reluctance to report or act on behalf of a child, or where services for child protection are developing, and appropriate alternative care arrangements are not available. The initial role of the child psychiatrist may then be advocacy and education about the established consequences for emotional development and well-being of deprivation and abuse. Therapeutic interventions for children cannot develop without provision of basic needs and a legal and welfare system needs to be in place. Where systems are emerging, it is the current reality that a child subject to sexual abuse may be removed from the family, be at risk of being socially ostracized and placed in the only alternative care available—usually an orphanage. Where family rights supersede those of the child, the child may be forced to remain within the abusive environment. Preventive education aimed at helping children become aware of the need to protect themselves from abuse may be particularly challenging in situations where sex education in itself is not considered culturally appropriate.

Where child protection services are well developed and in place, difficulties arise in different ways. Developing a framework for decision-making about abuse that also respects cultural differences can be problematic, particularly when there is cultural dissonance between clinician, child protection services and family. On the one hand, what may be regarded by the family as appropriate practice, such as physical punishment, could lead to allegations of abuse. This needs to be handled particularly sensitively, and careful assessments made about what would be the appropriate intervention for the child and how the family should be supported.

Some special issues

Children working or living on the street

Official estimates put the number of children who are a regular part of the labour force as 10 million children in Africa and 18–20 million in India. Whereas the majority of children employed are in developing countries, ethnicity and poverty place children at risk of hazardous employment in industrialized societies too (UNICEF 1997), yet there are few studies of the psychopathological effects of young children working. There are particular concerns about the risks experienced by street-based children and youth, of whom there are more than 100 million worldwide. However, a distinction needs to be drawn between those who work the streets (begging, selling goods, offering services) but who return home to their families each night, and those who live and work on the street outside the context of family support. The available evidence suggests that the risks are particularly great for the latter group (Campos *et al.* 1994).

In poorer countries, economic factors constitute the predominant reason for children taking to the street, or being placed in

employment. However, other influences include harsh parenting, abuse within home or at work. Loss of family and displacement as a result of war has led to a sharp increase in the numbers of homeless street children (UNICEF 2000). Many families whose poverty has led them to place a child in a labour situation will not necessarily welcome their child back unless they, in turn, have access to income generation opportunities.

Subsequent outcomes for employed and for street children vary considerably according to the extent to which they become involved in peer group networks which may be socially supportive. Children may also be subject to abuse, victimization and liable to become involved in substance misuse. Examples of the situation of street children derive from studies in Ethiopia (Lalor 1999), Colombia (Aptekar 1989), Brazil (Campos *et al.* 1994), Honduras (Wright *et al.* 1993) as well as the overview of the problem provided by international agencies such as UNICEF (1997). Interventions for employed children or street children range from sociopolitical change and poverty alleviation programmes to the provision of alternative systems for supportive care and learning that build on the children's functional abilities (UNICEF 1997). Studies looking at the development of competence in adversity (Masten & Coatsworth 1998) may provide a theoretical underpinning for the development of programmes that foster competence. Systems to encourage participation of street children in informal education, providing opportunities for them to generate income for themselves but also participate in normative experiences, may constitute the priority line of intervention. These systems will be required before providing psychotherapeutic help becomes at all meaningful (Campos *et al.* 1994).

The situation for homeless youth in industrialized countries is rather different (Craig & Hudson 1998; Slegers *et al.* 1998; Fietal *et al.* 1992). A case-control study in London showed that childhood adversity, low educational attainment and prior psychiatric disorder all predisposed to homelessness. One-fifth of the homeless had attempted suicide. A 1-year follow-up showed that two-thirds of those with psychiatric disorder remained symptomatic, over half had been involved in petty crime, and just under one-third had committed more serious offences. Two-fifths had substance abuse or dependence. Satisfactory accommodation outcomes were achieved by two-fifths; these were more frequent in those of ethnic minority status, better educational achievement, and where accommodation plans were negotiated through a resettlement agency. Successful resettlement may well depend on integrated services that address persistent substance abuse and mental disorder, as well as the immediate housing need.

Refugee and displaced children

Hodes (2000) provided a succinct review of the evidence on the psychological problems experienced by refugee children, with a particular focus on those in the UK. United Nations' figures put the figure of refugees (of all ages) worldwide as 21.5 million, with some 6 million in Europe, but far greater numbers in Africa

and Asia (United Nations High Commissioner for Refugees 1999). Until recently, most attention has focused on the situation of adults, but there is a growing literature on children. There has been an especial concern over the problems faced by refugee children who are unaccompanied by their parents. The numbers involved in the UK have risen hugely in the 1990s — from 197 in 1992 to 4405 in 1999.

Most of the systematic studies of refugee children (with or without comparison groups of various kinds) have been undertaken in North America. These have included Cambodian children who had experienced massive war trauma (Kinzie *et al.* 1986; Sack *et al.* 1994, 1997), as well as those without much direct experience of war (Tousignant *et al.* 1999). All studies have shown, not surprisingly, that the rates of psychopathology are substantially higher than in non-refugee populations. Nevertheless, it has also been evident that well over half have not shown any type of mental disorder. Moreover, the forms of disorder have been quite varied, although post-traumatic stress disorders have been a prominent feature in those exposed to severely traumatic specific experiences.

In considering service implications, it is important both to appreciate the considerable heterogeneity in the experiences of refugees and to note the operation of a complex mixture of risk and protective factors (Hodes 2000). The experiences that led to their becoming refugees are obviously relevant, with the psychopathological risks increased for those suffering violence, torture and family disruption (Williams & Westermeyer 1986; Ahearn & Athey 1991; Rousseau 1995). However, in addition there are the more long-term experiences of poverty, persecution, serious accommodation problems, lack of appropriate health care (Gosling 2000) and breakdown of community ties prior to, and after, seeking asylum. The children may also be affected by the occurrence of mental disorders in the adults looking after them. The need to learn a new language and to adapt to a new host culture constitutes a further challenge, although school attendance often makes both of these much less of a problem for children than for their parents.

Sharp distinctions are sometimes drawn between refugees or asylum-seekers who have suffered persecution, and immigrants who have moved country voluntarily in order to better their economic circumstances. However, the two groups overlap to a considerable extent in their background circumstances, their experiences in the new host country, and in their service needs, although there are also differences with respect to the frequency of their experience of severe stress and trauma (Guarnaccia & Lopez 1998; Hodes 2000). It has been suggested that the most at risk are the children who have been active combatants in war (UNICEF 2000). Clearly, this will have placed them in a situation quite inappropriate for their age, but systematic data are lacking on the extent to which this puts them at risk for mental disorder, as distinct from risks to the normal processes of growing up. Vulnerability to disorder may depend on the extent to which they are forcibly conscripted and also brutalized to ensure participation (Richman 1993).

Many refugees remain as displaced persons, either in their

own country or in neighbouring ones. Their situation is likely to be much affected by the continuing conflicts that led to their situation, by the poverty they continue to experience in developing nations with scarce resources, and by life in refugee camps (which is the case for many) or by the need to be on the move.

The situation for those coming to an industrialized country is very different in many important respects, but feelings of alienation and isolation may be experienced in spite of having reached a place of relative safety. The key sociocultural, education and legal issues have been discussed by Richman (1998) and Rutter & Jones (1998). Schools constitute an extremely valuable resource for these children, not only in providing predictability but also in offering a site for therapeutic interventions (Richman 1993; O'Shea *et al.* 2000; Yule 2000).

Families, if cohesive, are likely to constitute a protective feature but so too are community ties if they were maintained or reconstituted after arrival in the new country. In planning services and therapeutic interventions, it may be helpful to draw on cultural resources and contexts as illustrated by the positive outcome in Guatemalan refugee children in a camp in Mexico (Miller 1996). Resources there included a camp organization that retained community structure, a degree of family organization despite bereavements, and the teaching of Guatemalan history so children could understand their situation. In very different circumstances, retention of cultural context led to a better outcome for Finnish returnee children (Vuorenkoski *et al.* 2000). In the UK too, it is important to appreciate that refugee groups often include mental health professionals who may be able to provide a counselling role as well as providing a link with mental health services (Dihour & Pelosi 1989). The underlying concept—the importance of retaining cultural context while also adapting to new experience—is very relevant for programmes involving refugee children. The coping strategies developed by Sudanese refugee children included seeking companionship, wishful thinking and praying (Paardekooper *et al.* 1999); these, while indicating the despair of the children, also pointed to ways in which culture-related coping strategies may be strengthened.

The appreciation of culture-mediated forms of distress and the need to draw on local approaches to bereavement and healing are essential not only in war situations but also when dealing with any large-scale trauma or bereavement (Cairns & Dawes 1996), or with issues related to chronic or terminal illness. This need is highlighted by the pandemic of children and young people with HIV and whose families are dead or dying as a result of AIDS (Brown *et al.* 2000; see also Mellins *et al.*, Chapter 49).

Alternative care for high-risk groups

Community attitudes to the concept of fostering and adoption, as well as the resource implications for statutory and voluntary agencies, may determine service development in this area. In many societies with a functional extended family system, children who are orphaned or subject to neglect by a parent will be absorbed into the family system, and the concept of adopting a

child from outside the family will be viewed as unacceptable. In these contexts, the only alternative care available may be institutional. Within these contexts, fostering and adoption initiatives on a large scale will require public education as a way of creating a climate for change. This may be equally relevant when promoting adoption and fostering for children by ethnic minority groups. Where fostering and adoption are not part of the sociocultural climate of a country, the alternative provision will be institutional care. The limitations and inadequacies of institutional care need no repetition (see Rushton & Minnis, Chapter 22). The situation of children in Romanian orphanages reflected the impact of a state's policy on vulnerable children, whereas the progress of Romanian adoptees in the UK is an example of the considerable (although sometimes incomplete) recovery that is possible for children even after extreme deprivation, provided intervention is early (Rutter *et al.* 1998; see also O'Connor, Chapter 46). Where institutional care is the only feasible option, child mental health professionals have a role in highlighting issues that must be addressed to minimize disadvantage. The ability of residential settings to be child-centred and encourage development of emotional links with caring adults, thereby minimizing serious psychological problems, is demonstrated in an Eritrean study of war orphans (Wolff & Fesseha 1999).

Adoption and fostering of ethnic minority children is a separate and somewhat politicized issue. Flexible policies for fostering and adoption to ensure a stable early placement for children must include the consideration of transracial placements where no 'match' from a cultural or ethnic point of view is possible, with training of adoptive parents on how to deal with issues of identity and culture. The majority of studies (Tizard 1991; Rushton & Minnis 1997) indicate that transracially adopted children are well adjusted, although more problems may arise with adolescence and some studies indicate that there may be more problems than in non-adopted comparison groups (see also Cohen, Chapter 23; Rushton & Minnis, Chapter 22).

The issue of transracial placement is not only one for ethnic minority groups within a majority community, it is also a live issue in many non-Western cultures, e.g. in South Asia transracial adoption is seen on the one hand as offering a better place economically for children, but it is also accompanied by fears that children may, thereby, be exposed to racism and be divorced from what would have been their culture of origin.

Organization of services in developing countries

The basic principles underlying the provision of services apply across developing and industrialized nations and across culturally and ethnically diverse societies (World Health Organization 1977). However, there are also important differences that influence organization and service delivery (Nikapota 1991; Hackett & Hackett 1999; Rahman *et al.* 2000). Thus, the extent to which physical ill-health and malnutrition affect children, together with the likelihood (or otherwise) that they will receive skilled attention, will have necessary consequences for the

medical assessment of children referred for mental disorders (see A. Bailey, Chapter 10). Similarly, the overall patterns of disease in countries will have implications for different patterns of aetiology for mental retardation. The overall level of resources available will also influence the extent to which the main care has to be at the primary level, and the extent to which specialized services are provided by paediatricians or general psychiatrists rather than clinicians specifically trained to work with children. Similarly, resources will determine the extent to which care is provided by professionals or volunteers who have received just a focused training that prepares them to be skilled in delivering a limited range of well-defined services.

Nevertheless, it would be a mistake to view these considerations as specific to developing countries. Throughout the world, there has been an appreciation of the need to be concerned with primary prevention (see Offord & Bennett, Chapter 52); to develop parent training programmes (see Scott, Chapter 56); to liaise with paediatricians (see Rauch & Jellinek, Chapter 62); to practise in non-medical settings (see Nicol, Chapter 64); and to meet mental health needs in primary care services (see Garralda, Chapter 65). These developments have included focused training of nurse specialists and therapists of various kinds (Marks 1992; Gournay *et al.* 2000) mainly for work with adult mentally ill, but there have been some initiatives in the child mental health field such as the training of parent advisers in the UK (Davis *et al.* 1997), and training teacher counsellors in India (Kapur 1997). Protocols for the diagnosis and management of mental disorders and for the basic use of neuroleptics and anticonvulsants (World Health Organization 1996) have mainly been developed for the treatment of serious adult disorders but they are becoming more used with children as well. These all fit in with the World Health Organization (1977) summary of needs with respect to parent and community education about children's emotional needs and behaviour; early intervention to promote development among high-risk groups of young children; and task-orientated training of personnel in primary health care and education about the management of simple behaviour problems (World Health Organization 1977).

Accordingly, the need in developing countries is not to work with a different set of principles, but rather to use the same principles to adapt the specifics to local resources and local contexts. The same considerations apply within industrialized societies to the variations of services as required for rural communities and inner city populations, or for geographically concentrated populations (as in the Netherlands) or geographically scattered ones (as in many parts of Scandinavia). Similarly, the need to pay attention to cultural attitudes in primary prevention programmes arises in much the same way within industrialized and developing countries—as evident, for example, in views on sex education, family planning and substance abuse. In all cases, effective planning requires knowledge and responsiveness to cultural acceptability, while also accepting that sometimes there may be a need to help families appreciate why certain interventions may be helpful if they are introduced and undertaken in the right way.

The location of access points within primary care will also need to be based on what is culturally appropriate. Schools are often a valuable point of contact (Hendren *et al.* 1994; Kapur 1997). Where education is a high priority, and concerns about children's learning trigger help-seeking behaviour, the location of primary care developments within schools may be particularly appropriate, especially if the health network is not comprehensive and used mainly for physical illness.

First-line management and parent training programmes should use strategies that derive from, or do not conflict with, prevailing cultural ideas. It may be most effective to combine traditional approaches with the introduction of new ideas. A programme in Turkey has demonstrated the effectiveness of this strategy (Kagitcibasi 1997). There are a number of initiatives to train primary care staff to deliver mental health care (Murthy 1998). Task-orientated training in primary care may also require the use of strategies that facilitate recognition of problems. Use of a clinical problem-solving approach based on the conceptual framework underpinning child psychiatric assessments can be effective across all cultures, adapted to fit the knowledge base and cultural context of the specific group of workers being trained. One such approach, developed for use with primary health care workers in Sri Lanka (Samerasinghe *et al.* 1997), is currently being evaluated.

Training and research

Training objectives to meet clinical and service needs should include an understanding of cultural influences on family functioning and on expressions of distress; risk and protective factors as they vary, or are the same, within and between cultural groups; skills to ensure culturally sensitive clinical approaches; knowledge about social policy and the legal framework for children within different contexts; skills for teaching, training and advocacy within primary care groups in line with current trends with regard to service delivery. Thus far, the content should not differ from well-thought-out training programmes already established. However, to ensure the further development of cross-cultural psychiatry, as well as psychiatry within different cultural contexts, some content derived from a sociological and anthropological perspective is important. Of particular importance are discussions on discrimination and racism; the impact on families of poverty and disadvantage (see Friedman & Chase-Lansdale, Chapter 15); and factors contributing to professional bias and how it may be avoided (Ridley *et al.* 2000). While this becomes most obvious in relation to intercultural differences, bias may equally exist among professionals working with intracultural groups, and may also occur as a result of training that creates a cultural distance between a professional and his or her culture. There is a growing body of evidence of the manner in which attitudes and confidence in racial stereotypes influences psychiatric diagnoses among ethnic minorities (Fernando 1995) and on how social factors can lead to bias (Littlewood 1992).

The importance of training in research skills cannot be

overemphasized. One of the most important ways in which knowledge on psychopathology and therapeutic approaches can develop cross-culturally is through the development of research expertise in non-Western cultures, in both quantitative and qualitative methodologies. This is an area where training alone may not be sufficient for progress because of the very significant resource implications. Research directions need to adopt approaches derived from cross-cultural as well as cultural psychiatry and psychology (see Rutter & Nikapota, Chapter 16).

Finally, it must be an objective of training to increase the confidence, as well as the knowledge, of the clinicians and researchers originating from or working within non-Western cultures. This requires an acceptance of both similarities and differences across cultures, and an acknowledgement of the current dominance of Western cultural values in much of the available empirical evidence.

Conclusions

Service implications that arise from cultural and ethnic issues relate just as much to intracultural groups as to cross-cultural situations, although the issues in the latter context are more obvious. There are service implications, some of which are relevant in all cultures, but the ways in which these are addressed will of necessity vary according to the magnitude of the problem, sociocultural context and resources available. There is a dearth of systematic evaluation of different therapeutic approaches used cross-culturally, and of the use of culturally derived therapeutic strategies.

Introduction

The maltreatment of children continues to be an abhorrent and pervasive societal problem. In the past two decades, however, there has been a greater awareness among health professionals that physical, psychological and sexual abuse of children does occur and its identification, assessment and management must be handled sensitively and carefully by all involved. There has been much debate about what services can be delivered in order to minimize child abuse and neglect, and most conclude that a multisector interdisciplinary approach is the most effective (Hallett & Birchall 1992; Murphy 1995). This chapter aims to outline various strategies for child protection and their theoretical and evidential basis and to explore the role of community and mental health professionals.

The public health perspective

It has been suggested, both at national and international level, that child abuse and neglect be considered within the broader context of the community and the welfare of children and their families (National Commission of Inquiry in the Prevention of Child Abuse 1996; World Health Organization 1998, 1999; Department of Health 2000a). From a social welfare perspective, the UK Department of Health (2000a) advocated a comprehensive framework to identify children in need of protection. This involves an assessment of children's developmental needs, the capacities of parents or caregivers to respond appropriately to those needs and the impact of wider family and environmental factors on parenting capacity and children. From a health service perspective, the World Health Organization (1998) devised three integrated strategies for child protection in Eastern Europe.

1 Safe motherhood and perinatal care: this is designed to promote effective perinatal care through the use of appropriate technology for birth, neonatal care and breastfeeding. The aim is to promote paternal bonding to the child and sensitive parenting through positive birth experiences supported by family members.

2 Integrated management of childhood illnesses: designed to provide basic care and promote the prevention of the most common childhood illnesses causing morbidity and mortality in children under 5 years of age. The aim is to reduce child death and disability and limit the stress to parents of caring for a sick child.

3 Child protection: this focuses on preventive and protective strategies, with particular attention to the psychosocial determinants of health. Risk factors associated with child abuse and neglect are identified and intervention offered to those families deemed to be 'at risk'. Symptoms and signs of abuse and neglect are monitored and categorized into those requiring immediate protection and referral (red condition), those requiring further investigation and observation with home-based interventions (yellow condition) and those requiring continued availability of health and social care (green condition). The aim is to prevent pathological and coercive patterns of parenting before they become entrenched in the family.

All three components include the improvement of health professional skills (through training and information), health care systems and family and community practices. Thus, child maltreatment has become a public health issue, the prevention of which is the responsibility of all health professionals.

A holistic approach to child protection is compatible with the United Nations Convention on the Rights of the Child, which became international law in 1990 with the UK as a signatory (Save the Children UK 1997). From an international perspective, the World Health Organization has also adopted a worldwide public health strategy to prevent violence and injury and promote the physical and mental health of women and children. Indeed, spouse and child abuse are considered to be intrinsically linked (Jaffe *et al.* 1990; Carroll 1994; Browne & Hamilton 1999). The World Health Organization (1999) has defined and described violence as a 'health burden' to personal health, health systems and government finances.

Financial cost of child abuse and neglect

There are obvious financial costs in the provision of short- and long-term care of victims. However, the World Health Organization (1999) also listed hidden costs such as:

- medical care for victims (including long-term disabilities);
- mental health and substance abuse programmes for victims or offenders;
- criminal justice system expenditure on prosecution and treatment of offenders;
- legal costs for public child care and the rehabilitation of family breakdown;
- social welfare costs for social work provision and the prevention of delinquency;

- costs to the educational system in providing specialist educational provision for children who are developmentally delayed or who underperform at school.

In addition, there are social and economic multiplier effects, e.g. the impact on productivity through lost days at work from family violence and the impact on the quality of life for victims of violence in the family.

The costs of family violence, to both the individual and society, are immense. Over 10 years ago Gelles (1987), reporting figures from a National Crime Survey in the USA, noted that 192 000 incidences of family violence resulted in 21 000 hospitalizations, 99 800 days in hospital, 28 700 emergency department visits and 39 000 physician visits. For the individuals concerned 175 500 days were lost from paid work. For society \$44 million were spent in direct medical costs in order to provide the necessary health care to victims of family violence.

Miller *et al.* (1996) took a broader perspective and were the first systematically to estimate the financial costs to society in the USA of 2 million child abuse and neglect cases. They identified the staggering costs of medical care at \$570 million, mental health at \$5110 million and public programmes at \$3050 million. When other factors, such as loss of school achievement and future earnings, were taken into account, together with the possibility of delinquency and criminal damage, a further cost of \$3680 million was added to the bill. This brought the total economic cost to \$12 410 million.

Recently in England and Wales, the National Commission into the Prevention of Child Abuse (1996) reported in their publication *Childhood Matters* that the cost of child protection represented £735 million annually. Personal social services were responsible for 71% of expenditure, the Home Office 21%, the health service 6% and the welfare service 2%. It was also estimated that the consequences of maltreatment in childhood were responsible for at least 10% of the expenditure of the mental health services and the correctional prison services as a result of one in five victims becoming offenders (Falshaw *et al.* 1996). Hence, a further £348 million could be added to the cost of child abuse and neglect in England and Wales. Thus, the argument that more money should be spent on prevention is obvious when the abuse and neglect of children is costing the UK and USA governments over 1 billion pounds per annum. However, few child protection systems employ or resource strategies for prevention.

Child protection systems around the world

There is no consistent approach to child protection at an international level, despite the UN Convention on the Rights of the Child (United Nations 1990). International comparisons of child protection systems have many problems because of a lack of agreed definitions on what constitutes child abuse and neglect. Nevertheless, the International Society for the Prevention of Child Abuse and Neglect carries out regular surveys of

volunteer informants from countries around the globe. The latest survey was prepared by the Kempe Children's Center, at the University of Colorado School of Medicine (Bross *et al.* 2000) and involved 58 countries representing 31% of the world's population (excluding China). The percentage of countries represented from each region was as follows: Africa 20.3%, Asia 22.9%, South America and the Caribbean 61.1%, Europe 75.6%, Australasia and Oceania 76%, and North America 100%.

In 26 countries, incidence studies and annual statistics are available from a register of cases, although these registers are not strictly comparable because of the different definitions and methodologies used. Thirty-two countries are reported to have an official government policy with regard to child protection, although less (27) had case management systems that could track cases. In 56.4% of the total sample, a mandatory system of reporting cases of child abuse and neglect was a part of the country's legislation. In the remaining countries (including those in the UK) a voluntary system of reporting existed (the influence of mandatory reporting is discussed in Emery & Laumann Billings, Chapter 20).

The responses to child abuse, where appropriate, are reported to involve criminal investigations in 89.7% of countries, treatment for the child in 70.7% of the countries, removing the child during the investigation in 69% of countries and treatment for the offender in 50% of the countries. The survey concluded that punitive responses to child abuse and neglect were more common than therapeutic approaches.

International surveys offer a broad picture of child protection awareness but provide little scientific evidence for effective child protection services. Those countries that have a legal mandate to report child abuse and neglect may not necessarily implement and act upon the law. The threshold for intervention will differ dramatically from country to country, depending on definition and operational criteria. The prevention services offered to children and families are often not universal, but depend on available resources from region to region. Finally, the treatment of sex offenders and violent offenders may be little more than mental health provision.

It is beyond the scope of the chapter to compare the variations in child protection systems. Those that are well developed, in North America, Western Europe, Australia and New Zealand, are based on similar principles, such as a multidisciplinary approach. These systems are beginning to influence other parts of the world by the development of UN sponsored guidelines (World Health Organization 1999). These guidelines identified the following principles of good practice.

- Clear policies, protocol and programmes.
- Data collection monitoring and evaluation.
- Co-ordinated and comprehensive services for victims and offenders.
- Training and provision of a child-friendly approach.
- Prevention strategies with families, parents and caregivers (e.g. home visiting).
- Community-based intervention and support.

- Interdisciplinary and multisector approaches involving policymakers.
- International collaboration and partnership.

The child protection system in England and Wales, which has been developed over the past 25 years, will be given as an example of good practice.

Child protection system in England and Wales

As with most countries, the development of a child protection system begins with legal reform. The introduction of the Children Act (Department of Health 1989) was a milestone in this process. It brought together a number of separate pieces of legislation to develop policy, practices and procedures that are in the best interests of the child (a person under 18 years of age). The Act was designed to clarify the legal situation for children within England and Wales and find a balance between the protection of children and recognizing the rights of parents and families. Nevertheless, the child's welfare is given paramount consideration (Section 1.1). A similar approach has been taken to legal reform in other parts of the world (e.g. Australia, New Zealand, Ireland, Hungary).

The Children Act (1989) sets out the statutory responsibilities of local authorities for investigations and the provision of child care (Herbert 1993). It is their primary duty to safeguard and promote the welfare of children who are 'in need' and to promote the upbringing of such children by their families. They provide a range of services appropriate to the level of need identified for the child and the family (Section 17.1). The services are offered by a number of different agencies and cover a wide range of difficulties and family support (e.g. maltreated children, disabled children, learning difficulties, parenting skills, family crises).

The criteria 'in need' is applied to children who are likely to suffer 'significant harm' through maltreatment, impairment of health and/or impairment of development, and relates to child protection work under Section 47. The emphasis in child protection is for multiagency work. Any person who has knowledge or suspicion of a child suffering some form of significant harm refers their concerns to the police or social services.

Although there is no legal mandate to report British cases of child abuse and neglect to the police and social services, there is a clear expectation that doctors 'must refer these concerns to the statutory agencies' (Department of Health 1994, p. 5). Indeed, it could be argued that withholding information about ongoing child maltreatment, even on the basis of patient confidentiality, is professional malpractice. The National Health Service Executive have stated that 'all health service staff have a duty to protect children' (Department of Health 1996, p. 15).

Referrals may come from any person involved with the child (e.g. doctors, health visitors, teachers, nursery workers, neighbours, babysitters), an agency involved with the family (e.g. community health, probation, housing) or even the child in

question. Therefore, either the police or social services may be the first statutory agency to receive the referral but information is then shared between them. The division of responsibility is that social services are ultimately responsible for child care decisions while the police are responsible for criminal issues and proceedings.

Recent government proposals for interagency co-operation (Department of Health 1999, 2000b) will place child protection work within the context of wider health, welfare and social services for children in need, but continue to recognize the central role of police officers and social workers in protecting children from maltreatment.

It is the statutory duty of social services departments and police forces within each local authority jointly to investigate allegations of child maltreatment or where 'there is reasonable cause to suspect that a child is suffering, or likely to suffer, significant harm'. In consultation with other agencies, a case conference may be called under the framework published in *Working Together Under the Children Act 1989* (Home Office *et al.* 1991). The provisions of the Children Act (1989, Section 44) allow members of the police, health and social services to remove a child to a place of safety for their protection and well-being, after applying to court for an Emergency Protection Order.

Under the auspices of area child protection committees, who lay down multidisciplinary procedures at a local level, child protection case conferences are held; these conferences aim to make informed decisions about what action is needed to safeguard the child in question and to promote his or her welfare. Those representatives attending the case conference, which may be social workers, health professionals, teachers, police officers, local authority lawyers, parents and substitute carers, formulate proposals for a care plan and whether the child should be placed on the Child Protection Register. In doing so they may ask a court to issue a Child Assessment Order or an Exclusion Order (for the alleged offender).

It has been estimated that 1.45% of the 11 million children in England are subject to a child protection (Section 47) inquiry each year. Of these 160 000 referrals, 75% receive a family visit during a joint investigation and 1% experience an emergency separation. One-quarter of the children referred are the subject of a Case Conference, 15% are placed on the Child Protection Register and 2% are taken into public care (Department of Health 1995a, p. 56).

Categories of registration in England and Wales

The definitions of child maltreatment recommended as criteria for the purposes of registration on Child Protection Registers throughout England and Wales (Home Office 1991, pp. 48–49) classify cases into one of four separate categories, based on the most recent incident.

1 Neglect: the persistent or severe neglect of a child, or the failure to protect a child from exposure to any kind of danger. This includes cold and starvation or extreme failure to carry out im-

portant aspects of care that results in the significant impairment of the child's health or development, including non-organic failure to thrive.

2 Physical injury: actual or likely physical injury to a child, or failure to prevent physical injury (or suffering) to a child, including deliberate poisoning, suffocation and Münchausen by proxy syndrome.

3 Sexual abuse: actual or likely sexual exploitation of a child or adolescent. The child may be dependent and/or developmentally immature.

4 Emotional abuse: actual or likely severe adverse effect on the emotional and behavioural development of a child caused by persistent or severe emotional maltreatment or rejection. All abuse involves some emotional maltreatment. This category is used where it is the main or sole form of abuse.

All the above categories are used for both intrafamilial and extrafamilial maltreatment perpetrated by someone inside or outside the child's home or extended family. Mixed categories are also recorded, which register more than one type of abuse and/or neglect occurring to a child. The new guidance *Working Together to Safeguard Children* (Department of Health 1999) retains the above categorical system with the minor exception of the term 'physical injury' which has become 'physical abuse' (Department of Health 2000b).

Severity

Definitions related to the severity of maltreatment are still rare (see Table 70.1), as are those which attempt to take into account the sequential pattern of maltreatment. The severity of maltreatment, the duration, and whether inside or outside the family, will all greatly affect the traumatic consequences for the victim (Briere 1992; Davenport *et al.* 1994). For example, there are likely to be different dynamics and consequences for a child involved in 'repeat' maltreatment by the same perpetrator, compared to 're-abuse' by another perpetrator (Hamilton & Browne 1998). There may be different responses and interventions required, dependent on the child's adverse experiences and patterns of victimization (Finkelhor 1995).

Children on the Child Protection Register in England

Since 1989, the Department of Health has accurately assessed each year the number of children and young persons on the Child Protection Register in England. The estimates are based on annual statistical returns from 150 local government authorities. The overall rate was 27 children per 10 000 under 18 years of age. The highest rates were found in very young children under 1 year (71 per 10 000). The likelihood of being on the registers then decreases with age. Therefore, 70% of children on registers are aged under 10 years. Boys and girls were equally represented in all age groups. However, girls account for 60% of those registered for 'sexual abuse'.

Local authorities in England record each child on their protection register in only one of the eight categories presented in

Table 70.3, choosing the one that provides the most accurate picture of the situation.

Overall, 14 600 girls and 15 400 boys in England were considered to require protection from maltreatment on 31 March 2000 together with 300 unborn children, and nearly one in four (23%) of them were 'looked after' by local authorities (in care). Of the 7100 children in care on 31 March 2000, 70% were placed with foster parents, 7% were living in children's homes, 18% were placed with parents and 5% in other types of placement (Department of Health 2000b).

Similar registration rates for child abuse and neglect (30 in 10 000) children were reported previously by the NSPCC (Creighton & Noyes 1989; Creighton 1992). Furthermore, the NSPCC claim that their figures for reported physical and sexual abuse were not increasing (Creighton 1992). By contrast, the Department of Health claim a slight decrease in the number of registrations over the past 10 years (Department of Health 2000b).

During the year 1999–2000, 14% of registrations involved children who had been previously registered and perhaps taken off the register prematurely. This figure was less than in previous years where one in five children placed on the Child Protection Register had been previously registered at some time.

Importance of early intervention

It is evident that over two-thirds (69%) of children on the Child Protection Register are under the age of 10 and over one-third (39%) are under 5 years of age (Department of Health 2000b). Hence, the majority of abused children cannot be expected to be proactive in preventing their own abuse. While helplines are excellent for teenagers, they do not prevent the maltreatment of younger children (Browne & Griffiths 1988). Furthermore, many children will be abused before they have the opportunity of being exposed to school-based prevention programmes. Therefore, health professionals involved with families from the time of birth must be proactive rather than reactive in the protection of children. This is especially important for newborns, as children under 1 year have the highest rate of registration (71 in 10 000).

The most telling indicator that there is a need for early intervention is the level of fatal abuse and serious injury in the UK to children under 5 years of age. Home Office figures (Central Statistical Office 1994, p. 47) show that at least two children a week die as a result of non-accidental injury and a further two children per week become disabled for life as a result of the injuries they have suffered (Browne & Lynch 1994). Four out of five of these children are fatally assaulted by parents or step-parents (Browne & Lynch 1995; Wilczynski 1997) and two-thirds are already known to child protection agencies for previous physical injury or non-organic failure to thrive (Greenland 1986, 1987). Despite this knowledge, universal health visits to the homes of families with young children in England have been drastically reduced (Health Visitors' Association 1994; Leahy-Warren 1998).

Table 70.1 Severity of child maltreatment. (Adapted from Browne & Herbert 1997.)

<i>Less severe</i>	
Minor incidents of an occasional nature with little or no long-term damage—either physical, sexual or psychological	
Physical	Injuries confined in area and limited to superficial tissues, including cases of light scratch marks, small slight bruising, minute burns and small welts
Sexual	Inappropriate sexual touching, invitations and/or exhibitionism, sexualized behaviour in the child
Emotional	Occasional verbal assaults, denigration, humiliation, scapegoating, confusing atmosphere
Neglect	Occasional withholding of love and affection. Child weight paralled to or slightly below third centile with no organic cause. Developmental delay. Unwashed skin and hair
<i>Moderately severe</i>	
More frequent incidents and/or of a more serious nature, but unlikely to be life-threatening or have such potentially long-term effects	
Physical	Surface injuries of an extensive or more serious nature and small subcutaneous injuries, including cases of extensive bruising, large welts, lacerations, small haematomas and minor burns/scalds
Sexual	Non-penetrative sexual interaction of an indecent or inappropriate nature, such as fondling, masturbation and digital penetration, sexualized behaviour in the child
Emotional	Frequent verbal assaults, denigration and humiliation, occasional rejection. Child occasionally witnesses family violence and intoxicated parent(s)
Neglect	Frequent withholding of love and affection, child non-organic failure to gain weight. Poor hygiene and cleanliness. Parent(s) occasionally depressed or mentally ill
<i>Very severe</i>	
On-going or very frequent maltreatment and/or less frequent incidents with potentially very severe physical or psychological harm. Delay in seeking help and/or incongruent story for injuries to child	
Physical	All large and deep tissue injuries and broken bones including fractures, dislocations, subdural haematomas, serious burns and damage to internal organs
Sexual	Sexual interaction involving attempted or actual oral, anal and/or vaginal penetration Symptoms include repeated urinary infections, vaginal discharge (STD), vaginal/anal bleeding and injury
Emotional	Frequent rejection, occasional withholding of food and drink, enforced isolation and restriction of movement. Child frequently witnesses family violence and intoxicated parent(s)
Neglect	Frequent unavailability of parent, guardian or spouse. Child sometimes left alone, non-organic failure to thrive, severe nappy rash with skin lesions. Parent(s) frequently depressed or mentally ill
<i>Life-threatening</i>	
Long-term or severe psychological and physical harm that results in life-threatening situations (including perpetrators failing to seek help for injuries to child or child self-harming)	
Physical	Deliberate or persistent injuries which have the potential of child's death or near death (e.g. poisoning or choking)
Sexual	Incest, coerced or forced penetration over a prolonged period. Underage pregnancy
Emotional	Persistent rejection, failure to nurture, frequent withholding of food and drink, enforced isolation and restriction of movement. Terrorizing and confining the child. Child witnesses psychotic episodes in parent(s)
Neglect	Persistent unavailability of parent, guardian or spouse. Child often left alone, non-organic failure to maintain weight Frequent illness and infection because of poor hygiene

Levels of prevention

The prevention of child maltreatment is traditionally classified into three levels.

1 Primary prevention: involves 'universal services' for the whole population.

2 Secondary prevention: involves 'targeted services' by identifying high-risk populations and offering intervention before abuse and neglect occur.

3 Tertiary prevention: involves 'specialist services' for treatment of families and institutions where parents and caregivers are already abusing and/or neglecting their children. At this level, intervention is offered only after abuse and/or neglect has occurred.

Examples of strategies for prevention at each of the above levels are listed in Table 70.2. However, the primary care of children and their families is limited usually by allocated resources to the health sector. Most countries offer child protection services only to those families most at risk of maltreating their children (Bross *et al.* 2000).

Primary prevention

Primary prevention techniques attempt a fundamental change across society (see MacMillan *et al.* 1994a,b), e.g. public awareness campaigns that challenge misconceptions and aim to increase people's understanding of the extent and nature of

Table 70.2 Strategies for prevention (Adapted from World Health Organization 1999).

Primary

Prenatal, perinatal and early childhood health care that improves pregnancy outcomes and strengthens early attachment
 Promoting good parenting practices
 Family support such as home visiting
 Public awareness activities (through media and campaigns)
 Community education programmes
 Availability of social supports and community networks
 School-based activities towards non-violence

Secondary

Perinatal and ongoing identification of high risk children and families
 Clearly established referral system of social and health services
 Substance abuse treatment programmes
 Community-based family-centred support, assistance and networks
 Information available about community resources and safety planning
 Schools-based social services for high stress environments

Tertiary

Early diagnosis and identification
 Interdisciplinary services to ensure medical treatment, care, counselling, management and support of victims/families
 Reintegration in a child-friendly community/schools
 Adequate child protection laws and child-friendly courts

physical and sexual violence against women and girls. Such approaches to primary prevention are far from easy. The campaigners have to balance the need for a clear message against oversimplifying the problem. For example, the claim that one in every two children will be sexually assaulted by the time they reach adulthood is based on a broad definition of maltreatment, which includes non-contact sexual abuse. Thus, individuals who think in terms of contact sexual abuse will regard the message as exaggerated. In addition, for messages to appear clear they need to be very specific. Hence, some campaigns do not consider the sexual abuse of young boys who are often equally at risk.

An equally controversial approach to the primary prevention of sexual abuse promotes changing the behaviour of the victim, through school education programmes for children (MacMillan *et al.* 1994b). Nevertheless, a New Zealand programme (Briggs & Hawkins 1994) was found to be effective because of teacher commitment, parental support and age-appropriate material. One important ingredient of the programme was the development of children's self-esteem. Research has shown that sex offenders target children with a low sense of self-worth who appear vulnerable and unsure of themselves, with a need to be cared for (Elliott *et al.* 1995). Thus, assertion training needs to go hand in hand with the development of self-esteem.

A more traditional approach in the UK is the use of community nurses to universally help parents with children under 5 years old, as part of the primary health care system (MacMillan *et al.* 1994a). Indeed, there is a need for health visitors to discourage parents from physically punishing their children. In fact, one

in five parents ($n=457$) admit to severe physical assaults on their children; 16% of mothers and 21% of fathers (Nobes *et al.* 1999). This is not surprising when the UK government condones the use of physical punishment by caregivers to control children (see the parliamentary report *Protecting Children, Supporting Parents: A Consultation Document on the Physical Punishment of Children*, House of Commons 2000). However, the use of cognitive-behavioural techniques by community nurses to promote positive parenting skills and self-esteem in all parents and children is considered financially unrealistic, because of the need for training and small caseloads (Browne 1989; 1995b).

Evaluation of community-based approaches

Olds *et al.* (1993) showed that the cost of providing home visiting per family was \$US1582 and this intervention by a nurse saved \$US1762 in the first 2 years of the child's life. Hence, there was an overall net saving (dividend) of \$US180 per family (in the 1980s). There was a 56% saving in family aid, 26% in food stamps, 11% in medical aid and a 3% decrease in child protection cases. There was also a 5% increase in income tax received from an increase in maternal part-time employment as a result of the professional advice given.

Home visitation approaches with mothers under 21 years of age, single parents and mothers with serious financial problems have been evaluated in the long term by Kitzman *et al.* (1997). They showed that home visits had positive benefits for the mothers as well as the children and that these benefits lasted for up to 15 years after birth of the first child. Olds *et al.* (1997) compared low-income mothers visited by nurses in the home with low-income mothers with no formal home visits. They demonstrated the following significant differences, 15 years later, for those who had been visited and offered advice and support:

- less child abuse and neglect;
- less births after the first child for unmarried women;
- less family aid received;
- fewer problems with alcohol and drugs; and
- fewer arrests by police.

Therefore, it may be argued that one way to prevent, or at least ameliorate, the above social problems is by maintaining well-resourced community-based health care services for families and children, especially those who are on low incomes (e.g. single mothers and teenage parents). In Queensland, Sanders *et al.* (in press) developed the Triple P-Positive Parenting Program, which is a multilevel family support strategy for the prevention and treatment of behaviour and emotional problems in children (e.g. eating and sleeping problems) that create parental stress and frustration. Similar approaches have been adopted in the UK (Herbert 1988) which have since been used for the prevention of family violence (Browne & Herbert 1997).

Parent-held records

Children who have experienced family violence, breakdown and/or separation are more likely to develop emotional prob-

lems and therefore could be considered to be a high-risk group, in priority for services. Therefore, managers of community health could adopt a secondary or tertiary prevention approach using information from parent-held records.

It is difficult to introduce the concept of child protection in parent-held records because of the sensitive nature of the topic (Armstrong-Esther *et al.* 1987). However, parent-held records are a potential source of information both from and for parents. Parent-held records are issued to every parent upon the birth of their child and are used to record all information about the child's physical growth, health, development, immunizations and consultations with health professionals. They also include advice and information on topics such as feeding, growth, development, general child care and sources of medical help and family support. This information could be expanded to cover the social and psychological growth, health and development of the child. Currently, this is a serious omission from parent-held records.

Secondary prevention

Secondary prevention involves professionals screening families and providing interventions aimed at giving special attention to high-risk groups before child maltreatment occurs within or outside the family. As with other problems in child health and development, the risk approach to child protection can be seen as a tool for the flexible and rational distribution of scarce resources and their maximal utilization. Therefore, community nurses now prioritize and 'target' their home visits to families on the basis of an assessment of need (Browne & Lynch 1998). They are often instructed to screen routinely for predictive characteristics in all families who come in contact with the service they are providing: counselling, home visits and clinic, health centre or hospital care.

Health and social services using this approach require the ability to identify parents and children in need of help from those characteristics (risk factors) of the child, parents, family and social environment that are associated with an increased risk of undesirable outcomes. The process requires resources from each local community to:

- develop methods for detecting risk factors;
- train health care and social workers in these methods; and
- provide intervention strategies to prevent or ameliorate undesired outcomes.

The surveillance and monitoring of child health, growth and development is regarded as good practice throughout the world (Hall 1995; World Health Organization 1999). However, there is a paucity of research into the specific components and methods used in various screening and assessment programmes for child maltreatment.

Predicting child maltreatment in the population

A number of articles have been written on the prediction of child abuse (Lynch & Roberts 1977; Altmeier *et al.* 1979, 1984;

Starr 1982; Leventhal 1988; Ammerman & Hersen 1990; Adler *et al.* 1991; Ammerman 1993; Agathanos-Georgopoulou & Browne 1997), many of which have presented a list of characteristics common to abusing parents and to abused children (Browne & Saqi 1988a).

The Child Abuse Potential (CAP) inventory, developed in the USA, has taken a multifaceted approach (Milner 1986). Indeed, the CAP inventory is one of the few self-report questionnaires (160 item) that has been evaluated in terms of its reliability (internal consistency and temporal stability) and construct validity. However, the relevance of checklists and inventories for the prediction of child sexual abuse remains questionable, especially when the epidemiological differences between sexual and physical abuse are considered (Jason *et al.* 1982; Browne 1994). Nevertheless, certain risk factors are the same, such as poor relationship with parents, step-parenting, marital conflict, alcohol and drug abuse (Finkelhor 1980).

Community nurses have been significantly influenced in their work by such inventories, using the characteristics as 'early warning signs'. However, reviews of the relative value of these characteristics for the practical and routine monitoring of families have emphasized a need for caution (Barker 1990; Howitt 1992). The danger of predictive claims was demonstrated by Browne & Saqi (1988a), who retrospectively evaluated a typical checklist completed by community nurses around the time of birth. The checklist was developed from a number of demographic and epidemiological studies carried out in the UK, with special reference to non-accidental injury to children in Surrey, England.

In a prospective evaluation (Browne 1995a, 1995b), community nurses completed the 12-item checklist on all children born in 1985 and 1986 in three health districts of Surrey, England. In total, 14252 births were screened for the potential of child abuse and neglect and 7% (964) were identified as 'high risk'. This population cohort was then followed up for 5 years and in 1991, 106 families had attended a case conference for suspected or actual maltreatment of their newborn child. Table 70.4 presents the percentage of abusing and non-abusing families that possessed the checklist characteristics (risk factors), in order of relative importance for prediction. In addition, it shows the percentage of families with a particular characteristic that go on to abuse and/or neglect their newborn in the first 5 years of life (conditional probability).

It was found that fully completed checklists, with the relative weighting for each factor taken into account, could correctly classify 86% of cases. The screening procedure was sensitive to 68% of abusing families and correctly specified 94% of the non-abusing families. Surprisingly, nearly one-third of the abusing families had few risk-factor characteristics of any weight and were incorrectly identified as 'low risk' around the time of birth. The most worrying aspect of the checklist is that 6% of the non-abusing families were incorrectly identified as high risk for potential child abuse because they were found to have a number of heavy-weighted risk factors.

Table 70.3 Percentages and rates of registrations by categories of child abuse by which they were recorded during the year ending 31 March 2000 ($n=29\,300$). (Adapted from Department of Health 2000b.)

Category of abuse	Number of children	Percentage	Rate per 10 000
Neglect, physical injury and sexual abuse	300	1	<1
Neglect and physical injury	1900	6	2
Neglect and sexual abuse	600	2	1
Physical injury and sexual abuse	600	2	1
Neglect (alone)	10 100	35	9
Physical injury (alone)	6 700	23	6
Sexual abuse (alone)	3 600	12	3
Emotional abuse (alone)	4 800	17	4
Unknown*	700	2	1
<i>Total</i>	<i>29 300</i>	<i>100</i>	<i>26</i>

*Refers to categories used but not recommended by Department of Health (1991) or no category available.

Table 70.4 Relative importance of screening characteristics for child abuse as determined by discriminant function analysis (from Browne & Herbert 1997; p. 120).

Checklist characteristics	Abusing families (%) ($n=106$)	Non-abusing families (%) ($n=14\,146$)	Conditional probability(%)*
n =Parents with a child under 5 (baseline)			0.7
1 History of family violence	30.2	1.6	12.4
2 Parent indifferent, intolerant or overanxious towards child	31.1	3.1	7.0
3 Single or separated parent	48.1	6.9	5.0
4 Socioeconomic problems, such as unemployment	70.8	12.9	3.9
5 History of mental illness, drug or alcohol addiction	34.9	4.8	5.2
6 Parent abused or neglected as a child	19.8	1.8	7.6
7 Infant premature, low birth weight	21.7	6.9	2.3
8 Infant separated from mother for more than 24 h post-delivery	12.3	3.2	2.8
9 Mother <21 years old at time of birth	29.2	7.7	2.8
10 Step-parent or cohabitee present	27.4	6.2	3.2
11 Less than 18 months between birth of children	16.0	7.5	1.6
12 Infant mentally or physically handicapped	2.8	1.1	1.9

*Conditional probability refers to the percentage of families with a particular characteristic that go on to abuse and/or neglect their newborn in the first 5 years of life.

The relatively low prevalence of child maltreatment combined with even the most optimistic estimates of screening effectiveness implies that a screening programme would yield large numbers of false-positives (Daniel *et al.* 1978; Dalglish, 1998). The checklist detection rate would mean that for every 14 252 births screened it would be necessary to distinguish between 72 true risk cases and 892 false-positives in the 7% of cases (964) identified as high risk. This would indicate the requirement of a second screening procedure to be carried out with the high-risk families perhaps based on the significant differences found between abusing and non-abusing parent-child relationships (Browne & Saqi 1987, 1988b; see also Verhulst & van der Ende, Chapter 5). Thus, a second screening could possibly distinguish the true potential maltreatment cases from the false-positives by the use of behavioural indicators. A more difficult problem

would be to distinguish the 34 missed cases of potential child abuse from the 13 254 correctly identified non-abusers, as they would be mixed up in a population of 13 288 low-risk families.

Leventhal (1988) provided evidence from longitudinal cohort studies that suggested that prediction is feasible. However, he concluded that improvements in the assessment of high-risk families are necessary, including the further development and use of a standardized clinical assessment of the parent-child relationship.

Parent-child relationships in high-risk families

The aetiology of child abuse and neglect is complex. It is now generally acknowledged that the causes of child maltreatment

are multifactorial (Belsky 1988; Ammerman & Hersen 1990, 1992; Browne & Herbert 1997), involving characteristics of the parent and child, the social system of the family and demographic and cultural situation of the community. Given a particular combination of these factors, an interactional style develops within the family and it is in the context of this interaction that maltreatment occurs.

Browne & Herbert (1997) proposed that the chance of risk factors resulting in child maltreatment and other forms of family violence are mediated by and depend on the interactive relationships within the family. A secure relationship between the parent and child will 'buffer' any effects of stress, facilitating coping strategies by the parent. In contrast, insecure or anxious relationships will not 'buffer' the parent under stress and any overload, such as an argument or a child misbehaving, may result in a physical or emotional attack.

The detection of early signs indicating a malfunction in the caregiver–infant relationship has been considered by Crittenden (1985; 1988) who discussed the role of the parents' thought processes in the distortion of interactive patterns in maltreating families. She discovered that two patterns, (i) co-operation/interference and (ii) involved/withdrawn, significantly discriminate abusing and non-abusing families. Furthermore, Stratton & Swaffer (1988, p. 201) also stated 'there are good theoretical grounds for supposing that the beliefs that abusive parents hold about their children are an important factor in determining whether, and in what ways, a child will be abused'. The results of their work show that abusing mothers attribute more control and more internal causes to their children and less to themselves in comparison with a non-abusing group of mothers of handicapped children. They went on to suggest that causal attributions held by abusive parents, both in general and with respect to their children, should be a powerful indicator of the chances of child maltreatment. The implications of this research work for intervention with maltreating families is discussed by Crittenden (1996).

Evaluating parent–child relationships

It is unlikely that health professionals who visit the family will directly witness physical assaults on children. However, pathological aspects of the parent–child relationship may be evident through observable attitudes, behaviours and interactions between the parent and the child. Indeed, Browne (1995a) and Browne & Herbert (1997) identified and reviewed five important aspects to the assessment of high-risk parent–child relationships.

1 Parents' knowledge and attitudes to child-rearing: those who maltreat their children often have unrealistic and distorted expectations about their child's ability and the way he or she should behave.

2 Parents' perceptions of their child's behaviour: those who maltreat their children have more negative thoughts about the behaviour of the child and perceive their children to be more irritable and demanding than other children. They may attribute a

'bad' disposition to the child and interpret certain age-appropriate behaviours as deliberate or intentional non-compliance.

3 Parents' emotions and responses to stress: those who maltreat their children are significantly more harsh in their disciplinary methods, which are applied in an inconsistent way compared to non-maltreating parents. They are more impulsive and less appropriate in the way they manage their child and the stress arising from ineffectual attempts to control their child's behaviour may often escalate into violence.

4 Quality of parent–child interaction and behaviour: those who maltreat their children are often described as being more aversive, negative and controlling in comparison to non-maltreating parents. They are less sensitive and responsive to their children, which results in less frequent positive interactions.

5 Quality of child to parent attachment: those children who are maltreated are significantly more likely to develop insecure/anxious attachments to their parent(s) as a result of the insensitive care taking they receive. Those who are rejected will often form an avoidant attachment pattern and those who receive inconsistent parenting will often form an ambivalent attachment pattern to their parent(s) (see review of 13 studies by Morton & Browne 1998).

Ethics of screening and evaluation

There are ethical issues raised by any process of assessment, especially where the intention is to screen for indicators of children 'in need', and account must be taken of parents' understanding of the function of such assessments. Nevertheless, all practices and procedures concerning child protection are based on the principle that the interests of the child are always paramount (Department of Health 1998, 1999).

Screening and assessment programmes have to be sensitive to needs of parents as well as children. Parents expect to be consulted about and participate in decisions that involve their children (Hall 1995). Indeed, the Department of Health (1995b) has issued guidelines about the essential principles for working in partnership with parents on child protection issues. It is suggested that 'working in partnership' will promote effective work with families by maintaining citizen's rights and empowering parents. It is hoped that parents will participate by providing information and becoming involved in decisions about the care and development of their children.

It needs to be made clear to the parents that a high number of risk factors for adverse outcome identifies them as a 'family in priority' for support and services. Negative labels such as 'high-risk family' should never be used. The parent/health professional joint evaluation of a child's need for protection therefore requires a personal (home visit) approach with parents, involving experienced health visitors, who are in regular contact with families and where there is no stigma attached to the home visit.

Tertiary prevention

Tertiary prevention or treatment involves professionals offering

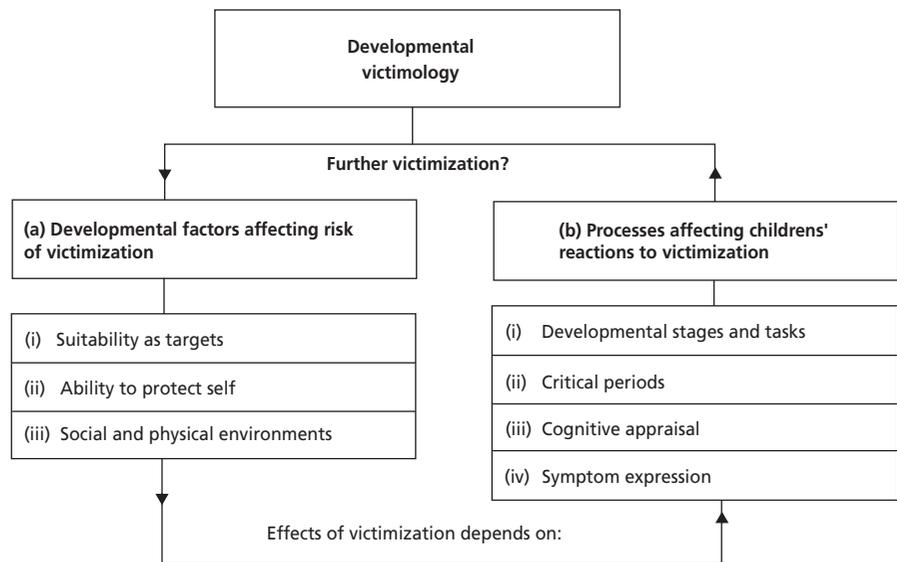

Fig. 70.1 Developmental Perspective of the victimization of children (from Browne & Hamilton 1997).

intervention only after the maltreatment has occurred. This has some limitations when recurrent and fatal abuse and neglect are considered. Physical re-abuse occurs in at least half of all cases referred for intervention (Magura 1981; Depanfilis & Zuravin 1998), and sexual abuse will recur in the majority of cases where the offender remains in the family (Bentovim 1991; Fisher & Beech 1998). There is also some evidence that services available are insufficient to provide appropriate support and therapy to abused children and their families (Browne & Falshaw 1998). In a study of 202 sexually abused children in London (Prior *et al.* 1994), 37% received no therapy; yet all these children had described contact abuse and there was a professional consensus that the abuse had occurred. It could be argued that this approach offers too little, too late.

Limitations of tertiary prevention

Finkelhor (1995) identified those factors that are likely to influence the possibility of victimization and its effects on the potential for further victimization of the individual (see Fig. 70.1). Factors associated with the initial incident of abuse and victimization (Fig. 70.1, left stem) will in turn affect the child's vulnerability to further abuse. This vulnerability will be modified to a greater or lesser degree by individual factors such as the child's reaction to a previous abusive incident. These factors can be developmental (e.g. the time of attachment formation to a primary caregiver) and cognitive (e.g. appraisal of the abusive incident). Together, developmental and cognitive factors determine the behavioural symptoms present in the child (e.g. lack of self-confidence), which may act as a signal to potential abusers that the child is an easy target. Such processes may influence the way a victim behaves which may result in increased vulnerability. For example, many children who have been sexually abused go on to develop age-inappropriate sexualized behaviour and acting out which may attract the attention of a potential abuser. The abuser

may then use the child's behaviour to justify his or her own actions and make the child feel responsible for their own further victimization. Previous literature has suggested that sexual victimization in childhood increases the risk of further sexual abuse in adulthood (Fromuth 1986; Russell 1986; Gidycz *et al.* 1993; Mayall & Gold 1995).

Browne & Hamilton (1997; 1998) claimed that, for many children, victimization occurs on more than one occasion, with the same perpetrator (repeat abuse) or different perpetrators (re-abuse). It is generally considered that repeat or re-victimization will lead to more severe trauma. Hence, memory for victimizing events may be lost from conscious memory, while those children who experience a single event may be less traumatized and details of the incident will be remembered (Terr 1991; Whitfield 1995).

Recurrent abuse of children

It is generally acknowledged that maltreatment of children frequently consists of more than one incident. In a review of 45 studies, Depanfilis & Zuravin (1998) reported repeat victimization rates of up to 50% in families followed up over a 5-year period and up to 85% for families followed for up to 10 years. This confirms other USA research, e.g. Finkelhor *et al.* (1986) who found that 40% of female sexual abuse consisted of more than one incident, with an average length of time between victimizations of 31 weeks.

In England, Hamilton & Browne (1999) studied 400 children referred to 10 child protection units in one police service area. Within the 27-month follow-up period, one in four children ($n=54$) were subject to at least one re-referral. Once maltreated, it was found that children were more likely to be maltreated again. The majority of re-referrals (61%) occurred within 330 days of the index referral, with the greatest risk being the first 30 days.

These figures are remarkably similar to US studies of recurrent maltreatment (Fryer & Miyoshi 1994; Fluke *et al.* 1999).

Police service response in England was not significantly related to the rate or type of re-referral. A large number (64%) of index referrals led to 'no further action' police responses. This is likely to reflect the factors influencing decisions to bring charges, such as the interests of the child, insufficient evidence and the decision of the Crown Prosecution Service. In the minority of cases (13%), the referral did result in a 'caution' or 'charge' for the offender which may act as a deterrent. However, the victim may still be vulnerable to abuse by other perpetrators. Indeed, it was found that once a child has been referred on at least two occasions, their risk of re-referral over the next 27 months more than doubled. This may reflect increased vulnerability or, alternatively, vigorous monitoring by child protection agencies.

Social services involvement was also not associated with re-referral status. Therefore, the findings of Hamilton & Browne's (1999) study would suggest that the actions taken during a child protection joint investigation are not effective in preventing the recurrent maltreatment for at least one-quarter of those children referred.

The above findings provide more general evidence to alarming reports from English studies specific to the sexual abuse of children. Prior *et al.* (1997) found that only 35% of sex offenders were charged, 5% cautioned and 56% of cases resulted in no further action. Furthermore, self-reports from convicted male child sex offenders, on average, claim 6 years of undetected offending prior to their first arrest (Elliott *et al.* 1995).

Risk factors for recurrent maltreatment

Risk factors that indicate a high probability of recurrence of all forms of abuse and neglect fall into two main categories, according to recent research in the USA (Depanfilis & Zuravin 1999) and UK (Hamilton & Browne 1999).

- *Child vulnerability*: behavioural problems/conduct disorder, learning difficulties, medical problems (e.g. failure to thrive), previous referral for self or sibling.
- *Family stress*: partner abuse, drug or alcohol abuse, adult psychiatric problems, adult learning difficulties, adult criminal convictions, social support deficits.

Not surprisingly, all these risk factors are associated with fatal child abuse and neglect to children less than 5 years of age, especially when the caregivers are young and inexperienced (Greenland 1986, 1987; Strang 1992; Browne & Lynch 1995; Wilczynski 1997). Indeed, Greenland's (1986, 1987) Canadian studies in Ontario provide evidence highlighting the limitations of tertiary prevention. He found that one in five severely physically abused children had been previously assaulted prior to their hospitalization for the most recent injury. Between 10 and 16% (depending on the study reported) had brothers and sisters who had also been assaulted previously or who had died as a result of abuse and neglect.

The above evidence demonstrates the need to develop more effective strategies to prevent and detect the victimization and

repeat victimization of children. The Sex Offender Act (Home Office 1997), which concentrates on convicted perpetrators of sexual assault, will only help identify and monitor a small proportion of the individuals who commit such crimes (Wyre 1997). A comparable Violent Offender Act is yet to come into existence. Hence, there is a urgent need for the prevention of child maltreatment and to ensure that all offenders receive treatment.

Managing the risk of sex offences against children

Research findings from the Home Office estimated that at least 110 000 men in the 1993 population of England and Wales had a conviction for an offence against a child (Marshall 1997). Overall, sexual assaults on children made up the majority of serious sexual offences committed by men under 40 years of age.

Disclosure of information by health professionals to warn communities (or particular sections of a community, such as educational establishments, youth clubs, etc.) about the danger posed by particular sex offenders can be seen as a way of reducing offending behaviour in a particular locality. Under the Sex Offender Act (Home Office 1997), public protection panels have been set up to act as a forum for the 'risk assessment' of offenders who have been put on probation and/or just released from prison. Most used the Thornton (1997) scale to assess risk. These panels can comprise probation, police, social services, housing services and whoever it is felt could give information or aid the assessment and prevention process.

Thus, public warning systems form part of the overall strategy for managing risk and positive steps being taken to track and control the activities of sex offenders. The limitations of current policy are that it focuses selectively on known or convicted sex offenders. It is evident that there is a larger group of sex offenders whose behaviour is hidden or suspected but not subject to criminal court proceedings (Wyre 1997).

Relationships between the perpetrator and victim affect the strategies used by the offender, as well as the frequency and duration of the abuse (Faller 1990). This will affect the chances of the sex offender being discovered. Offenders who are familiar with the victim are more likely to use psychological means of coercion (such as bribery) and maintain the child in a secret abusive relationship. By contrast, the use of physical force runs a greater risk of detection. Elliott *et al.* (1995) found that in offences in which physical force was used the offender was usually a stranger to the child. However, sex offenders do not always behave to 'type' (Fisher & Maire 1998) and the early detection of sex offences can only occur through an awareness and understanding of different types of offenders and their associated *modus operandi* (see Glaser, Chapter 21 for sex offender typologies).

It is reported that some sex offenders, especially adult males who have abused boys, have been sexually abused themselves (Browne 1994; Dobash *et al.* 1994; Elliott *et al.* 1995) but this is

neither a necessary nor sufficient causal factor of sexual offending. In fact, many offenders see this as a way of denying, minimizing and distorting their behaviour. Similar denial tactics are used if alcohol consumption is involved (Allam *et al.* 1998).

Choice of victim also appears to be related to 'deviancy'. Beech (1998) found that highly deviant men were more likely to have committed offences against boys, or both boys and girls. They were also more likely to have committed both extra- and intra-familial offences. Furthermore, it has been found that those who target extrafamilial boys and those offenders who target both sexes are at higher risk of re-offending (Hanson & Bussiere 1996; Proulx *et al.* 1997; Hanson & Harris 1998).

High sexual deviancy (Hanson & Bussiere 1996) and the presence of a high number of paraphilias (Prentky *et al.* 1997) have also been known to predict sexual recidivism. More importantly, 'criminogenic needs'—those attitudes, values and beliefs that support antisocial behaviour—have been deemed to be strong predictors of sexual abuse (Andrews & Bonta 1994). A criminal lifestyle in general is a good predictor of sexual recidivism (Hanson & Harris 1998). Indeed, Browne *et al.* (1998) found that previous involvement with the police and convictions for violent offences were predictive of the 37% of sex offenders who drop out of community treatment programmes. Those men who do not complete treatment still pose a significant risk to women and children (Abel *et al.* 1988).

Treatment programmes

Sex offender treatment programmes are based on two explanatory models for sex offending that identify:

- 1 factors that promote a sexual assault cycle, such as distorted thinking, compensatory feelings and abusive behaviours (Wolf 1988); and
- 2 the preconditions for the sexual abuse of a child, such as motivation to abuse, mastering internal and external inhibitors and overcoming victim resistance (Finkelhor 1984; Finkelhor *et al.* 1986).

In a recent evaluation of the Prison Sex Offender Treatment Programme (Beech *et al.* 1998), it was found that 67% of men attending showed a treatment effect with significant changes in some or all of the main themes targeted. Long-term treatment (160 h) was more effective than short-term treatment (80 h) in creating change, especially for those offenders who showed high deviancy.

Similarly, a recent audit of a community treatment programme (Browne *et al.* 1998) showed that 81% of sex offenders showed some improvement, with all those completing a programme (63%) showing significant changes in one or more of the following six treatment modules (Allam *et al.* 1997).

- 1 Cycles and cognitive distortion.
- 2 Self-esteem, social skills and assertiveness training.
- 3 Sexuality.
- 4 Role of fantasy in offending.
- 5 Victim empathy.
- 6 Relapse prevention.

A review of seven other community treatment programmes (Beech *et al.* 1996) demonstrated that the above findings are typical. One of the few studies of treatment effectiveness (Marshall & Barbaree 1988) found that treated offenders had less re-convictions than non-treated offenders at both 2-year follow-up (5.5 and 12.5%, respectively) and 4-year follow-up (25 and 64%, respectively).

The need for comprehensive assessment and treatment of sex offenders, using cognitive-behavioural methods was emphasized by Fisher & Beech (1998). They listed 13 preconditions for a sex offender to accomplish before they consider the risk small enough for the man to be reunited with his family, even for therapy. In fact, family therapy has met with limited success in this area (Bentovim 1991). However, they also emphasized the need for work with other members of the family, especially the abused child to prevent the possibility of sibling abuse (Deblinger & Heflin 1996).

It is important to point out that the treatment programmes described above are limited to North America, Western Europe and Australasia. Few examples of such programmes exist elsewhere. Indeed, in Eastern Europe they are more likely to institutionalize the child than prosecute or treat the offender.

Child protection in Eastern Europe

The Convention on the Rights of the Child (Article 9) recognizes the right of all children to grow up in a family environment and the responsibility of states to support parents in the task of child-raising (Article 18). However, many post-communist societies have continued the practice of institutionalizing not only children who are orphaned, disabled or abandoned, but also those who come from families that are considered at risk of child abuse and neglect. In fact, the proportion of children aged 0–3 years in institutional care has actually increased in some Eastern European countries (World Health Organization 2000).

After 50 years of separate ideologies, networking between Eastern and Western Europe has led to new challenges in the theoretical understanding of children's needs. For example, most of Eastern Europe is unfamiliar with the writings of John Bowlby's (1969) attachment theory, and have developed theories based on classical conditioning much more extensively than in the West. This theoretical orientation has led to the maintenance and use of institutions to address the needs of children in adversity, rather than the development of substitute parenting (foster care and adoption).

The importance of attachment theory in highlighting the limitations and negative consequences of childhood institutionalization cannot be overestimated. It is widely recognized that the practice of institutionalization prevents children from developing to the best of their capacity. The social and emotional deprivation experienced by children in institutions can lead to physical and developmental retardation, which has lifelong implications (see O'Connor, Chapter 46).

New programmes are being formulated in order to empty the institutions of children, and either return them to their natural family or to a substitute foster family with a view to national adoption. A model of good practice from Timisoara (Romania), developed by the child psychiatrist, Dr Violeta Stan (1999), was the development of mother and baby homes and alternative family-based homes for abandoned, abused and neglected children who are taken into care as an emergency.

Mother and baby units

These small (shelter) homes give special support to parents, especially mothers who are at high risk of abandoning their children. The unit provides them with an alternative and safe living place and teaches them essential coping and parenting skills. The objective is to promote maternal bonding and child attachment, through breastfeeding, provision of adequate child and antenatal care, education on the child's developmental needs and support towards the mother's search for a stable socio-economic living condition.

Alternative family-based care for young children and babies

These small community homes serve as an intermediate placement for abandoned babies, abused and neglected children. They are established on the principles of family-based care and attachment theory. Child-friendly furnished and equipped apartments (provided by the local authorities) are staffed with four professional caregivers that constitute the child's surrogate family; each unit can receive up to five children each. Each child has a clearly designated surrogate mother who is sensitive to the child's attachment behaviour to the primary caregiver. The child joins his or her surrogate siblings in this new home. Provision is made that a minimum of one and a maximum of two of the five children within each apartment group are physically and/or mentally handicapped, in the interest of promoting integration. The children visit the community's crèche, kindergarten and school. The local community is encouraged to help, play and care for the children. To promote infant attachment to a primary caregiver, substitute Romanian parents are found quickly, under a fostering and adoption programme located in the area. Similar approaches have been reported in the Czech Republic (Sobotkova 2000).

These approaches attempt to repair a desperate situation where abandoned, abused and neglected children were the subject of secondary abuse and neglect within large institutional settings. This is important for the future parenting behaviour of these children.

Attachment theory and child maltreatment

Despite disagreement over the degree of influence, a history of

child maltreatment places an increased risk on an individual of maltreating their own children as a parent (Buchanan 1996). In their review, Morton & Browne (1998) proposed the theory of attachment (Bowlby 1969; Ainsworth *et al.* 1978) as one of the primary mechanisms for the intergenerational transmission of childhood maltreatment. Over time, a child develops a set of expectations based on prior experiences of interactions with their caregiver and this affects the way they see themselves (Ainsworth 1980).

Where a caregiver has consistently responded to the child in a sensitive and appropriate way, the child sees him or herself as worthy and competent in eliciting the caregiver's attention. By contrast, a maltreated child sees him or herself as unworthy and unable to elicit care, because of the unresponsive and rejecting behaviours of the parent. This early mental representation is said to be the prototype for future relationships and may be the priming process by which maltreatment continues from one generation to the next (Ricks 1985).

Indeed, studies (Boswell 1995; Falshaw & Browne 1997) have shown that three out of four young people held in secure accommodation for antisocial behaviour problems have a previous history of child abuse and neglect and should be recognized as both victims and offenders (Falshaw *et al.* 1996).

It is in this area that mental health professionals, child and adolescent psychiatrists can contribute to ensuring that the mental health needs of abused and orphaned children are addressed at the earliest possible opportunity in order to repair any attachment disorder. This approach would help prevent family violence from one generation to the next and its associated mental health problems. Intergenerational expression of family violence is most readily seen by the association of spouse and child abuse (Kashani & Allen 1998).

Family violence and mental health

The importance of the links between spouse abuse and child maltreatment has been recently recognized for child protection work (Browne & Hamilton 1999). Indeed, both child physical abuse and/or child sexual abuse are thought to occur in approximately half of Australian families where there is violence between the parents (Goddard & Hiller 1993). In the vast majority of cases this involves the father seriously assaulting the mother as well as the children. Where both spouse abuse and child maltreatment are occurring in the family, mental health problems, alcohol and drug dependency appear to be the most significant risk factors for violence (Browne & Hamilton 1999). In the USA, surveys of battered women typically show that 60% of their partners have an alcohol problem and 21% have a drug problem (Roberts 1987) and the majority of female victims suffer from mental health problems as a result. Some authors propose that these are the major causes of family violence (Pernanen 1991). However, it is more likely that alcohol and drug dependency relieves the man of the responsibility of his behaviour and gives the wife justification for remaining in the relationship in

the hope that he will control his addiction and end his aggression. It is true that alcohol and drugs appear to exacerbate pre-existing emotional problems, which increases the likelihood of violence. However, the majority of individuals who abuse drugs and alcohol admit they have been violent to their dependants while not under the influence of alcohol and drugs (Sonkin *et al.* 1985). Indeed, mental health problems, alcohol and drug dependency are not the causes of family violence but rather conditions that coexist with it, along with many other factors. Nevertheless, they are often used as excuses for violent behaviour – personally, socially and legally.

Interventions aimed at the protection of children must first address these associated factors, as individuals addicted to alcohol and drugs or suffering from mental illness can rarely benefit from social services interventions. The interagency co-operation between health and social services is a necessary prerequisite in such cases. However, adult mental health services are considered by Reder & Duncan (1999) as the missing link in the child protection system because their staff rarely contribute to the work of area child protection committees or to case conferences. This is despite the increasing evidence in the literature of a relationship between parental mental health problems, especially substance misuse, and child maltreatment (Browne & Saqi 1988a; Falkov 1996, 1997; Wilczynski 1997; Cleaver *et al.* 1998; Falkov 1998; Sanders *et al.* 1999).

Child and adolescent psychiatrists have been much more proactive in developing integrated management therapy and legal interventions for child abuse and neglect (see Furniss 1991; Bentovim 1992; Harris Hendricks *et al.* 1993; Black *et al.* 1998). Indeed, the role of the child psychiatry team in child protection has been concisely described by Davison & Nicol (1997).

A report from the NHS Advisory Service on Child and Adolescent Mental Health Services (NHS Health Advisory Service 1995) advocated collaboration in the planning and provision of services. This will ensure that interacting factors such as family discord, child abuse, socioeconomic disadvantage, discrimination, physical and learning disabilities and physical and mental health problems are considered as a whole. Without such an approach they predict a continuing spiral of child abuse, juvenile crime, family breakdown and adult mental health problems. The report recommended the development of primary or direct contact community services which, if implemented universally, could revolutionize the advice and support available to families.

Conclusions

In the past 20 years there has been debate on what services can be delivered in order to minimize the maltreatment of children. Reviews on the causes of maltreatment (Browne 1988) have emphasized a growing recognition that child abuse and neglect are products of a poor parent–child relationship. Wolfe (1991, 1993) observed that there have been promising developments in early interventions that address parental competency and family support to promote more positive parental knowledge,

attitudes, skills and behaviour. He claimed that personalized programmes such as home visits over a period of 1–3 years stand out as the most successful interventions in achieving desired outcomes in terms of fewer child injuries, emergency room visits and reports to protective agencies. Indeed, Olds *et al.* (1993, 1994) showed that home visits save on US government spending in relation to disadvantaged families in both the short and long term.

Individual counties must take a lead from the United Nations and see child abuse and neglect as a major public health problem with the same seriousness and requirement for resources as cancer, heart disease and AIDS (Merrick & Browne 1999). An international co-ordinated effort in child protection is necessary to ensure each child's right to optimal health and development. This requires an increase in the level of funding for education and training, and for prevention and treatment of child abuse and neglect on a global level.

The Law Concerning Services for Children with Social and Psychological Problems

Michael Little

Introduction

Practically everything a clinician does takes place within a legal framework. Nevertheless, the clinician is not often constrained by law. The boundaries established in professional guidance are seldom contradicted in law.

The law concerning children with social and psychological problems is closely intertwined with the development of services for those children. Many practice innovations have been enshrined in law as society seeks to rationalize its response to children's needs. At other times, legal measures have been used to compel changes in practice. There are similarities between the philosophical and theoretical underpinnings of the law and those of several of the health professions, particularly psychiatry (Nye 1980). Increasingly, decisions of law have been made in a practice context and have been used to encourage co-operation among professionals. The courts have become more reliant upon psychiatric and other expert opinion (Ash & Guyer 1986; Wald *et al.* 1988; Brophy *et al.* 2001).

Even so, the relationship between the law and services for children with problems is not always harmonious. As understanding and clinical practice improves, or when societal expectations outstrip those of the professions, it is possible for law and services to be contradictory or even to clash (Stone 1999). In some countries, the legal context can establish an atmosphere of constraint, even when there are few practical limitations on clinical decision-making. For example, when Gutheil (1995) wrote about legal issues in psychiatry, half of the chapter was devoted to legally defined malpractice.

Cutting across the relationship between law and practice are five broad themes.

- 1 The relationship between children's needs as defined by clinical and research experts and the rights of children and others in society as enshrined in law.
- 2 The need to choose between the competing rights of individuals.
- 3 The uneasy relationship between evidence as it is applied at the clinical case level and evidence used with respect to classes of case.
- 4 Understanding the way the law conveys complex social issues and what this says about clinical practice.
- 5 The amount of latitude the law affords services for children in need and the consequent dilemmas this can pose for practitioners.

This chapter explores these broad themes with illustrations of

the intersection of law and services for children at the clinical case-by-case level, and also with regard to classes of cases. Illustrations extend beyond child psychiatry to include other professions, such as social work. As similarities and differences between legal jurisdictions are so informative, an international perspective has been taken, although illustrations tend to be limited to Europe, North America and Australasia.

The broad context

Theoretically, in most nations, it is possible for anybody to offer any service providing the recipient of that service is a willing participant. If a service is intended to make somebody do something or prevent them from doing something, or if public money is needed, then some form of legislation will be required (Eekelaar, in press). Many services for children in need have evolved from activity pioneered by voluntary organizations operating with the consent of children and families, but once activities require the dispensation of parental or children's consent, or public financial support, they must be authorized by statute. There is a close connection therefore between legal and financial frameworks. The law defines what services an agency can provide, who must pay and how much. Laws generally permit rather than guarantee expenditure.

In the context of children in need, one of two legal doctrines run through the primary legislation of most Western developed nations (Bulkley *et al.* 1996). *Parens Patriae* evolved in response to the needs of orphans but has been used to restrict parents' authority when a child's physical or mental health is jeopardized (*Prince v. Mass.*, 321 U.S. 158 1944 United States). Current thinking tends to put the needs of the child as paramount, so legal thinking attempts to capture the 'best interests of the child' (British Medical Association 2001). These broad doctrines have little impact on precise mechanisms for deciding whether a child's health has been jeopardized or that an action is or is not in the child's best interests. Such mechanisms vary considerably from country to country.

Crossing national boundaries are ethical principles (Rosenberg & Eth 1995) of autonomy (that patients give their informed consent to treatment), *Primum Non Nocere* (that a clinician's motivation is first to do no harm), beneficence (to prevent harm and promote well-being) and justice (to ensure some principle of equality of treatment). These lead to practical guidance of a general nature (British Medical Association 2001) or relating

to specific case types (Department of Health *et al.* 1999). Providing accessible information, avoiding compulsory powers, trying to comply with the consumer's wishes, establishing collaborative trusting relationships and involving children and families in decision-making are now widely accepted as good practice.

It is rare for ethical guidance to run counter to legal statute and ethical practice will reduce and delay direct involvement of the law in clinical decision-making. For example, compulsory measures are a rarity in the treatment of eating disorders with significant mortality rates, such as anorexia nervosa. Individuals with this disorder are generally at a developmental stage that suggests competency to make valid choices about their care but poor nutrition may impair cognition and lead to refusal of treatment or accepting only ineffective treatment. However, such situations, which often appear to the lay reader to demand court oversight, are usually tackled effectively by well-managed clinical intervention. Summaries of good practice emphasize the importance of treating anorexia nervosa as a mental disorder, establishing trust with patient and parents, giving the patient sufficient information to assess the risks of treatment and its alternatives and always asking patient consent even when compulsion becomes necessary (British Medical Association 2001). Approached in this way, the requirement for clinical decisions that require legal sanction—to remove patient consent, to detain or feed by artificial means—become the exception rather than the rule (Herzog & Becker 1999).

A similar picture emerges with respect to confidentiality. In some areas of children's services (e.g. child protection) this is a thorny issue. Ethical guidance is clear. People, regardless of their age, status or mental capacity, are entitled to expect that information about them provided to, or discovered by, a professional agency is not passed to another person or agency without their consent (General Medical Council 2000). The duty of confidentiality can be breached in the public interest, e.g. to prevent or detect a serious crime or to protect another person from serious harm.

Good ethical practice can ease professional anxiety, reduce the requirement for unnecessary legal intervention and protect both the referred child and colleagues potentially at risk. It is important to explain to children not only their rights to confidentiality, but also the professional duty to prevent harm to others. In difficult cases (e.g. where the child may disclose maltreatment) giving the child time to make an informed decision and recording how this will be done will help. Where it does not put the child at risk, parents should be involved in this process. Where confidentiality is going to be breached, it is necessary to explain to the child what is happening and why (Department of Health *et al.* 1999). Such ethical guidance is rooted in the 'best interests of the child' doctrine.

Even when law is not explicit on this matter, it is generally accepted that professionals uncovering direct evidence of child maltreatment should report it. The manner in which the professional engages with the child can make a considerable difference

to the way in which the principle is enacted and to outcomes for the child.

The law adapts to the vicissitudes of societal attitudes towards children and the evolving understanding of children's needs. In the last century, children gradually acquired rights of their own and there was less of an inclination to view them as property of their parents (Eekelaar 1991). The relationship between state and family and the child's position within that has been subject to sociological analysis that combines legal and social dimensions. Fox-Harding (1991) classified state intervention in family life on four dimensions: rate of separation of children from home, propensity to support children at home, respect for children's rights and acknowledgement of parent's rights. Such analysis is helpful in understanding broad social dimensions of law regarding children. Clinicians will recognize these themes in the opinions and motivations of other professionals, managers of services and consumers.

The recent acknowledgement of children's rights has probably resulted in some international convergence in laws regarding children. There are charters and constitutional treaties that cross judicial boundaries and, in the case of the US Supreme Court and the Articles of the European Convention of Human Rights, they can act as the arbiter at the final point of appeal, as well as a fundamental point of reference in legal rulings regarding children in need. Landmark rulings by the European Court carry similar weight (Fortin 1999). However, the convergence in legislation and acknowledgement of cross-border treaties probably mask marked differences in clinical practice, its organization and management.

The United Nations Convention on the Rights of the Child, ratified by 191 countries, is widely cited. Other than encouraging a general resurgence of interest in children's rights, it is difficult to assess the convention's impact on children with social and psychological problems, although in some countries, e.g. New Zealand, it is widely cited in judgements (Pipe & Seymour 1998). A country's imprimatur on the Convention cannot be taken as an indicator of effective policies or practice.

In most countries, domestic law has adapted to increasing knowledge about the complexity of children's needs by encouraging—in the European and Australasian context at least—multidisciplinary approaches and by inviting a wide range of professionals to decision-making fora. This shift has been accompanied by a move from paper to oral evidence and for a diversification in the places in which decisions are made. A clinician might typically be expected to have a rudimentary understanding of health, education and social care legislation and guidance and will find him or herself practising that understanding in administrative, quasi-legal and court settings.

Most fundamental decisions concerning a child's life, e.g. whether or not he or she is guilty of a crime, where the child should live and with whom he or she should be in contact with, are made in a court. In Europe, there has been a trend toward replacing courts with administrative procedures and conferences of professionals. New Zealand's Children and Young Persons and Their Families Act 1989 took decisions away from profes-

sionals and placed them in the community and gatherings of family members.

In most developed countries, laws distinguish between criminal matters, concerning whether a crime has been committed and what should happen to the offender, and civil matters, judging the rights of private citizens such as parents (*Lessard v. Schmidt* 1972; Stone 1999). The civil law also differentiates between the public domain (concerning the involvement of the state in family matters) and the private domain (dealing with relationships inside the family). The Children Act 1989 (England and Wales) is a rare example of legislation using one set of principles and orders to deal with both domains of the civil law. Although it does not have a direct impact on practice, the single framework for all children creates a helpful context for clinical practice.

For a practitioner, there is considerable overlap between criminal and civil law. When a father is accused of sexually abusing his child, the child may be asked to give evidence in the criminal case. To preserve the accuracy of testimony, the treatment of the child may be delayed until the criminal case is concluded. Civil procedures may operate in parallel, deciding where the child should live, with whom the child may have contact and whether any services are necessary, possibly requiring another decision about whether the child was maltreated using a different standard of proof.

These themes will be evident in the following discussion of the relationship between the law and practice and the way in which evidence is assembled in different legal contexts. The following evidence does not cover the detail of the law but it does address common underlying principles as they impinge on clinical practice. The evidence comes in two parts, the first dealing with decisions about individual children, the second with decisions about classes of children.

The law and professional behaviour: decisions about individual cases

A clinician's primary task is to assess the child's circumstances, make some prognosis of likely development and use this information to fashion an appropriate intervention. The law may become involved if there is parental (or other carer's) disagreement with the professional view, if the child is in disagreement or if the state has to pay for the intervention. Cutting across these issues is the child's competency to give a perspective. In certain cases this may be tested in law.

There are seven ways in which clinical practice typically interacts with the legal process and which exemplify issues of interest to practitioners. A distinction is made between civil and criminal law, although in children's issues there can be considerable overlap. In some jurisdictions, children's crimes are adjudicated in civil court. The reader will bear in mind that many of the legal decisions described below are increasingly taken in administrative or quasi-legal contexts, such as statutory meetings of professionals.

Civil issues

First are decisions to resolve disputes between relatives, most commonly separating parents, about who will look after or have contact with the child (and who should supervise contact). In some circumstances, disputes centre on aspects of the child's upbringing or elements of the parental relationship, such as domestic violence. Acrimony between adult relatives can cast doubt on the quality of evidence given by one party, such as when one parent accuses the other of maltreating the child.

Mental health professionals may be drawn into such cases to give evidence about the health of a parent or child, the likelihood of maltreatment and the benefits of treatment or restraint. Most countries have courts specializing in such cases. In New Zealand and in some parts of Australia, the USA and the UK, mediation is encouraged to help relatives resolve disputes, calling in additional professional help as necessary. There is reasonable evidence to suggest the court may have a stigmatizing effect on the participants and thus prejudice the effectiveness of any decisions made. Clearly there is less stigma to involvement in a meeting of family members to resolve family problems, but the success of alternative mechanisms is not yet known.

Second are decisions to allow the state to look after the child away from home, including the terminating of birth family rights to allow another family to adopt the child (see Rushton & Minnis, Chapter 22). Most countries have developed legislation that permits four types of separation, each type implying an increasing amount of compulsion.

1 In some jurisdictions (e.g. the UK, New Zealand and some parts of Canada) children can be looked after in state-provided placements (usually foster parents) with the agreement of relatives.

2 Some children are made subject of a court order (e.g. a residence order in England and Wales or subsidized guardianship in the USA) that permits the state to support a relative other than the parent to look after the child.

3 Small proportions of children are removed by court order for short periods and subsequently return to live with relatives.

4 An even smaller proportion is taken from birth parents into the care of the state. Most of these children return to relatives but some are subsequently adopted or remain long in state placements.

There is considerable evidence that most children separated from home eventually return home to live with relatives. The success of such reunions varies by jurisdiction (Bullock *et al.* 1998a). The pattern reflects the strength of family ties even where relationships are damaged, and the state's relative ability to provide enduring substitute care. Evidence also shows that contact during separation generally improves the chances of successful reunion, although in a minority of cases it can be damaging to the child and jeopardize the placement. Evidence on the effect of contact on child outcomes is more equivocal (Quinton *et al.* 1997; Masson 2000a). In many European countries evidence about reunion rates has influenced legislation so that there is a prescription of parental involvement and contact unless

there is evidence that to do so would put the child at risk. In England and Wales, when the state assumes parental rights through a court order, responsibility for the child's upbringing is shared with parents (Ryan 1998).

Third are decisions to sanction care or treatment of the child (British Medical Association 2001). Frequently, but not always, these are taken in the context of resolving problems about domestic relations or a child's legal status. The types of issues encapsulated in this category are varied. There are questions about the medical treatment of children, e.g. when procedures known to be in the child's best interests are contrary to parents' beliefs. Related to this are questions regarding children's mental health. Most countries require a legally sanctioned medical diagnosis for intensive treatments including hospital stays. If children need to be locked up for their own safety or that of others some legal sanction is usually required, particularly if the child has not been convicted of a criminal offence. There are then questions about the length of detention or points of release for young people detained for indefinite periods following a serious crime or diagnosis of mental illness.

Legal decision-making in this area is unusual because it occurs at several points in the child's development, including the end as well as the beginning of treatment. The complexity of the decision-making usually demands a formal court setting, although specialist panels with professionals to advise a court or the executive have been tried, e.g. in decisions regarding the care of grave offenders in the UK.

In each of the categories just described, the clinician is trying to help the court or other decision-making body decide whether the child has or will suffer any developmental impairment. Each example illustrates the changing social environment in which the clinical decision is made. In the context of family disputes, there is a tendency toward allowing family members to resolve their own disputes and participate in decision-making about a child's future. In the context of decisions about a child's separation from birth relatives, there is the tendency to presume continued parental involvement in the child's upbringing and, wherever possible, to permit voluntary arrangements between relatives and a clinician acting as an agent of the state. In the context of decisions about children's care and treatment, clinical judgement is weighed against other considerations, such as the child's rights to autonomy and liberty (English 1992).

Crime

Fourth are decisions about the care or treatment of children arrested for or convicted of crime. In the case of first minor offences, clinical decision-making is generally little different than in the context of other children in need. In Europe and New Zealand, most such decisions are made outside of court. As convictions accumulate and become more serious, the court becomes increasingly important in deciding the child's future. This can considerably limit clinical focus, particularly in those cases—the majority—in which antisocial behaviour is just one aspect of the child's pathology.

All developed countries make some distinction between blame and guilt on the one hand and the child's capacity to know right from wrong—their responsibility—on the other (Rutter *et al.* 1998). Most countries (but not all US states) have a minimum age of criminal responsibility which varies between 7 (e.g. Ireland) and 18 (e.g. Belgium) years (Krisberg & Austin 1993; Pease & Tseloni 1996). Some European countries and some US states also require the prosecution to demonstrate that accused children knew the full implications of their actions, particularly when grave offences have been committed. Decisions about criminal responsibility have been the source of considerable controversy. Some research is being undertaken but, as yet, little is known about the effects of such judgement regarding either what is done to or on behalf of the child or the eventual outcomes. Important categories of children, e.g. intervention with those convicted of grave crimes prior to the age of criminal responsibility, are largely missing from the literature.

In the USA, the age at which a child can be tried in an adult court is viewed as more important than the age of criminal responsibility. A clinical perspective is not required in all such decisions. In Florida, for example, the decision to transfer can be made by a prosecuting attorney or public defender acting on the client's behalf—but where it is required the social pressures on the professional are immense. Any forensic judgement will be subject to social judgements about the child's relative well-being if tried in a juvenile or adult court.

Fifth are decisions regarding the care and treatment of children who have been victims of crime. When the accusation is serious, including possible physical and sexual abuse by parents or others, the child may be called on to give evidence (see also Ceci *et al.* Chapter 8; Emery & Laumann Billings, Chapter 20; Glaser, Chapter 21). There is much discussion about the low rate of conviction in child maltreatment cases. The implication is that the guilty are being found not guilty. However, the primary motive of the law in these criminal cases is to establish the guilt of the accused, not to protect the child (Densen-Gerber & Lothian 1985). Mental health professionals will be much more concerned with protecting the child from the additional trauma that can result from a rigorous trial and the damaging effects of a not guilty finding upon children who have given evidence against the alleged perpetrator.

There has been considerable discussion, largely inconclusive, about appropriate clinical treatment of children whose parents are being prosecuted for their maltreatment. In such cases, evidence gathered from the children as part of a diagnosis can be used by prosecution and defence at the subsequent trial. Theoretically—the empirical evidence on this matter is scant—any treatment on behalf of the child could prejudice that child's testimony in court. Furthermore, the clinician will be mindful of the potential of the trial to undermine any rehabilitation efforts. There is insufficient knowledge to draw any clear conclusions on effective practice in such contexts save to call for more research.

Sixth are civil actions for compensation by or on behalf of children who have been victims of crime. Despite their frequency, decisions about compensation for children who have

been victims are poorly documented. In the USA such cases are described as a tort brought by children (or adults acting on their behalf) against individuals or institutions. Until recent rediscovery of the scope of child maltreatment, parental tort immunity existed in most US states and many still impose a time limit within which legal redress can be sought (Bulkley & Horowitz 1994). In Europe and Australasia, civil actions for wrongful acts done willingly have been relatively rare, although there has been a noticeable rise in out-of-court settlements by English and Welsh local authorities to children maltreated while in their care. In some countries, there are legally defined administrative arrangements for state compensation. The Criminal Injuries Compensation Board in the UK has varied its policy regarding financial payments to child victims, including those maltreated. Little has been written about policies in this area or effects of payments to victims.

In the three case types just given, there are evident contradictions in societies' perspectives toward children. Consequently, there are ambiguities and inconsistencies in the law and legal processes that hinder more than facilitate clinical decision-making. Whereas the civil context has emphasized parents' rights and perspectives, the criminal context brings children's rights and perspectives into relief. Herein lies some of the confusion in the law. While there has been a general acceptance that children should be accorded rights similar to adults and that the child's perspective is an essential element of effective decision-making, there is relatively little consensus about the corresponding responsibilities of children. For example, the increasingly punitive legal responses to young offenders evident in most Western developed nations sits uneasily with a clinician's knowledge about the adolescent-limited nature of much criminal behaviour. There can also be a clash between society's intention to deter criminal activity of future generations—by imposing harsh penalties on the contemporary offender—or to protect future generations from maltreatment at the hands of their parents—by facilitating the admission of child evidence in court—and a clinician's concern for the well-being of an individual client.

Decisions regarding a child's competency

Seventh, and cutting across decision-making in each of the above categories, are questions about the child's competency to give evidence, to understand procedures and proposed treatments, to recognize the consequence of his or her actions and (in some jurisdictions) to stand trial in adult court. There is also the related issue of the child's competency to participate in research (Royal College of Psychiatrists, 2001).

There is considerable variation in the way these decisions are made. When determining the admissibility of children's evidence, some US states apply policies patterned on Rule 601 of the Federal Rules of Evidence that establish a presumption of competence for all persons unless that competency is challenged. A *voir dire* hearing in court makes a ruling applying principles for the admission of evidence described below. A similar situation exists in the UK. Other US states set an age (usually

between 10 and 14 years) of minimum competence. Such fixed thresholds rest uneasily with improving knowledge about children's competency (Melton 1981).

A number of principles guiding effective clinical practice can be drawn from available evidence (Rutter, 2001). Regardless of statute, a practitioner will assume that a child's evidence can be useful to clinical and legal judgement unless there is contrary evidence. A court will sometimes require a 'yes' or 'no' decision on admissibility. A clinician will work on the basis that children's evidence can be helpful in some respects but unreliable in others.

Practitioners will view children's competence in the context of their development. This has several consequences. It is not possible to say a child is competent at one stage in development but not at another. Children may display strong levels of understanding of a limited range of issues. Because children of different ages vary in cognitive and emotional development and intelligence, judgements about competence have to be taken on a case-by-case basis, taking into account the child's ability and the nature of the decision to be made. A child's competence may also change over time, an important consideration in protracted legal processes such as adoption.

Children's ability can be much influenced by the social and emotional context in which questions are asked. What is said in a protected clinical environment using appropriate methods, such as those described in the following section, may not be replicated in court or other quasi-legal settings. Children will also be strongly influenced by parents and other carers, especially when care has been inconsistent or dangerous. What a child says in the absence of parents or carers may not be repeated in their presence.

The nature of evidence in decisions about individual cases

The law makes a fundamental distinction between evidence from a lay person (who has personal knowledge of relevant facts) and that from an expert (who has special knowledge to help decision-makers understand technical, clinical and scientific issues). Professionals can find themselves in the position of being able to provide both lay and expert testimony. Myers (1996) defined as evidence 'any matter, verbal or physical, that can be used to support the existence of a factual proposition'. There are rules governing the admissibility of evidence. These vary in complexity depending on the jurisdiction and the context in which the decision is being made.

Decision-making contexts that adopt rules of court will generally distinguish between evidence reporting on what actually happened and evidence attesting to the strength or the accuracy of evidence. Experts are usually permitted to express an opinion in a way that other witnesses are not. Most expert testimony tends to be corroborative, e.g. establishing a pattern of behaviour consistent with a proposition (Lanning 1996). In cases of alleged child abuse, this might include X-rays or swabs suggesting a probability of maltreatment. In court, a further distinction is

made between substantive evidence, to prove that something happened, and rehabilitative evidence, to support or challenge the competency of the witness. Experts frequently offer and can be the subject of rehabilitative evidence.

Apart from rare exceptions, mental health professionals who provide expert evidence will be guided by the best interests of the child and not by the instructions of one of the parties to the case. Myers (1996) captures the principles of expert testimony under the acronym HELP: honesty, even-handedness, limits of expertise and preparation.

There have been important judgements, mostly outside of the children's area, about the reliability of expert evidence; such judgements bear on all cases coming to court. *Fyre v. US* 293 F. 1013, D.C. cir. (1923) United States, for example, stated that a novel scientific principle is admissible only when that principle 'gains acceptance in the field to which it belongs'. *Daubert v. Merrell Dow Pharmaceuticals Inc.* 113 S. Ct. 2786 (1993) United States, sets out the criteria against which a judge can assess the reliability of expert evidence. These include:

- 1 whether the evidence can or has been tested;
- 2 whether the methods used to produce the evidence are consistent with established modes of analysis; and
- 3 whether the results have been published in a peer-reviewed journal.

In other words, judgements about the reliability of expert evidence in the clinical context must adhere to similar criteria about judgements about reliability in the research context.

Scientific evidence, like most clinical decisions, usually deals in probabilities. The court will often expect an absolute judgement, e.g. about whether or not the child has been maltreated. For example, half of 10-year-old children with special needs in the care of the state and placed for adoption will eventually suffer a breakdown in that placement (Thoburn 1991). The court is likely to ask: 'Is *this* case in the 50% where it does happen or the 50% where it does not?' Regular use and illustration of probabilities in expert statements is therefore desirable. The different requirements for experts and courts are not incompatible, but do require some mutual understanding. Rutter (1998) commented that, in his experience, UK courts have come to appreciate that experts need to be able to express uncertainty when that is the case.

Different criteria are used to assess the reliability of witness statements. Bulkley *et al.* (1996) noted that in considering a child's statement, the court will consider motives to lie; whether more than one person heard the statement; the character of the child; hearing the statements; spontaneity; child's performance under cross-examination; and the possibility of family reunion.

The importance of children's evidence in the prosecution of abusers and the continuing struggle to improve methods for establishing children's competence has led to some research and innovation. Melton *et al.* (1992) reported that the amount of information remembered is in proportion to the age of the child but that there is considerable variation in children's developmental progress. The type of event being remembered and information being recounted also bear on childhood memory and, as

with adults, children's competence in presenting evidence is influenced by emotion as well as intellect. Like adults, children remember salient events better than peripheral events and, although trauma has an impact on memory, it does not lead to core facts being forgotten.

Ceci *et al.* (see Chapter 8) also conclude that children generally make competent witnesses and that even very young children can provide accurate information. In laboratory conditions, and in the absence of suggestive techniques, preschool-age children provide accurate albeit sparsely detailed reports. They recommend an interviewer using a neutral tone, a limited number of misleading questions and the absence of any motive or stereotype for the child to make a false report. They also remind the reader that, although it is rare, some children will give wildly misleading occasionally bizarre accounts.

There have been important innovations in this field, including testing of cognitive interview techniques developed by psychologists to enhance the quality of children's recall (Saywitz & Goodman 1996). These require the child to reconstruct all the events surrounding the point of interest for the interviewer, including partial information which may not be directly relevant to the facts of the case. Children are encouraged to re-tell the story from differing perspectives and in different orders. Saywitz *et al.* (1993) report increased accuracy in the range of 26–45% compared to standard interview techniques. Narrative elaboration, an analogous technique, involves the coaching of children to give high amounts of detail to all stories, including who was present, what happened, how they felt and what was said (each of these diversions represented to the child by simple drawings on cards).

This evidence, like that of Ceci *et al.*, puts great emphasis on the skills of the interviewer and the context in which the interview takes place. Saywitz & Goodman (1996) concluded that the quality of children's reports reflect the ability of the interviewer to use free recall open-ended questions (such as 'What happened?'), using a language and concepts that children understand in a setting in which children feel secure. Understanding the nature of the experience being recounted by the child in the context of ordinary child development acts as a guide to the quality of information being provided. All of this speaks to the need for specialized training for professionals involved in forensic interviewing.

This need for training acts as a reminder of an important limitation of some of the techniques described by Ceci *et al.* (Chapter 8). Although they may operate effectively in experimental conditions, they are difficult to administer in court. There are considerable ethical and methodological barriers to the effective evaluation of such techniques in court.

Another class of innovations focus on helping the child manage the intimidating context in which legal decisions are made. Much can be done prior to hearings to ensure that children are not excessively interviewed so adding to the trauma of the event about which they are reporting. Video and joint interviewing are now permitted in many jurisdictions. Children are frequently prepared for court settings, e.g. with tours of the court and

classes about the legal process (Plotnikoff & Woolfson 1995). In some European and a few North American jurisdictions, it is possible for the child to give the evidence out of sight of the accused, by the placement of a screen or by use of video or close-circuit television.

Most of these innovations have taken place in the context of efforts to prosecute people accused of child maltreatment, usually sexual abuse. The conviction rate is very low (2% in the UK) and has prompted creative prosecution practices in the USA, such as plea-bargaining to encourage one perpetrator to testify against another (Lanning 1996).

In summary, there have been important advances affecting the quality of evidence assembled about individual cases in the legal context (Brophy *et al.*, 1999) but such advances are unevenly applied in practice. All the evidence indicates the need for greater rigour and consistency in expert evidence. The application of scientific standards and methods can help. The ability to express opinions in terms of probabilities and to present counter evidence alongside that which supports the expert's statement will help. The ability of lawyers and administrators to use such evidence should improve with their exposure to it.

Evidence also points towards greater rigour and consistency in assembling the child's perspective. This area was viewed as largely unproblematic two or more decades ago. Subsequently, the dangers of misrepresentation produced much misunderstanding about the child's view, including questions about its usefulness, particularly for preschool-age children. The evidence summarized by Ceci *et al.* (Chapter 8) demonstrates the considerable advances made in the last decade and should leave readers in little doubt about the wisdom of listening to children. However, gathering and interpreting that evidence does require specialized skills and training.

Even a highly trained forensic interviewer will have a weather eye to the place in which that evidence will be tested. A clear view emerging from a skilled interview undertaken in a controlled environment may disintegrate in a less supportive court environment or in cross-examination. New techniques, e.g. using television or video may help, but much more work is needed to develop and evaluate new legal environments that are conducive to children giving evidence freely and ensure the accused have a fair trial.

The law and professional behaviour: decisions about classes of case

The preceding discussion has dealt with the relationship between law and clinical practice. Most professional decisions are made in a broad legal context. The law communicates important social values and expectations, and thereby has an influence on clinical decisions.

Reviews of the evolution of the law in any one jurisdiction capture this well. Eekelaar (in press) referred to several underlying themes in societal attitudes to children that have helped shape British legislation over the last five centuries. Laws have

been passed to help parents maintain authority over children. Attitudes towards the poor, especially those perceived as the undeserving poor, have had a strong influence on legislation (Pinchbeck & Hewitt 1969, 1973). Society's instrumental needs have also been manifest in children's legislation, e.g. in the establishment of apprenticeship systems from the mid-1500s onwards and in the direct connection between armed services requirements for recruits and the potential supply from industrial and reform schools. Vulnerable children, such as those abandoned or orphaned, have figured strongly in legislation, as have those viewed as a threat to society. On rare occasions, e.g. the Children and Young Persons Act 1969 in England and Wales and the Children, Young Persons and Their Families Act 1989 in New Zealand, the law has made a connection between these two groups. Much law has also questioned the authority of the family, as reflected in the last century by its propensity to sanction intervention on behalf of children born outside of marriage and in this century by a willingness to protect children from maltreatment by parents.

The law is regularly used to formalize arrangements to provide services previously offered on a voluntary basis. In England and Wales, the Children Act 1948 created children's departments to assume responsibility for the administration of services pioneered (and in some cases still provided) by voluntary agencies under the guiding hand of pioneers such as Barnardo and Stephenson. Most departments worked with children separated from home. When the potential for support of children at home (as a means to preventing separation) was realized and informal experiments were underway, the law was changed to legitimize the activity (the Children and Young Persons Act 1963). The way in which voluntary and professional organizations work to, and transgress, legal limits prior to legislative change has received little attention; Barnardo was prosecuted on several occasions for testing the limits of the law.

The law is often used to recognize a social need or social psychological deficits in children receiving insufficient attention from the state. In the USA, there have been many class actions taken on behalf of specific groups of children or adults (e.g. parents or grandparents) to compel a change in patterns of state intervention or professional behaviour. Class actions generally deal with groups of individuals with similar problems, who have been dealt with unlawfully and who represent similar future cases. Dicker (1990) summarized five such cases, dealing with day care and employment rights of poor mothers, race-segregated education of children, health care of mothers, the care and treatment of children placed in secure facilities and services for children with severe behaviour disorders. This last case is particularly interesting for the mental health reader.

In the late 1970s, complaints were aired about North Carolina's failure to provide adequate services for emotionally disturbed children (Soler & Warboys 1990). One such case, an 11-year-old referred to as Willie M., and diagnosed as emotionally disturbed with unsocialized aggression and other disorders, became the first named of four plaintiffs thought to be inappropriately placed in juvenile training schools or a state psychiatric

placement. At the time of the action, there were thought to be between 100 and 200 severely behaviour disordered and violent children in the class. The case was settled out of court and eventually resulted in the allocation of \$30 million per annum for an estimated 1000 children, leading to a range of services from community support to secure accommodation. As with many remedies resulting from class actions, a series of targets, e.g. the proportion of class members receiving appropriate services, were established along with a review panel to monitor the implementation of the programme. Despite the optimistic review of the effects of the litigation by some commentators, little is known about the effects of class actions, as measured in terms of outcomes for the children involved or the provision of services for those outside the class.

The law also establishes the administrative and managerial structures within which services for children with social and psychological problems are provided. There is huge variation among jurisdictions. Italy, for example, has 8100 local authorities, 196 local health agencies and 98 hospital trusts compared with 150 local authorities, 105 health authorities and 451 health trusts in England and Wales. In the USA, the big cities are organized around large centralized systems focused on administrative categories of children. New York City's Administration for Children's Services deals with child protection issues for children at home and in state care, thus assuming responsibilities that 32 London local authorities discharge in co-operation with seven health authorities and 38 other provider trusts.

For the last 20 years, controlling demand for health and social care services has resulted in elaborate administrative arrangements broadly framed in legislation but delivered by bureaucrats operating in private and public agencies. These administrative arrangements are variously described as care management, managed care or quasi-markets. Because they seek to ration professional help, these arrangements are perceived to have a marked impact on clinical decision-making. Their actual impact is largely uncharted. The arrangements have been more pervasive in adults than children's services, although problems of demand, supply and spiraling budgets are at least as evident if not more evident in children's services. The arrangements have been particularly controversial in the way they have been introduced in the USA, leading Stone (1999) to devote 10% of his overview of psychiatry and the law to managed care issues. Little is known about the effect different administrative structures have on professional behaviour, but changes in those structures are frequently used by elected and career policymakers to implement developments in thinking about children's needs.

The locus of children's legislative change also varies from country to country. In the UK, laws about children's social needs have emerged from government departments of health, interior and social security, whereas elsewhere in Europe, particularly in the south of the continent, the genesis has been education. These distinctions have a considerable impact on the character of specific laws.

In addition to communicating social values, legitimizing intervention and creating the administrative structures within

which these interventions are delivered, the law also changes in response to demand for greater clarity. For example, the Children Act 1989 in England and Wales emerged from a confluence of work by lawyers at the Law Commission to simplify and clarify a century of statutes regarding children and from work by central government policymakers to address weaknesses in children's services. The result was a single piece of legislation with a single set of orders for children in private and public law cases (White *et al.* 1995).

The nature of evidence in the broader context

To understand the way in which the law influences professional behaviour with respect to broad categories of cases, it is helpful to review the way in which the law is disseminated. First, there is legislation and, as has been seen, statutes can take several forms. Second, there are legal rulings requiring an authority or agency to intervene on behalf of a group of children, and for these interventions to be implemented to the satisfaction of the court. This category also includes judgements regarding individual children, setting standards (but not precise modes of intervention) for future children in similar circumstances. For example, in the case of *Gillick v. West Norfolk and Wisbech Health Authority* (1986) UK, the UK House of Lords ruled that a child of any age possessing sufficient understanding and intelligence could consent to medical procedures. This judgement was in response to a mother asking for assurance that her children would not be given medical treatment (specifically, be prescribed a contraceptive pill) without her agreement. Third, the law can be administered through guidance from a relevant government department or a letter from a Minister of State or senior official. This is commonly used to prescribe the actions of members of weak or new professions, e.g. social work. Fourth, where a profession is strong, as is the case with medicine, the professional body will assume some of the responsibilities of government by regulating its member's behaviour to a standard at or beyond that agreed with policymakers.

The law requires a different burden of proof in civil and criminal cases. In a criminal case, it is necessary to prove a matter beyond reasonable doubt and a court will routinely consider a greater amount of evidence admitted under stricter rules than would be necessary in a civil case. Generally speaking, the further from court a case is decided, the weaker will be the application of these rules of evidence. So, in the UK, a decision by police and youth justice professionals to administer a final warning to a young offender, while ensuring the principles of due process are adhered to, has more of the qualities of a civil than a criminal proceeding.

In all court cases, decisions must be made about the appropriate level to hear the case. In the UK, in civil public and private law cases a process known as concurrent jurisdiction is in place allowing all cases to be heard in all courts with the most complex cases being heard in a higher court. Judges and lay magistrates

can pass a case to a higher or lower court if they feel it is inappropriately placed.

In criminal cases, most jurisdictions have established special children's or youth courts, excepting the most serious cases or those cases where adults and children are jointly charged. This provision has been eroded in the USA where it is of doubtful benefit because lower courts will, under public pressure, pass sentences as severe, and sometimes more severe, than those passed down by adult courts. The adult court generally has a different range of sentences from which to choose.

How do legal decisions about classes of case impinge upon clinical work? Practitioners can recognize the importance of social messages being transmitted in the law. These must never be permitted to drive clinical practice but they do provide the context in which practice decisions are made. It is not necessary for the practitioner to agree with all elements of this broader social context but understanding can help.

The mechanism used by law to communicate a social message betrays important features of that message. There is value in looking at the intention of central and local government agencies as expressed not only in legislation, but also in guidance and administrative procedure. In many developed nations, with increasing competition for parliamentary time to debate legislation, important policies are now communicated through a range of procedures in addition to legal statute.

The practitioner will want to evaluate the potential effect on the consumers of services created by the mechanism by which law is communicated. Often, a better outcome can be achieved without administrative or court hearings and, in the worst cases, the decision-making context can undermine clinical objectives. The chaining of groups of offenders by hand and ankle as they enter court in some states in North America is clearly not conducive to agnostic clinical decision-making. Finding the appropriate type and level of court in which to hear a case is also important.

Some clinical assessment will expose gaps in legislation. By highlighting the absence of effective mental health services in North Carolina, practitioners altered the balance of provision. The Willie M. decision also illustrates the limited effects of practitioner-induced legal changes. There is no evidence to suggest that the class action improved outcomes for children. The responsibilities of the advocates of change are also apparent from the case. Because there is a limit to resources allocated to children in need, increasing or improving services in one area can imply a decrease or deterioration of services in another.

Discussion

Running through the preceding description of the law are five broad themes. First is a tension between children's rights and their needs. Where the legislative framework is progressive, need tends to take precedence over rights as a guiding principle. This situation will be enhanced if the constituent professional organizations are strong and self-governing or are strongly in-

fluenced by government. Where the legislative framework is weak, or the legal power is broadly distributed, e.g. in the USA, rights have a strong bearing on judgements about individuals and client groups. The same situation is true in developing countries that have few laws governing services for children with social and psychological problems.

In some respects this relationship between needs and rights mirrors the relationship between family and state. Needs of children are determined by professionals, ideally working with parents and child. Rights are determined by the wider community and, as such, must capture the state's response to children.

Whether the guiding principle is needs or rights, problems occur. The case *T & V v. United Kingdom*, *European Court of Human Rights* (1999) dealt with two boys convicted of murder, tried in an adult court and sentenced to indefinite terms of detention (the period of detention to be decided by a Minister of State in consultation with officials and expert advisers). They were placed in secure accommodation with a reasonable standard of treatment and education. There is every reason to believe the needs of these two boys were met and there is some evidence to suggest that their treatment will produce reasonable outcomes, having taken account of their backgrounds. However, the court found that the rights of the children had been scanted. The adult court was not comprehensible to the boys, thus denying them a fair trial (Article 6), and the absence of judicial review of the period of detention was a breach of the right to liberty (Article 5). These rights will be redressed, but there is no certainty that the change will better meet children's needs.

In the UK and some other parts of Europe, attention to the needs of children has involved bypassing some aspects of due process in the law. When crimes are minor, for example, and a child admits to a crime, a final warning can be administered without a thorough test of the child's guilt. Such a procedure would be less likely and certainly less explicit in the USA where protection of legal rights results in more prosecutions, more restrictive and longer sentences which are arguably counterproductive to the meeting of children's needs.

The same dilemma can manifest itself in a different way with respect to the ethics of research. The Royal College of Psychiatrists' (2001) guidelines regarding research involving human participants start from the principle that everyone should be able to benefit from the fruits of research but that individuals should also be able to weigh up the risk and benefits of their participation in that research. The guidance searches for a balance between the needs of patients (and other recipients of services) for interventions rooted in reliable evidence and for the rights of the individual to know the consequences of taking part in research. The legal burden is considerably eased when the professional groups that comprise children's services engage in constructive dialogue about practical response to the changing social context.

A second cross-cutting theme concerns primacy when the rights of individuals compete. What is best for the child is not always acceptable to the parent. Parents' decisions are sometimes disapproved of by grandparents or other relatives. Where

adoption is 'open,' meaning that birth parents have some contact with the child, it is possible for the rights of all parties to clash.

These issues are manifest in the US Supreme Court judgement the case of *Troxel et vir v. Granville*, Supreme Court of the United States, N99-138 (2000). Brad Troxel committed suicide, leaving a common-law wife and two daughters. His partner later married a man who legally adopted the children. Troxel's parents, unhappy with the amount of access they were allowed to their grandchildren, began a legal battle to increase it. They were supported by a powerful consumer lobby group with 38 million members which views protecting grandparents' rights as one of its roles (grandparents are the primary caregivers of 1.4 million US children). As is often the case where there are fragmented or weak legal frameworks, other interest groups filed their own petitions. In the Troxel case, these included those supporting traditional family structures and those advocating on behalf of non-traditional families, where the functional parent may have neither biological nor legal ties to the child. These diverse interest groups were looking to preserve the fundamental rights of legal parents to choose the people and ideas that may influence their children.

The case exemplifies the nature of decision-making when the law is primarily concerned with an individual's rights and not the needs of many. There are tensions between the competing rights of individuals (the children, the birth and adoptive parent and grandparents) and those of classes of individuals (grandparents, religious groups, non-traditional families).

Competing rights of individuals and groups are particularly evident in the USA (Bulkley *et al.* 1996). Parents' rights to autonomy, privacy and integrity are overridden when there are compelling state interests, e.g. to protect children from maltreatment. Because parents also have the right to due process, they must be notified about abuse inquiries regarding their child. In some states (e.g. Minnesota), parents are read their legal rights prior to a protection inquiry commencing, in much the same way that accused criminals are read their legal rights. Children in the USA always have the right to a lawyer in criminal cases and in some states in child protection cases. In addition, there are other parties with rights, e.g. unmarried non-custodial biological fathers.

A third overarching theme concerns the place of evidence in clinical and case class decision-making. Rights are not amenable to evidence because they are generally concerned with process not outcomes. It is possible to measure the proportion of cases where rights have been scanted but this will not provide a measure of the well-being or progress of children or others involved in the case. Needs are much more amenable to scientific study, although assessments of need are generally only partially dependent on research-based judgements. The same dilemma can be expressed in terms of legal and clinical requirements for certainty of judgement. A court must aspire to certainty, whereas a clinician used to research methods and findings will feel comfortable when dealing with probabilities.

The use of weighted variables can assist the court. For example, in trying to help a court decide on the wisdom of reunifi-

cation in the context of a child in state care, it is known that 70% of those who go home to relatives stay at home. Log-linear analysis suggests that if the child and family are prepared for the anxieties associated with reunion, the chances of stability after reunion increase by about 2.5 : 1 (Bullock *et al.* 1998a). If a clinical assessment of family relations reveals them to be of a fairly high quality, the odds of stability are further increased by a ratio of 3.5 : 1. If the child is not an offender, the odds rise again by 1.7 : 1. In other words, if all three criteria are met, the odds of stability after reunion are eight times higher than if opposite conditions existed.

The preceding discussion presents an important challenge for researchers. There is little authoritative evidence about the efficacy of contrasting legal processes. This is because of the general lack of research interest but also because of the difficulty of undertaking robust evaluation.

In the testing of specific interventions for specified groups of children in need, methods are clear. Generally, some form of controlled trial or other quasi-experimental design will be used, notwithstanding ethical considerations that must be taken into consideration. The goal of the evaluation is always to measure the impact of the intervention on children's outcomes (Rossi *et al.* 1999). In the legal context, the evaluation must focus on the amount of change in the process and its eventual impact on child outcomes. The mechanisms mediating between process, intervention and outcome can be complex. Take, for example, family group conferences pioneered in New Zealand for bringing together family members to make decisions about a child's future, as an alternative to court and other professionally orientated decision-making fora. The primary goal of these conferences is to change the process; to encourage family members to make their own decisions. The conference encourages commitment to decisions made. These processes may result in different decisions than would have been reached in court, or they may result in the same decisions differently applied. Evaluation in these contexts demands innovative and rigorous ways of working. Similar innovation is required in testing the effects of innovation in court, because controlled experimentation is practically impossible.

A fourth cross-cutting theme concerns the way the law communicates the complexity of competing social pressures to the practice context. Sometimes it does this well, other times badly. Rigorous clinical assessment and evidence from research are among these social pressures. The law can accommodate sound diagnosis or the results of research if they are effectively communicated in the contexts in which the law is administered and in a form that facilitates legal decision-making.

There are exceptions to the courts' requirements for certainty of judgement and they tend to occur when the law becomes ineffective in respect to both the process and the outcome. There is strong evidence that courts can hinder rather than improve chances of obtaining accurate evidence and making reliable decisions about children's future in parental separation or divorce cases. A common alternative is mediation, which takes the decision-making process out of the court and permits

greater ambiguity with the intention of producing agreement (not necessarily binding) around important aspects of the child's upbringing. The use of plea-bargaining or allowing other offences to be taken into account at the sentencing stage, strategies commonly used to protect children from the rigours of the court, are other examples of legal acceptance of indefinite judgements.

Much of this discussion is relevant to the way in which the law changes. In the case of children, the weight of public opinion that has gathered periodically about their welfare, protection or about the potential threat they pose to society has led to significant shifts in legislation. Masson (2000b) charts the impact of ideology, scandals and inquiries in the context of child welfare and protection laws in England and Wales. The preceding pages highlighted a difference between legislation that has evolved in a considered way and that which has resulted from strenuous and expensive legal battles.

Several influences are evident in most legislative frameworks (Department of Health 1995; Bullock *et al.* 1998b). First are the moral sensitivities of a society, often bound up in existing legislation. Second are the pragmatic concerns of politicians, policy-makers and professionals regarding their ability to deliver an agreed law, legal framework or judgement. If, for example, the moral tone of a nation demanded that all parents hitting their children were to be imprisoned, the volume of potential offenders would nevertheless make the passing of any law impracticable. Third are the perspectives of consumers of services, parents and children and the providers of services. Advocacy groups have strongly influenced children's legislation passed in the UK, Australasia and USA in recent years. Fourth is scientific evidence about children's circumstances, the aetiology of social and psychological problems and evaluations about the efficacy of different interventions. Good legislation, legal frameworks and important court judgements successfully accommodate these four dimensions.

There can be conflicts between these dimensions. A society's moral sensibilities shift. Consumers come to new perspectives and the strength of their advocacy waxes and wanes. New research results are published. The pragmatic concerns of policy-makers and professionals shift over time. Effective legislation and legal frameworks must endure to accommodate such changes. Mental health professionals are both an influence on the changing legal framework but also must change their behaviour to conform to the developments.

Reliable evidence is arguably the most recent of the four influences on legislation. In the legal context it remains sparse. Building up an evidence base, encouraging innovation in research methods and a critical culture while demonstrating the practical value of research results to lawyers and colleagues with legal authority over children's lives should be a priority.

A final broad theme concerns the amount of latitude afforded by the law to practitioners working with children in need. Interventions for children are organized by health, education, social and police services. Each agency is subject to its own legislation. Children's needs cross these agency boundaries. In many cases,

professionals can choose from several legislative routes, a choice that can have profound impact on children's outcomes. For example, a child with a conduct disorder can, depending on the manifestation of the behaviour, be dealt with by mental health, special education, child welfare or youth justice agencies, each operating to a different legal framework (Bullock *et al.* 1998c). In England this could involve the Mental Health Act 1983 (providing rights to patients placed in secure facilities), Department of Education *et al.* (1994), a government health and education departments circular (setting out arrangements for children placed in residential education placements), the Children Act 1989 (providing the procedures for placing children away from home and the use of secure provision), or several pieces of youth justice legislation (dictating what should happen if a child commits a crime).

It is suggested that socioeconomic status is an important factor in determining which legislative route is taken, with wealthier children being processed through mental health and education while poorer children gravitate to child welfare and youth justice. In fact, there is little empirical evidence for this proposition, although there are many more children being processed through the mental health sector in the USA where there is no comprehensive health insurance and private policies can extend to mental health of children.

Where there is choice, the practitioner must balance the effectiveness of services designed to meet children's needs provided by each sector and attention to competing rights of people involved in the child's life. The decision will take into account predicted changes in the child's development alongside known alterations to legal rights and quality of interventions as the child gets older. Youth justice may appear a benign route for a first-time offender in England because it will permit the introduction of a range of community-based services, but a child staying in this sector for several years will eventually leave the practitioner with few choices beyond incarceration.

The dilemmas also occur within sectors and can be illustrated by the decision to remove children from their parents. Given the preceding evidence and discussion, what are the implications for practice? Wherever possible, the practitioners will want to elicit the views of and work alongside both child and family members. In several jurisdictions, separation is permitted by voluntary agreement between the child's carer and the state, and there is some evidence that this route is more likely to produce better outcomes for the child (Packman & Hall 1998). Where the child is to be removed against parents' wishes, a court hearing will be required. In England and Wales, the clinician is required to demonstrate significant impairment to the child's development or that the child is beyond parental control. Where assessments concentrate on sound evidence of impairment in all areas of the child's life and not on disputes about whether or not an abusive incident has occurred, there is some evidence of improved outcomes (Department of Health 1995). The practitioner will be mindful that, depending on the jurisdiction, up to 92% of children looked after by the state eventually go home, so keeping relatives involved in the child's life can be beneficial. By

implication, at least 8% of separated children will not return, creating the dual challenge to practitioners of selecting those cases where contact and reunion will hinder the child's development and finding effective stable alternatives to the family home. In both of these areas there is a requirement for better research and development. Presently, practitioners' choices are restricted not by the law, but by a lack of knowledge and effective services for the most vulnerable children.

Conclusions

The range of services available for children with social and psychological problems does not vary greatly from one country to another. However, there is considerable variation in legal frameworks and laws. In some instances these have a bearing on professional decision-making; in most they do not. There is little evidence that the age of criminal responsibility makes a great deal of difference to the treatment of young offenders, although the places in which the decision is made (juvenile or adult court) probably does. Even the court can have limited impact. In some contexts, the court is presented with cases about which there are many disputes but where the weight of professional opinion is compelling, e.g. in the UK over 90% of applications for an order to adopt a child in state care are granted (Murch *et al.* 1993; Department of Health 1999). Much work is being undertaken, but there is little evidence to date to suggest that decision-making fora outside of the court are improving outcomes for children.

There are interesting paradoxes not covered in this chapter worthy of investigation. It is noteworthy that those countries that give particular attention to the rights of specific groups are as likely, if not more likely, to take away the rights of those groups. The USA places great weight on the rights of its citizens yet it assumes rights over a greater proportion of its children than any other Western developed nation, with high rates of state care, adoption, incarceration of young people and placement in mental health facilities. The USA is particularly zealous in the assumption of parental rights of particular classes of citizens, particularly African-Americans who are greatly overrepresented in child protection, care, adoption and youth justice proceedings, and whose rights are specifically protected in that constitution.

At the clinical level, there is scope for new work to evaluate the effect of the legal process on child outcomes. To an extent this demands some attention to the way outcome as a concept applies in the study of legal process. Four examples serve to illustrate the point. First, there is a need better to understand the influence of the context in which a decision is made. Does a policeman giving an informal warning to a young offender come to a different conclusion about guilt than a court making the same decision with the same facts? Does an administrative gathering of professionals reach a different decision about a child's maltreatment than a family group conference primarily managed by the family themselves?

Second, do legal contexts achieve the objectives of those governing that context? In some jurisdictions, the court will review its own decisions, but most judges, magistrates and case conference co-ordinators know little about how their judgement is implemented. Also valuable in this context would be to clarify the relationship between decisions made in a legal context and a clinical or research diagnosis of chains of effects in children's lives.

Third, more can be learned about the impact different legal contexts have upon children's life chances. Much has been written about the damaging effect of adult court. Over the last century, much was done to move the decision-making process away from the court and nearer to the genesis of the child's problem. The sentiments behind these developments are laudable, but it is not known whether they have a great bearing on children's life chances.

Finally, there is scope to revisit the concept of legal due process as it is applied to children. It is evident from the literature underpinning this chapter that there are strengths and weaknesses in both the USA's careful protection of legal representation and due process for children and the tendency of European states to bypass these rights as a mechanism to protect the child from harm. This aspect of rights amenable to measurement and further research in this area has the potential to greatly enhance the well-being of children.
